In accordance with European legislation, natural mineral water is defined as microbiologically wholesome water from an underground aquifer. Natural mineral waters are evaluated, for example, in the Czech Republic according to:

(i) the total mineralisation as mineral waters:
  - very slightly mineralised (dissolved solids content is lower than 50 mg/l)
  - slightly mineralised (dissolved solids content is 50–500 mg/l)
  - moderately mineralised (dissolved solids content is 500–1500 mg/l)
  - highly mineralised (dissolved solids content is 500–5000 mg/l)
  - strongly mineralised (dissolved solids content is higher than 5000 mg/l)

(ii) the content of dissolved gases and of important components as mineral waters:
  - carbonic (CO_2 content is higher than 1 g/l)
  - sulfuric with contents of sulfur (sulfan (i.e. hydrogen sulfide) dissociated to various degrees and thiosulfates) higher than 2 mg/l
  - iodine (iodide content is higher than 5 mg/l)
  - others, such as waters with increased content of silicic acid (above 70 mg/l) and fluorides (above 2 mg/l)

(iii) the actual pH, only in the case that water is:
  - strongly acidic (with pH below 3.5)
  - strongly alkaline (with pH above 8.5)

(iv) radioactivity of radon, waters with radioactivity above 1.5 kBq/l caused by the radioactive gas radon (^{222}Rn)

(v) spring temperature into:

- cold waters (with temperature up to 20 °C)
- tepid waters (with temperature up to 35 °C)
- warm waters (with temperature up to 42 °C)
- hot waters (with temperature above 42 °C)

(vi) osmotic pressure into:

- hypotonic (with osmotic pressure lower than 710 kPa)
- isotonic (with osmotic pressure 710–760 kPa)
- hypertonic (with osmotic pressure above 760 kPa) and also by other properties.

7.2.2 Production

Most water requires some type of treatment before use. Depending on the type (surface water or ground water) and quality of the water resource, the production of drinking water is achieved by various technological processes. Some water resources directly meet the requirements for drinking water, while other resources only require disinfection, aeration or deacidification (removal of dissolved carbon dioxide and oxygen). Treatment processes typically consist either of chlorine disinfection only, or of direct or conventional filtration and chlorination. Surface water sources from protected catchments are typically treated by chlorination only and those from impacted catchments by conventional coagulation, flocculation, sedimentation, filtration and chlorination. Some resources require more complex treatment of the water, such as increasing the concentrations of Ca^{2+} and HCO_3^- ions (in soft water), reducing the concentration of Fe^{2+} and Mn^{2+} ions (using special manganese removal equipment), removal of NH_4^+ ions, heavy metals, radioactive substances (radon and radionuclides) and other treatments. Groundwater sources are typically treated by aeration and chlorination.[1] These issues are addressed in detail in water technology books.

7.2.3 Quality requirements

7.2.3.1 General requirements

Drinking water contains varying amounts of inorganic salts (cations and anions formed by dissociation of various salts), dissolved gases (carbon dioxide, oxygen and other gases) and indicators of pollution, for example soluble portions of humus from the soil (called humins or humic substances) and contaminants (e.g. phenols and petroleum fractions) and various bacteria. The presence of carbon dioxide and oxygen can increase the number of ions present; if the water is in contact with metals (copper, iron and other metals) it can corrode kitchen and manufacturing equipment. Water containing high concentrations of iron and manganese ions is useless for many purposes. The presence of bicarbonates, sulfates and chlorides of calcium and magnesium has practical significance in determining **water hardness** and also its suitability and applicability for the production of foods and also for other purposes. Water hardness is assessed according to the level of bicarbonates (temporary hardness, also known as carbonate hardness) and those of sulfates and chlorides (permanent hardness or non-carbonate hardness). Water hardness is often expressed in German degrees (°dH or dGH), American degrees (mg/l), English degrees (°e or °Clark) or French degrees (°f). For example, 1°dH corresponds to 10 mg of CaO or 7.17 mg of MgO in 1 litre, 1°e corresponds to 64.8 mg of $CaCO_3$ per 4.55 litres, 1°f corresponds to 10 mg $CaCO_3$ per litre ($1°dH = 1.252°e = 0.5603°f$). Water with a hardness of 0–7°dH is known as soft water, with 7–14°dH as moderately hard water, with 14–21.3°dH as hard water and with >21.3°dH as very hard water. Temporary hardness can be removed by boiling or by adding calcium hydroxide. Calcium (or magnesium) bicarbonate is thus transformed into insoluble carbonate during cooking:

$$Ca(HCO_3)_2 \rightarrow CaCO_3 + H_2O + CO_2$$

Calcium hydroxide reacts as follows:

$$Ca(HCO_3)_2 + Ca(OH)_2 \rightarrow 2\ CaCO_3 + 2H_2O$$

Removal of temporary and permanent hardness in practice can be done using ion exchangers or by the addition of sodium carbonate:

$$CaSO_4 + Na_2CO_3 \rightarrow CaCO_3 + Na_2SO_4$$

Quality requirements for drinking water include microbiological, biological, physical, chemical and radiological aspects. Some of these quality requirements are shown in Table 7.1.

Bottled water is a selected high-quality ground water suitable for continuous use by the population. The only treatments allowed prior to the bottling of waters are some physical processes (chemical processes are used only rarely) to remove unstable components, such as iron and sulfides and to (re)introduce carbon dioxide. To protect the biological and microbiological quality, chlorine and its compounds should not be used. Bottled waters, other than those labelled 'natural mineral water', are expected to conform to essentially the same standards as the public water supply and they are therefore suitable for giving to infants or for preparing feeds. As with tap water, bottled waters should be boiled and cooled before using to make up infant formula feeds. Local standards differ by country. In the Czech Republic, for example, bottled water for infants is not modified by any of the procedures described above. The hygienic quality asurance is possible only by ultraviolet radiation

[1] The European Parliament and the Council have established a framework for Community action in the field of water policy, known as the Water Framework Directive. The Drinking Water Directive relates specifically to water intended for human consumption For example, in the United Kingdom the Water Quality Regulations prescribe maximum values for substances that affect wholesomeness and the Drinking Water Inspectorate polices the water companies. In the United States, the Environmental Protection Agency (EPA) sets standards for tap and public water systems under the Safe Drinking Water Act (SDWA).

Table 7.1 Selected quality requirements for drinking water.

Parameter (units)	Value	Parameter (units)	Value
Indicator		Chromium (μg/l)	50
Colour, odour, taste, turbidity	–[a]	Copper (mg/l)	2
Conductivity (μS/cm at 20 °C)	2 500	Lead (μg/l)	10
Hydrogen ion concentration (pH units)[b]	≥6.5 and ≤9.5	Mercury (μg/l)	1
Oxidisability (mg/l O_2)	5	Nickel (μg/l)	20
Aluminium (μg/l)	200	Selenium (μg/l)	10
Ammonium (mg/l)	0.5	Bromate (μg/l)	10
Chloride (mg/l)	250	Fluoride (mg/l)	1.5
Sulfate (mg/l)	250	Cyanide (μg/l)	50
Iron (μg/l)	200	Nitrate (mg/l)	50
Manganese (μg/l)	50	Nitrite (μg/l)	0.5
Sodium (mg/l)	200	Acrylamide (μg/l)	0.1
Total indicative dose (mS/year)	0.1	Benzene (μg/l)	1
Coliform bacteria (number/100 ml)	0	Benzo(a)pyrene (μg/l)	0.01
Microbiological		1,2-Dichlorethane (μg/l)	3
Escherichia coli (number/100 ml)[c]	0	Epichlorohydrin (μg/l)	0.1
Enterococci (number/100 ml)[c]	0	Trichloroethene, tetrachloroethene (μg/l)	10
Chemical		Trihalomethanes – total (μg/l)	100
Antimony (μg/l)	5	Pesticides (μg/l)	0.1
Arsenic (μg/l)	10	Pesticides – total (μg/l)	0.5
Boron (mg/l)	1	Polycyclic aromatic hydrocarbons (μg/l)	0.1
Cadmium (μg/l)	5	Vinylchloride (μg/l)	0.5

[a] Acceptable to consumers and no abnormal change.
[b] May be reduced to pH 4.5 for still water in bottles or containers.
[c] The unit is number/250 ml for water in bottles or containers.

or ultrafiltration. It is also possible to stabilise this water by carbon dioxide to at least pH 6. The requirements for bottled water are the highest for water for to be given to infants.[2] Compared with drinking water, the values of many parameters are several times lower.

7.2.3.2 Food industry requirements

The food industry generally has high requirements for water quality, particularly in microbiological terms. For example, water is one of three basic brewing raw materials. Water hardness and its overall chemical composition is an important factor determining the quality of beer produced in every brewery. Water with a certain higher hardness is more suitable than soft water. For example, Dublin has hard water, which is suitable for producing Guinness, while Munich and Pilsen have softer water, which is particularly suited for producing lager beer. It is known that the calcium content is 14 mg/l in the Pilsner brewery waters, while in Munich brewing waters it reaches 109 mg/l. Both brewing waters also differ in their levels of magnesium (4 and 21 mg/l), bicarbonates (42 and 171 mg/l), sulfates (19 and 79 mg/l) and chlorides (9 and 53 mg/l), respectively. As a result of the water quality (among other reasons), these two beers have a completely different character (organoleptic properties). Beers of lighter colour require lower concentrations of bicarbonates and calcium and higher concentrations of sulfates, while in beers of darker colour it is the opposite; it is related to the buffering capacity of the water, which, together with the pH value,

[2] In many countries there are strict limits on the permissible concentration of nitrate in drinking water and in many surface waters. The limit is 50 mg/l of nitrate in the EU and 44 mg/l in the United States (equivalent to 11.3 and 10 mg of nitrate nitrogen in 1 l, respectively). These limits are in accord with WHO recommendations established in 1970 and reviewed and reconfirmed in 2004 and ensure that drinking water will not cause methaemoglobinaemia, also known as blue-baby syndrome (see Section 6.6.1.2). For example, the permissible concentration of nitrate in bottled water for infants in the Czech Republic is only 15 mg/l.

influences the course of the fermentation. The presence of iron and manganese in large quantities is undesirable (iron concentration is limited to a value of 0.2 mg/l and manganese concentrations have to be even lower).

The dairy industry requires water with a low concentration of magnesium, otherwise the butter has a bitter taste. The iron concentration should not exceed 0.1 mg/l and manganese should be absent. Canning industries, likewise, have similar requirements for the water they use. Higher nitrate concentrations are undesirable in the preservation of vegetables and meat.

The food industry also contributes significantly to the total volume of waste water (mainly from meat processing plants, sugar refineries, breweries and dairies).

7.3 Water in foods

The water content in foods is highly variable. It is related to the chemical composition of the food raw materials (the original animal and plant tissues), the manner of their processing to give the final products and the storage of these products. Water makes up 50–90% by weight of the raw materials of plant and animal origin and of many foods; the rest is called **dry matter**. According to their water content, foods are divided into foods with high, medium and low water contents. The amount of water (water activity) significantly affects the organoleptic characteristics of food (texture, smell, taste and colour) and their shelf life, resistance to microbial attack, enzymatic (biochemical) and non-enzymatic (chemical) reactions that occur during processing and storage.

7.3.1 Water content

The water contents of selected foods are given in Table 7.2.

7.3.1.1 Foods of animal origin

The water content of meat depends on the species (origin) and in particular on the fat content. Owing to its relatively high fat content, pork meat tends to have lower water content (raw pork fat contains about 13% water), while beef has a higher water content. The liver contains 67–72% water. The water content in meat products is highly variable, typically ranging from 30 to 70%. Poultry meat has somewhat lower water content than the meat of other farm animals. Fish generally contain more water. Less oily fish naturally contain more water; fatty fish have a lower water content. For example cod, carp, tuna, mackerel, trout and eel contain 81, 78, 71, 68, 66 and 65% water, respectively.

As the fat content varies, so does the natural water content of milk, within certain limits (87–91%). Soft cottage cheese contains 78% water, while other cheeses can contain less water (52% Camembert, 37–40% Cheddar, Emmental and Roquefort, and 30% Parmesan cheese).

In butter, and therefore in its substitutes (including margarines), the water content varies over a relatively small range. Most butters and margarines contain 16% water. Some special products, such as butter and margarine spreads, and products with reduced fat content, contain around 50% of water; rendered lard contains only traces of water.

The water content of eggs is relatively constant (on average 74%); egg white contains more water (about 88%), while the water content of egg yolk is about 49%.

The amount of water in honey depends upon the type and quality of the honey. Good quality honey essentially has a low water content (generally about 17%). Honey is likely to ferment and lose its freshness if the water content is higher than 19%.

7.3.1.2 Foods of plant origin

The natural water content in the edible part of fruits and fresh fruit juices mainly depends on the type of fruit. Bananas have a relatively

Table 7.2 Water contents in selected foods.

Food	Water content (%)	Food	Water content (%)
Pork meat	30-72	Sugar (saccharose)	0-0,5
Beef meat	35-73	Fruits (juices)	81-94
Chicken	63-77	Vegetables	60-93
Fish	65-81	Potatoes	75-80
Milk (cows')	87-91	Legumes	10-12
Cheeses	30-78	Cereal grains	11-14
Eggs	74	Bread	35-45
Butter, margarines	15-18	Pasta products	9-12
Oils, pork lard	0-0.5	Nuts	3-6
Honey (syrups)	19 (40)	Beer	90-96

low water content (about 76%), while there is more water in pears (about 83%), apples (85%), peaches (89%) and strawberries (90%). Oranges and lemons usually contain 86–87% water. Dried fruits normally contain 12–25% water.

Fresh root vegetables (such as carrots and parsley) are usually about 90% water; cabbage contains about 92% water and lettuce and tomatoes about 95%. There are slightly lower water contents in some bulbous vegetables (89–93% in onion, 83–89% in leek and 61–68% in garlic).

The water content of all cereals is virtually the same as the water content in flours and dry pasta products (9–14%). White bread usually contains 35–36% of water; there is more water in rye bread (38–45%).

7.3.1.3 Other foods

The water content in beverages varies depending on the amount of added sugar and the concentrations of other substances. Fruit juices made from fresh fruit have approximately the same water content as the original fruit. Cola drinks usually contain about 90% water. Vegetable oils and sugar contain only traces of water.

The water content in beer depends on the concentration and strength of the original wort and the degree of fermentation. In other alcoholic beverages, such as liquors, water content depends primarily on the amount of ethanol and on the added sugar.

7.3.2 Changes in water content

Changes to the water contents in foods and food raw materials take place in almost all modes of storage and during all methods of culinary and manufacturing processing. Storage of raw materials and foods in packaging materials that are permeable to water and water vapour leads to a decrease in water content through desiccation. In foods that become moist easily (dehydrated fruit juices and instant beverages such as coffee and tea), the water content increases during storage under humid conditions.

In the manufacture of certain foods such as bread, but also of a wide range of meat, poultry, fish and other products, water is intentionally added to the raw material in a specified amount. The water content also increases significantly during the steeping of pulses, whose chemical components (mainly polysaccharides) are able to bind water. Thermal processing of food by drying, cooking, baking, frying, grilling and roasting usually decreases the water content. In cooked meat, myofibrillar proteins such as actin and myosin contribute significantly to water losses, as they release a certain amount of water during thermal denaturation, which leads to aggregation of these proteins. On the other hand, connective tissue proteins such as collagen bind water.

Losses of water and of water-soluble substances likewise occur during freezing and thawing of foods, depending mainly on the speed of these two operations. If the processes are slow, losses are higher, due to cell damage by large ice crystals, than in the rapid freezing and thawing when the ice crystals are small.

A certain amount of water may also be formed by chemical reactions. Examples are thermal reactions during coffee roasting. The water naturally present in green coffee and water formed by the dehydration of carbohydrates during roasting escapes as steam, along with other volatile products of pyrolytic reactions.

Examples of changes in water (dry matter) content of some common foods of animal and plant origin in different culinary procedures and during industrial processing are shown in Table 7.3.

7.4 Structure

An oxygen atom in the ground state $(1s^2)(2s^2)(2p^4)$ has four valence *p* electrons, two of which are unpaired (Table 7.4). The electronic structure of hydrogen (1*s*) allows connection (hybridisation) of unpaired valence electron of two hydrogen atoms to two unpaired valence electrons *p* of the oxygen atom to four sp^3 orbitals. Two orbitals are bonding (molecular) orbitals, therefore two σ bonds or single covalent bonds O–H are formed and two orbitals are non-bonding orbitals. In the water molecule, H_2O, both elements have the energetically most favourable configuration of the electrons, as in the atoms of the noble gases helium and neon, respectively.

If we imagine the oxygen atom of a water molecule located in the centre of gravity of a regular tetrahedron (the optimal spatial arrangement is tetrahedral from an energy perspective), covalent bonds O–H lead to two tetrahedron vertices and the other two vertices lead to orbitals of the non-bonding electron pairs of oxygen atom (Figure 7.1). The water molecule, like other molecules, is geometrically and physically characterised by the bond (valence) angles of the three connected atoms H–O–H, bond length (distance between the centres of the atoms of oxygen and hydrogen) and energy of the covalent bonds O–H. The bond angle of the O–H covalent bond in a molecule of water is almost identical to the ideal tetrahedral angle (109°28′). The bond angle is 109°6′ in ice, 105° in liquid water and 104°30′ in steam. Differences from the ideal tetrahedral angle are explained by the different repulsive non-bonding forces between the pair of non-bonding and the pair of bonding orbitals (Figure 7.1). The H–O bond length of 0.096 nm is found from the sum of the covalent radii of individual atoms (0.066 nm for oxygen and 0.030 nm for hydrogen). Information about the arrangement of the atom nuclei in space can be obtained from the bond angles and lengths of covalent bonds. Details on the external surface of the molecule result from an imaginary hard sphere called the van der Waals radius, used to model the atom, which is a measure of the maximum distance between the atoms where the van der Waals attractive forces with parts of the water molecule play a role (Figure 7.2). The van der Waals radius is larger than the covalent radius that expresses the spatial requirement of an atom in a covalent bond (0.120 nm for hydrogen and 0.145 nm for oxygen). The energy of covalent O–H bonds in a water molecule (dissociation energy) is about 461 kJ/mol. Intramolecular delocalisation of electrons in covalently bound hydrogen atoms toward the electronegative oxygen atom results in the formation of partial positive charges on both hydrogen atoms (indicated by $\delta+$) and partial negative charge on the oxygen atom ($\delta-$). The water molecule is therefore a polar molecule (it is polarised) and represents an electric (permanent)

Table 7.3 Changes of water content in foods during processing.

Food	Water content (%)	Food	Water content (%)
Pork meat		Sauce (shoyu)	63
Raw	68	Meat (dried)	9
Baked	55	Meat soaked in water for 1 h	65
Fried	53	Meat soaked in water for 10 h	72
Fish (cod)		Meat soaked (10 h) and boiled	79
Raw	81	***Potatoes***	
Preserved	79	Raw	80
Fried	65	Boiled (in skin)	80
Dried (salted)	52	Boiled (peeled)	83
Dehydrated (salted)	12	Flour	8
Milk (3.5% of fat)		French fries (pre-fried)	74
Raw	87	French fries (fried)	55
Pasteurised	87	Crisps (fried)	2
Evaporated (no sweetened)	74	***Apples***	
Condensed (sweetened)	27	After harvest	85
Dried	4	After storage	84
Soybeans		Boiled with sugar (puree)	80
Raw	10	Dried	24
Soaked in water for 1 h	35	Juice	88
Soaked in water for 10 h	60	**Onion**	
Soaked (10 h) and boiled	71	Raw	89
Flour	8	Boiled	92
Curd (tofu)	85	Fried	42

dipole. The measure of the polarity is the dipole moment, which is, compared with other compounds, relatively high: $\mu = 1.85\,\mu_D$ or 1.85×10^{-30} C m, respectively. Electronegativity (the attractive force between the atom and the electron, which is at a distance of the covalent radius) of oxygen is 3.5 eV and that of hydrogen is 2.1 eV (1 eV = 1.6×10^{-19} J). The difference in electronegativities of the two atoms is a measure of bond polarity and expressed as a percentage of its partially ionic character (about 32%).

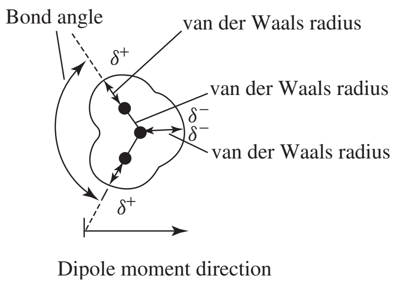

Figure 7.2 Spherical model showing a water molecule with bonding angle, dipole moment and van der Waals radii of hydrogen and oxygen atoms. Zapsalis and Beck, 1985, fig 1. Reproduced by permission of John Wiley and Sons.

Water is a chemical substance that contains 18 different isotopic variants of the H_2O molecule due to the existence of isotopes of hydrogen and oxygen (^{2}H, ^{3}H, ^{17}O and ^{18}O). In addition to undissociated water molecules also present are hydrated hydrogen ions (protons), called oxonium (hydronium) ions (H_3O^+ and trimers $H_9O_3{}^+$, respectively) and hydroxyl ions (HO^-) resulting from dissociation of water and all the variants, which also contain the aforementioned isotopes of hydrogen and oxygen. The natural content of hydrogen and oxygen isotopes is very low (e.g. the amount of ^{2}H is only 0.000 165%); it is therefore sufficient to assume in many situations that the water molecule contains only ^{1}H and ^{16}O isotopes. Significant concentrations of ions in solution, however, exist at extremely low or extremely high pH values, that is, in strongly acidic or strongly alkaline solutions. Biochemical reactions in living systems usually occur in neutral media (pH 6–8); only certain locations of the body may have pH values lower or higher. One ion of H_3O^+ or one ion of HO^- in a solution of pH 7 and at 20 °C corresponds to 7.14×10^8 undissociated water molecules. The concentration of ions H_3O^+ or HO^- is 1×10^{-7} mol/l, while the concentration of undissociated water molecules is 55.6 mol/l.

Food processing often takes place at the natural pH of the food materials of animal and vegetable origin, but the treatment of particular raw materials and the production of certain foods using acidifying or alkalising additives are also common, which strongly influence the course of many biochemical and chemical reactions.

7.5 Properties

Water, unlike related hydrides that contain elements of the sixth group of the Periodic Table (hydrogen sulfide known as sulfan, H_2S, and hydrogen selenide or selan, H_2Se), has fairly unique physical and chemical properties due to mutual interactions of water molecules. The properties of water simultaneously determine many properties of foods. Under normal conditions, water occurs in all three states of matter, whose mutual relations, depending on temperature and pressure, summarises the phase diagram. Water has an anomalous freezing point (ice melting point) and boiling point, high latent heat of fusion (melting or freezing), latent heat of vaporisation (boiling or condensing), specific heat capacity, relative permittivity (dielectric constant), surface tension, viscosity and other physical properties (Table 7.5).

Of note is the dependence of water density on temperature. Water has a maximum density of 0.999 97 kg/l at 3.98 °C and at all other temperatures the density is lower (Figure 7.3). At 0 °C, the density of water is 0.9998 kg/l, but the density of ice at the same temperature is only 0.9168 kg/l. In other words, ice has about a 9% greater volume than water. This increase in volume on converting water into ice (volume expansion) has destructive effects, especially on plant tissues during freezing. The opposite process has the same destructive effect, that is, melting ice (volume contraction) during thawing soft fruits such as strawberries. The destructive effects are also manifested on even more resistant animal tissues. Slow thawing reduces the amount of lost moisture that contains nutritionally valuable substances. The physical data for water, aqueous solutions of various substances and dispersed systems where water is the dispersion medium (solvent), are commonly tabulated and are necessary for engineering calculations in all food technologies.

7.6 Interactions

Water molecules interact with each other, with inorganic substances, as well as with almost any compound or functional group of the organic food constituents, such as proteins, lipids and carbohydrates. All these interactions significantly affect the properties of foods, such as their organoleptic properties,

Table 7.5 Some important physical properties of water compared with ethanol.

Property	Water	Ethanol	Property	Water	Ethanol
Melting point (°C)[a]	0.0	−114.2	Specific heat (kJ/kg)	4.2	2.4

Table 7.6 Overview of non-bonded-interactions.

Interactions	Examples
Electrostatic interactions	
Ion–ion	Ions of salts, ionised functional groups of proteins and carbohydrates
Ion–permanent dipole	Ions of salts -water, ionised functional groups of proteins–water, functional groups of carbohydrates–water
Hydrogen bonds	Water–water, functional groups of proteins and carbohydrates
Permanent dipole-permanent dipole	Functional groups of proteins and carbohydrates
Induced dipole-induced dipole	Functional groups of proteins and carbohydrates
Hydrophobic interactions	Hydrophobic functional groups of proteins and lipids

particularly texture, odour and taste. These interactions are also known as **non-covalent interactions** or **non-covalent bonds**, or, generally, as **non-bonded interactions**. They are caused by various attractive and repulsive forces.

Electrostatic attractive and repulsive forces (between ions and dipoles) arising from **electrostatic interactions** and forces that are due to the **hydrophobic interactions** have the greatest significance. These are listed in Table 7.6.

Electrostatic forces between **ions**[3] occur in the interactions of ions formed by dissociation of inorganic salts and in ionic interactions of ionised functional groups of organic substances such as ionised protein functional groups, for example ionised carboxyl groups ($-COO^-$), ionised amino groups ($-NH_3^+$) and ionised functional groups of some polysaccharides ($-COO^-$, OSO_3^-).

An important type of electrostatic interaction are interactions between ions and **dipoles** (permanent dipoles) that occur, for example, during interactions of salt ions with water molecules (the process is called hydration of ions) or during interactions of ionised functional groups of proteins and of some polysaccharides with water. The energy of interaction is several tens of kJ/mol (e.g. 21 kJ/mol in mutual interactions of ionised functional groups of proteins and 50–100 kJ/mol in interactions of monovalent salt ions with water).

Borderline cases of ion–ion and permanent dipole–permanent dipole interactions are the so-called **hydrogen bonds** or **H-bonds**. They occur in compounds containing hydrogen bound to one of the most electronegative elements (such as oxygen, nitrogen or chlorine). This hydrogen has a relatively small but significant affinity for other electronegative atoms. Examples are mutual interactions of water molecules (interaction energy is 17 kJ/mole), interactions of water with polar non-ionised carboxyl groups ($-COOH$) and amino groups ($-NH_2$) of proteins or hydroxyl groups ($-OH$) of carbohydrates and interactions of polar groups (e.g. carboxyl groups, amino groups or other functional groups of proteins). The energy of these interactions is about 12 kJ/mol.

Electrostatic forces between dipoles, known as **dipole interactions** (**dipole–dipole interactions**) are other significant non-bonded interactions. The interactions occur between all types of dipoles, also between permanent dipoles, which are **permanent dipole–permanent dipole interactions**. Examples are interactions between polar functional groups such as a carbonyl group, $-C{=}O$ (a special type of permanent dipole–permanent dipole type of interaction already mentioned are hydrogen bonds). Interactions of the dipole–dipole type are also important for non-polar molecules. At a certain time interval, the distribution of electric charge in non-polar molecules is not uniform. At this given moment, however, some electrons accumulate on one side of the molecule, creating a temporary dipole, which induces dipoles in other molecules. These interactions between induced dipoles are referred to as **induced dipole–induced dipole interactions**. The third and final type of interactions of the dipole–dipole type are interactions between permanent and induced dipoles, known as **permanent dipole–induced dipole interactions**. The sum of the attractive or repulsive forces between molecules or between parts of the same molecule are called van der Waals forces (binding energy is about 1–4 kJ/mol).[4] Special cases are forces between two permanent dipoles, known as

[3] Oppositely charged ions are attracted by the force F (arising from Coulomb's law) acting on a point charge q_1 as a result of the presence of a second point charge q_2: $F = q_1.q_2/4\pi.\varepsilon_0.r^2$, where q_1 and q_2 = electrically charged ions, r = their distance and ε_0 = permittivity of space.

[4] The attractive energy (E) of all types of interactions between dipoles is proportional to r^{-6}, where r is the distance between the centres of interacting molecules ($E = -C.r^{-6}$, C = London constant). With the increasing distance between dipoles (at around 1×10^{-8} m), the so-called retardation effect manifests and the attractive energy is then proportional to r^{-7}.

Keesom forces, forces between two induced dipoles referred to as London dispersion forces and forces between permanent dipoles and induced dipoles called Debye forces.

The hydrophobic interactions occur in non-polar molecules or non-polar functional groups. They are important especially for lipids and proteins. A non-polar substance or non-polar functional group in an aqueous environment is situated in an area surrounded by water molecules associated with each other. In order to create this space, some hydrogen bonds between water molecules must be disrupted, which requires the release of energy. As a result, the free energy of the system decreases and the decrease is compensated by a simultaneous decline in entropy (the system becomes less random, less disorderly and more organised). If two molecules of a non-polar substance are in the same area, the number of broken hydrogen bonds is lower than is the case when non-polar molecules exist separately and are separated by water molecules, because water molecules rearrange around this area so that they create the maximum number of hydrogen bonds. Transfer of non-polar molecules from a non-polar to a polar environment is therefore a spontaneous process, which is accompanied by a negative free energy change. For alkanes this negative free energy change is −10 to −15 kJ/mol and is higher for lipids. Water molecules, which otherwise create hypothetical six-membered structures are partially transformed during the re-organisation into more compact five-membered structures (see Section 7.6.1).

7.6.1 Interactions with water molecules

Water in all states of matter is a highly organised dynamic system. The dipole character of the water molecule allows its association with other water molecules through hydrogen bonds (called hydrogen bridges), which are the interactions of a hydrogen atom covalently bound to the electronegative oxygen atom of one water molecule with the electronegative oxygen atom of another water molecule. In comparison with the length of the covalent bond O–H (0.096 nm), the length of a hydrogen bond (O . . . H distance) is almost doubled and is 0.177 nm; the distance between two adjacent oxygen atoms of water molecules (O . . . O) is 0.276 nm (in ice at 0 °C). The dissociation energy of hydrogen bonds between water molecules is relatively high, at around 5% of the covalent bond O–H dissociation energy (about 25 kJ/mol).

Each water molecule in ordinary ice (called ice I_h, which is the only natural form of ice) associates with four other water molecules. The so-called coordination number (the number of neighbouring molecules located in the immediate vicinity of each water molecule) is therefore 4 (Figure 7.4). Taken together, water molecules in ice create a completely regular spatial association structure that is a hexagonal lattice (Figure 7.5). The crystal lattice structure is not static, since hydrogen bonds in the crystal lattice of ice and of water in liquid and gaseous states, as well as the covalent bond of the water molecules, are only temporary in character. The old links disappear and new links re-form, because hydrogen atoms oscillate, even at temperatures of −20 °C, between two neighbouring oxygen atoms: O–H....O↔O....H–O. The half-life of their duration is only about 10–11 s. Under normal freezing temperatures, only a small number of water molecules are not integrated into the crystal lattice of ice. The number of integrated water molecules in the ice lattice decreases slightly with increasing temperature and increased pressure.

Liquid water at 0 °C has about 90% of the molecules associated by hydrogen bonds as in ice, and in boiling water about 80% of the molecules are still associated. To a small extent, water molecules are associated even in the gas phase. In the liquid state, water molecules are associated in irregular clusters, aggregates of molecules, which are in equilibrium with randomly distributed free molecules. The number of water molecules in clusters is estimated at 200–400 (at 20 °C). Water molecules in clusters are regularly oriented and arranged in a lattice similar to the ice lattice. The duration of clusters is about 1×10^{-8} s.

Liquid water, however, has a greater number of other structures. In addition to the hexagonal lattice found in ice, compact structures, such as the five-membered rings, are also assumed. The consequence of the occurrence of these compact structures is an increase in the coordination number. The coordination number of water in ice at 0 °C is 4; the coordination number of water at 1.5 °C is 4.4 and this continues to rise with increasing temperatures. The average distance between adjacent water molecules also increases with the rising temperature. In ice at 0 °C, the distance of two neighbouring oxygen atoms of water molecules (O . . . O) is equal to 0.276 nm (Figure 7.4), while in water at 1.5 °C this distance is 0.290 nm. The higher water density at 3.98 °C is explained by an

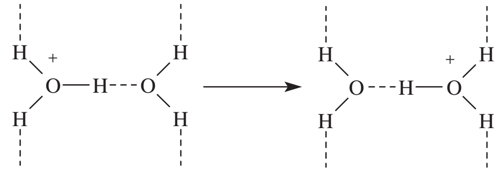

Figure 7.6 Interaction of oxonium ions with water.

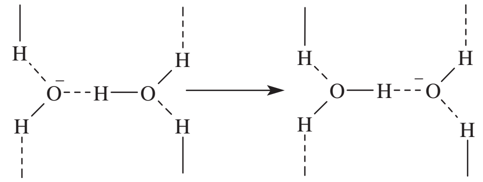

Figure 7.7 Interaction of hydroxyl ions with water.

increase in the value of the coordination number. At temperatures above 3.98 °C, the decrease in water density is due to the increased average distance between adjacent water molecules.

The disturbances in the lattice structure of ice and liquid water also occur in the presence of various non-electrolytes, such as sugars and ions resulting from dissociation of water or electrolytes, for example inorganic acids, hydroxides and salts. Water molecules are associated with protons (oxonium ions) arising by dissociation of water or any acids present. Each molecule of an oxonium ion is associated with three water molecules through very strong hydrogen bonds (dissociation energy is about 100 kJ/mol) and the coordination number is 3. The associated structure is not static, since hydrogen bonds are involved in the transport of protons to other water molecules. The interaction is very fast (about 1×10^{12} per second). Equivalent conductivity and mobility of oxonium ions and of hydroxyl ions is thus very high in comparison with other ions (Figure 7.6). By analogy, hydrogen bonds are also involved in the transport of hydroxyl ions (electrons). Hydroxyl ions are associated with three molecules of water; therefore the coordination number is 3, as in the case of oxonium ions (Figure 7.7).

7.6.2 Interactions with food components

Crucial for the properties of foods are processes taking place at the interface of water and air, water and other liquids and solids, and processes occurring in the aqueous phase of aqueous solutions and dispersions.

7.6.2.1 Interactions with inorganic salts

Inorganic salts are composed of ions, each bound by strong electrostatic attractive forces (interaction of the type ion–ion). This ion (electrovalent) bond generally occurs between two atoms of different electronegativity by transfer of one or more electrons from one atom to another. For example, sodium (Na) is a typical metal (alkali metal) with low electronegativity (0.9 eV) while chlorine is a non-metal (halogen) with high electronegativity (2.9 eV). The positively charged sodium atom with 11 protons and 10 electrons (sodium cation Na^+) arises by transfer of one electron to the chlorine atom, giving rise to a negatively charged chlorine anion Cl^- (with 17 protons and 18 electrons). Both ions gained the electron structure of the rare gases neon and argon, respectively. The crystal lattice of sodium chloride results from the individual cations and anions, cations are surrounded by anions and *vice versa*. Each sodium atom is surrounded by six equidistant chlorine atoms and *vice versa* (sodium and chlorine have the coordination number 6). In the crystalline state, ions have a substantially lower energy than the atoms from which they were formed (Figure 7.8). The result of strong electrostatic attractive forces between the ions is the high melting point (801 °C) and boiling point (1440 °C) of sodium chloride.

Crystals of inorganic salts dissolve well in dipolar water molecules. In order to produce the dissolution of crystals, water molecules break the electrostatic forces binding the ions in the crystal lattice. The energy of the hydrogen bonds between the water molecules (25 kJ/mol) is almost comparable to the energy of ionic bonds, which have electrostatic interactions between the ions (about 21 kJ/mol), and is high enough to overcome the electrostatic attractive forces. Ions released from the crystal lattice (cations and anions) are stabilised in aqueous solution by interactions with water molecules (interaction type ion–dipole). The process is called hydration (generally known as solvation) of ions (Figure 7.9). This leads to association of dispersed ions with several molecules of the dispersion medium (water) and hydrated ions interfere with the regular arrangement

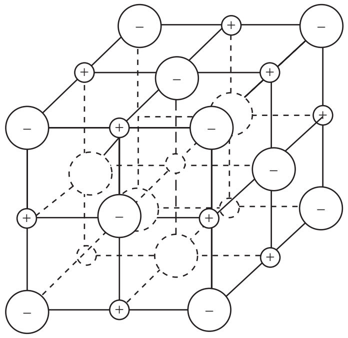

Figure 7.8 Crystal structure of sodium chloride: + = sodium cations, – = chlorine anions.

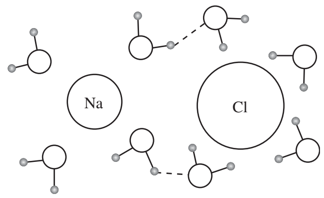

Figure 7.9 Water interactions with sodium and chloride ions. Fennema, 1985, fig 10. Reproduced by permission of Taylor & Francis – Marcel Dekker.

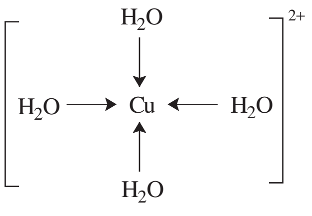
Table 7.7 Hydration of ions (in 0.5–1 mol/l solutions).

Ion	Number of water molecules bound by ion	Ion	Number of water molecules bound by ion
Na^+	8-9	Ca^{2+}	10-12
K^+	4	Cl^-	3
NH_4^+	4	Br^-	2
Mg^{2+}	14	I^-	3-4

of the water molecules (lattice) in their neighbourhood. The result is a somewhat lower water vapour pressure above the solution, lower water activity, higher boiling point and lower freezing point of solution compared with pure water. Also, some properties of ions (such as mobility) are significantly affected by hydration. The degree of hydration of different ions varies depending on the concentration of the ions and other factors (Table 7.7).

Hydration of dissociated ions releases a certain amount of energy called the **hydration energy**. The difference between the crystal lattice energy (energy of the ionic bonds) and hydration energy appears as a **heat of solution**, which is released (positive heat) into the environment or withdrawn (negative heat) from the surroundings. The heat of solution of sodium chloride taken from the surroundings is small (–86 kJ/kg, which corresponds to –5 kJ/mol), but a much higher negative heat of solution (–149 kJ/kg, –27 kJ/mol) arises by dissolving xylitol, which produces a perceived sensation of coolness in the mouth as it comes in contact with the saliva.

A number of metal ions, especially ions of transition metal elements (such as Cu, Zn, Fe, Co and Ni) exist in the form of relatively stable aqua complexes (hydrates) in aqueous solutions at the natural pH values of food materials. Aqua complexes of metal ions are often part of more complicated complexes of mineral compounds with various organic ligands. The binding of water is subject to electrostatic interactions between positive ions and coordinated water molecule dipoles. Generally, the molecules attached to the central ion are called ligands (**7-1**).



7-1, Cu^{2+} cation complex with water

The growth of the pH value leads to hydrolysis of aqua complexes and the formation of less soluble or insoluble hydroxides that have lower biologically availability or are fully available. For example, cupric, ferrous and ferric ions exist in acidic aqueous solutions as very soluble cations $Cu(H_2O)_4^{2+}$, $Fe(H_2O)_4^{2+}$ and $Fe(H_2O)_4^{3+}$, respectively, while in neutral and alkaline media these cations exist as the slightly soluble hydroxides $Cu(OH)_2$, $Fe(OH)_2$ and $Fe(OH)_3$.

7.6.2.2 Interactions with proteins

Proteins are soluble in strongly polar solvents such as water and in aqueous solutions of acids and bases. Certain proteins, known as prolamins, are only soluble in less polar solvents (such as ethanol). The majority of proteins form monodispersed systems (molecules in solution are separated by solvent), but some proteins form oligodispersed systems (see Section 7.8).

The interaction of water with proteins is of paramount importance for maintaining the structure and functional properties of proteins *in vivo*, but also influences texture and other functional properties of foods. Proteins contain essentially three types of functional groups interacting with water:

- **ionised polar groups**, such as amino and carboxyl groups, for example in protein-bound lysine $-(CH_2)_4-NH_3^+$ and glutamic acid $-CH_2-CH_2-COO^-$;
- **electrically neutral polar groups**, such as the ε-amino group of lysine in alkaline media $-(CH_2)_4-NH_2$ and the carboxyl group of glutamic acid in acidic media $-CH_2-CH_2-COOH$ or the hydroxymethyl group of serine $-CH_2-OH$;
- **non-polar groups**, for example alkyl groups of branched aliphatic amino acids valine, leucine and isoleucine, methylthiomethylene group of methionine $-CH_2-S-CH_3$ or aryl groups of aromatic amino acids, such as phenylalanine.

The degree of hydration of protein molecules, which depends mainly on their structure and pH, is expressed as the ratio of bound water weight and protein weight (in g of water bound by 1 g of protein). The degree of hydration is different for each protein, for example about 0.2 in ovalbumin, 0.3 in haemoglobin and up to 0.8 in native β-lactoglobulin.

The pH has a great influence on the ionisation of polar functional groups in the protein-bound amino acids, and thus on the ability of proteins to interact with water (bind water). Ionised functional groups of proteins interact with water in a similar way to salt ions. The ionised basic side chains of lysine and histidine bind about four molecules of water by hydrogen bonds, the acidic side chains of glutamate and aspartate bind about six water molecules, while the neutral carboxyl groups of amino acids (interaction of dipole–dipole type) bind two water molecules of as well as the polar non-ionised side chains of serine and other amino acids.

A thermodynamically disadvantageous situation will occur if a hydrophobic substance or a non-polar functional group of amino acids or proteins is an aqueous environment, because non-polar functional groups associate and the so-called hydrophobic interactions are especially important for maintaining the tertiary structure

of proteins, but also play a role in other situations. Interactions of water with non-polar functional groups of proteins are through the same mechanisms as the interaction of water with lipids. In addition to these interactions, there are also van der Waals interactions.

Only a small proportion of polar groups of native (undenatured) protein located in the hydrophobic area of the molecule are unable to bind water, for steric reasons. Thermal denaturation leads to changes in the higher structures of protein molecules (quaternary, tertiary and secondary) and new, previously inaccessible functional groups, can interact with water and the protein has an increased ability to bind water (30–45%) in the denatured state. If, however, denaturation leads to aggregation of denatured protein molecules, the functional groups of proteins react with themselves, thereby reducing the number of functional groups capable of entering into interactions with water, which decreases the ability of the proteins to bind water.

The behaviour of proteins is significantly affected by the presence of low molecular weight ions (cations and anions of inorganic salts). Many salts (including sodium chloride) increase protein solubility in concentrations up to about 1 mol/l. This phenomenon is explained by the fact that electrically charged dissociated polar groups on the surface of protein molecules bind salt ions via electrostatic forces tighter than water molecules. These ions can bring their own organised clusters of water molecules and the solvated (hydrated) proteins are stabilised. This so-called salting-in effect (see Section 2.4.3.1), in which the solubility of the protein increases slightly, is of great importance in the production of many foods. Water binding of proteins is a particularly important phenomenon in the meat technology sector. For example, if the pH of the meat decreases from 5.0 (which is approximately the value of the isoelectric point of muscle proteins) to about 3.5, the homogenate of muscle proteins may bind double the amount of water than at the initial pH of the meat. Examples are some procedures in cured ham production, when meat salting increases the ability to bind water. The addition of salt solutions for curing, usually by injection or massage, guarantees the desired water and salt contents and makes the meat tenderer. Sodium chloride and sodium chloride ions bind primarily to the myofibrillar proteins actin and myosin. In addition to sodium chloride, sodium and potassium phosphates, citrates and tartrates added to meat and meat products affect muscle pH and increase the meat's water-holding capacity (WHC) and also act as emulsifying agents for processed cheeses (see Section 6.3.4.2.3). In the manufacture of processed cheeses, the added phosphates and polyphosphates act as emulsifiers. They release the casein molecules from micelles and caseins then bind the milk fat or fat added.

At higher salt concentrations (about 1–2 mol/l), the reverse process may occur and many proteins are salted-out or precipitate. The concentration of available water molecules decreases as they are used to solvate (hydrate) the salt ions and the amount of water needed to dissolve the protein is lower. Salts compete for water with the protein. This phenomenon, called the salting-out effect, occurs rarely in food processing except in the surface layers of salted meat and fish and in some speciality meat and fish products with a high salt content.

7.6.2.3 Interactions with lipids

Lipid molecules, such as molecules of triacylglycerols or neutral polar phospholipids, tend to aggregate in an aqueous medium due to hydrophobic interactions of the non-polar parts of molecules. In living organisms, triacylglycerols are stored in the anhydrous form in special cells, adipocytes (fat cells), and act as reservoirs of energy. In hydrothermal processing of food, the fat is released from adipocytes and often accumulates on the water surface as it is adsorbed at the interface with air. Depending on the amount and structure, lipids form a monomolecular film, individual droplets or a continuous layer of fat on the water surface.

Polar lipids, such as glycerophospholipids, sphingolipids and cholesterol, are the structural basis of animal and plant cell biomembranes and cell organelles, such as the nucleus, mitochondria and chloroplasts. Polar lipids are amphiphilic molecules that adsorb on the surface of the water–air interface or water–oil dispersion and stabilise heterogeneous systems such as oil-in-water emulsions (o/w) and water-in-oil (w/o) emulsions. At concentrations higher than their solubility, polar lipids may form macromolecular aggregates called micelles and double films (double layers of molecules known as bimolecular lamellae), respectively. Biomembranes are organised clusters composed mainly of interacting heterolipids and proteins called lipoproteins. They regulate the chemical composition of the intracellular environment by managing the flow of nutrients and metabolic products and facilitate a series of biochemical processes.

7.6.2.4 Interactions with saccharides

The non-bonding interactions of water with monosaccharides, disaccharides, higher oligosaccharides, polysaccharides and other biopolymers containing carbohydrates (such as glycoproteins and glycolipids) take place through hydrogen bonds with electrically neutral hydroxyl groups or possibly with other polar groups. These interactions are of great significance in living systems and also influence the properties of many food dispersed systems.

7.6.2.4.1 Monosaccharides and oligosaccharides

Monosaccharides and disaccharides are generally very soluble in water and many form supersaturated solutions (syrups) during thickening. Similarly to dissolution of other solids, the forces holding the individual molecules in the solid state should be disrupted during the dissolution of carbohydrates. Such forces are cohesive forces of crystals that are, unlike the salt crystals, composed of neutral molecules. Intermolecular attractive forces are due to non-bonding interactions, usually to attractive forces between permanent dipoles. However, other non-bonding interactions, such as van der Waals forces, may also be present.

Water molecules located in the immediate vicinity of dispersed monosaccharide molecules are relatively tightly bound and contribute to the stability of some conformers or anomers. A glucose molecule, for example, is associated with 3.7 molecules of water. The $^4C_1$ glucose conformation (more than 99% of molecules)

is thermodynamically preferred, in which the bulky substituents (secondary hydroxyls) on carbons C-2, C-3 and C-4 are in the equatorial position, therefore far apart. The primary hydroxyl group at C-6, which apparently does not interact with water, and the hemiacetal hydroxyl group at C-1 of the β-anomer are also in equatorial positions. The conformer $^4C_1$ of β-D-glucopyranose thus has four equatorial hydroxyl groups interacting with water (the coordination number, in carbohydrates also called hydration number, is 4), while α-D-glucopyranose has only three equatorial hydroxyl groups interacting with water (hydration number is 3). The average number of equatorial hydroxyl groups of glucose in aqueous solution and the resulting number indicating the number of water molecules located in the immediate vicinity of glucose molecule is: $4 \times 0.67 + 3 \times 0.33 = 3.7$, because D-glucose solution contains approximately 67% β-D-glucopyranose and 33% α-D-glucopyranose in equilibrium.

The distance between the oxygen atoms of hydroxyl groups at C-1 and C-3 (or at C-2 and C-4) of the $^4C_1$ conformer of β-D-glucopyranose is 0.486 nm, and is almost the same as the distance between oxygen atoms in the lattice of liquid water (0.490 nm) and is lying in the same plane (in the ice lattice this distance is only 0.450 nm). By incorporation of glucose molecules into the water lattice, the relative positions of each layer of water lattice molecules virtually do not change and, furthermore, the glucose molecules stabilise the surrounding clusters of water molecules (Figure 7.10). The structural similarity in the interaction with water explains the ability of glucose to slow the formation of ice crystals in frozen confectionery products (similar to the effect of glycerol in mixtures with water that prevent ice from forming) and, particularly, its versatility in biochemical reactions and usability as a building block in living systems.

The range of interactions of other soluble carbohydrates with water also depends on their structure. The organised structure of water molecules is always relatively impaired. A ribose molecule, for example, is associated with 2.5 molecules of water, maltose and saccharose with 5.0–6.6 water molecules. In concentrated solutions of glucose and saccharose, the hydration number is lower, about 2 and 5, respectively. As with electrolyte solutions, solutions of carbohydrates likewise have reduced a water vapour pressure above the solution and lower freezing point and water activity, but the boiling point of the solution increases as compared with pure water (Figure 7.11).

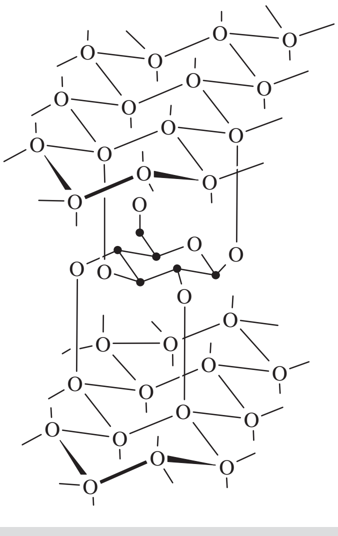


Figure 7.10 β-D-Glucopyranose in an ice lattice: O = oxygen atoms, • = carbon atoms (hydrogen atoms are not marked).

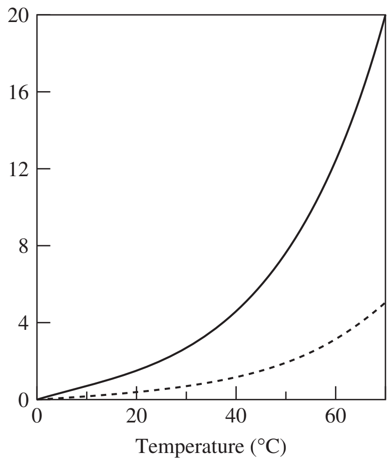

Figure 7.11 Changes of freezing and boiling points of water in comparison with saccharose solutions: c = saccharose concentration (%), —— change of freezing point (°C), – – – change of boiling point (°C).

7.6.2.4.2 Polysaccharides

In the solid state, all polysaccharides contain about 10–20% of water at normal atmospheric humidity. Their molecules or parts of their molecules are involved in different, more or less arranged, structures that create the crystalline and amorphous regions of the molecules. Components of starch (linear amylose with branched amylopectin) are arranged in starch granules, cellulose forms linear microfibrillar structures and agar and carrageenan molecules form double helices. Water is tightly bound in the amorphous regions of molecules by hydrogen bonds through a number of free binding sites (hydroxyl, carboxyl or other polar functional groups) that do not act in interactions with other binding sites of the same molecule (in intramolecular interactions) or with other polymer molecules (intermolecular interactions).

The solubility of polysaccharides and other functional properties depend on their structure. Linear polysaccharides dissolve with difficulty or they are completely insoluble. Such polymers are usually homoglycans with strong intra- and intermolecular non-bonding interactions. As a result of highly organised structures, some parts of the molecules even have crystalline structure and polar groups capable of interaction with water are not available. An example of a polysaccharide insoluble in cold water and soluble in hot water is amylose. Cellulose is insoluble even in hot water, but it is soluble in alkaline solvents.

Linear polysaccharides usually form unstable solutions. During collisions of molecules, some bound water is lost as a result of the

interactions of polysaccharide molecules that form larger aggregates of colloidal dimensions or even coarse dispersion, which may coagulate. These phenomena, illustrating the instability of linear polysaccharides, are well known in the retrogradation of amylose dispersions and starch gels. They also occur in dispersions of arabinoxylans.

Highly branched polysaccharides (such as glycogen, amylopectin and gum arabic) are more soluble than linear polysaccharides, as their mutually interacting functional groups are more distant from each other and thus facilitate hydration. Their solutions have very low viscosity compared with linear polysaccharide solutions of the same molecular weight and the same concentration. This is attributed to the effective volume, the average hypothetical spheres that make up the rotating polysaccharide molecules during thermal motion (Figure 7.12).

The tendency of branched polysaccharides to coagulation is very low. At high concentrations they form sticky pastes, which is probably due to interactions of side chains. After drying, these substances can easily re-hydrate.

Linear branched polysaccharides with a long main chain and a number of short side chains (such as guar and locust gums) combine the properties of linear and highly branched polysaccharides. Since the main chain is long, the viscosity of a solution is higher. Thanks to numerous short side chains, the intermolecular interactions are so strongly attenuated that the solubility and the ability to re-hydrate are high, and concentrated solutions are stable.

Polysaccharides with carboxyl groups hydrate rapidly and form viscous solutions or gels. Examples of these polysaccharides are soluble pectins. Their solubility and ability to form gels is dependent on the degree of polymerisation and the number and distribution of methoxyl groups simultaneously present in the molecule. The solubility generally increases with decreased molecular weight and an increase in the number of methoxyl groups. The pH, temperature and the presence of other substances in solution (saccharose and calcium ions) have a large influence. Other polysaccharides occurring in the form of polyanions (e.g. as esters of sulfuric acid, such as agar and carrageenans) are readily soluble and form highly viscous solutions and gels, such as pectins. The formation of polysaccharide sols and gels is described in Section 7.8.1.

Modified polysaccharides significantly change their properties even at a low level of substitution. The incorporation of acidic groups into molecules of neutral polysaccharides (such as starch phosphates or sodium carboxymethyl cellulose) increases the solubility and viscosity compared with the native polysaccharides. Substitution of neutral functional groups (e.g. in hydroxypropyl starch) increases the solubility, viscosity and stability in solutions. Alkyl groups (in cellulose ethers) facilitate hydration. At a higher degree of substitution, the hydrophobic nature of the polymer increases, along with its solubility in organic solvents.

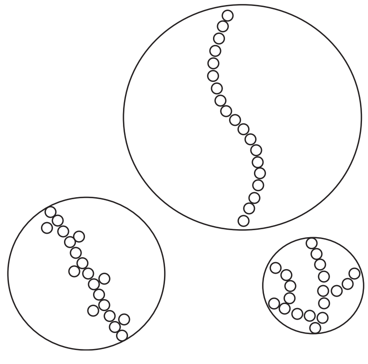

Figure 7.12 Schematic representation of effective volume of linear (A), substituted (B) and branched (C) polysaccharide molecules of the same relative molecular weight (number of monosaccharide units).

7.7 Phase interfaces

The outer boundary of liquid water (of any liquid phase in general), which is in contact with its vapour or the air, is called the **surface**. The surface forming a boundary between two or more separate phases (phase boundary), such as liquid–gas, liquid–solid, gas–solid, or, for immiscible materials, liquid–liquid or solid–solid, is called the **interface**. The surface or interface can be planar or curved. Thermodynamic properties of systems with planar and curved phase interfaces are different.

7.7.1 Surface tension

Water molecules present in the surface or in the interface have different properties in comparison with water molecules located deeper in the homogeneous liquid phase. The resulting attractive forces are directed into the liquid, because interactions with water molecules in the gas phase or with components in the air are insignificant (Figure 7.13). As a result of an imbalance of forces acting on molecules at the interface, a special type of force called **surface tension** is created in the surface.[5] This force acts in the surface plane in a way that resists all efforts to enlarge the surface,

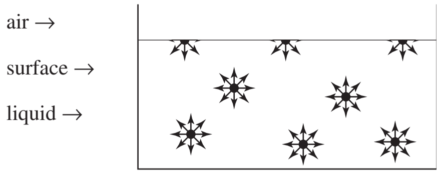

Figure 7.13 Forces acting on molecules of liquids. Zapsalis and Beck, 1985, fig 8.1. Reproduced by permission of John Wiley and Sons.

[5]Surface tension (γ) is defined as the isothermal reversible work that must be made to change the phase boundary by an area unit (A): $dw = \gamma.dA$. When changing the area of the phase boundary with the surrounding medium, not only is the mechanical work exchanged, but also the heat and the total surface energy (σ) is therefore the sum of the work (w) and heat (q) exchanged for a unit change of surface area: $\sigma = w + q$. Constant temperature and pressure leads to the relationship: $\sigma = \gamma - T.d\gamma/dA$, where γ = surface tension, T = absolute

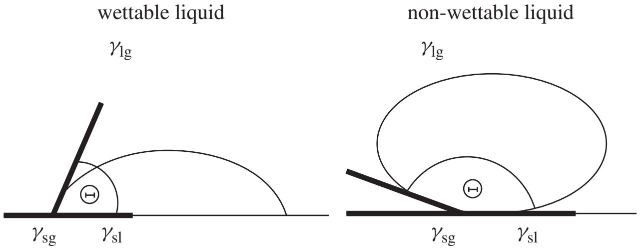

Figure 7.14 Wetting of solids by liquids: γ_{lg} = liquid-air surface tension, γ_{sg} = solid surface energy, γ_{sl} =solid-liquid surface tension, θ = wetting angle.

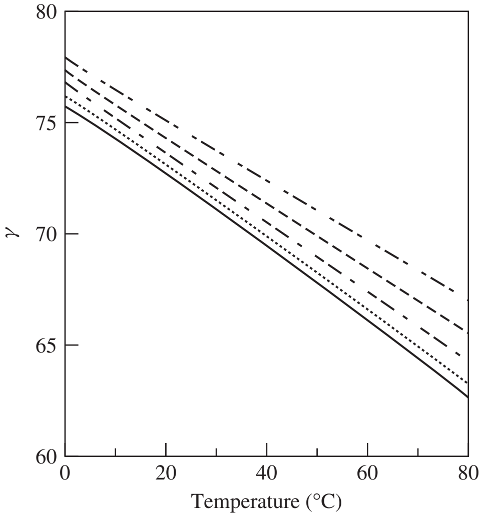

Figure 7.15 Dependence of surface tension of water and aqueous saccharose solutions on temperature and concentration: γ = surface tension (mN/m), temperature (°C), —— 0% (water), ······ = 10%, ·—·—·—· = 20%, —·—·—· = 30%, —··—·· = 40% saccharose solution.

thus tending to reduce the area of the phase boundary (total surface energy) to a minimum. The basic property of the liquid surface is that it tries to occupy the least possible area. The existence of surface tension explains many phenomena taking place at planar interfaces, such as the behaviour of liquids on the surface of other liquids and on the surface of solid materials.

If the liquid is not exposed to external forces (e.g. in a vacuum), it occupies a spherical shape as it gains the smallest surface at the given volume. On the surface of another liquid, it either forms a drop that has a lenticular shape, or can be spread over its surface. The liquid's behaviour at a given temperature depends on the size of the liquid–air surface tension, and on the interfacial liquid–liquid surface tension. On the solid surface the liquid also either spreads out evenly or forms a drop. The shape and size of the drop depend on how the liquid wets the solid surface, which is related to the liquid–air surface tension (γ_{lg}), surface energy of a solid (γ_{sg}), solid–liquid surface tension (γ_{sl}) and temperature (Figure 7.14).

When the surface of a solid substance is in contact with two immiscible liquids, one liquid creates a film between the solid substance and the second liquid. Which of the liquids forms a film depends on both the solid–liquid surface tensions and the liquid–liquid surface tension.[6] The surface tension of pure liquids (such as water) and aqueous solutions (e.g. solutions of saccharose) depends on the temperature: with increasing temperature, surface tension generally decreases (Figure 7.15).

7.7.2 Adsorption

7.7.2.1 Liquid phase-gas phase systems

The surface tension of interfaces between phases where one phase is composed of two or more components (e.g. an interface of an aqueous solution of a solute–air; so-called moving interface) is affected by the solute. For example, the surface tension increases slightly with increasing concentration of polar substances (e.g. salts or sugars, Figure 7.16), and decreases with increasing concentration of substances containing polar and weakly non-polar functional groups (such as lower alcohols and lower carboxylic acids). Surface tension, however, quickly drops to a certain constant value after the addition of **surfactants**. At this value of surface tension, surfactant molecules aggregate to micelles, which remain in the aqueous phase and therefore do not affect the surface tension. Surfactants are substances having in the molecule both hydrophilic (polar) functional groups and strongly lipophilic (hydrophobic, non-polar)

temperature, $d\gamma/dA$ = heat exchanged with the surrounding medium when changing the area of the phase boundary at the given constant temperature.

[6]During contact of more phases, the system is so arranged that the sum of its surface energies is minimal. Liquid A located on the surface of liquid B (three-phase system) will have lenticular shape when $(\gamma_{lg})_B < (\gamma_{lg})_A + (\gamma_{ll})_{AB}$, where γ_{lg} = surface tension of liquids and γ_{ll} = interfacial liquid–liquid tension (with the relevant index A, B or AB), which is always smaller than the surface tension of liquids with higher γ value. If $(\gamma_{lg})_B > (\gamma_{lg})_A + (\gamma_{ll})_{AB}$, liquid A is spread over the surface of liquid B.

In the case of contact of a liquid substance with the surface of a solid substance (three-phase system), the surface energy of the solid compound, the surface energy of a solid (γ_{sg}), interfacial solid–liquid tension (γ_{sl}) and surface tension of a liquid (γ_{lg}) are again applied. The arrangement of the system depends on their values. The liquid is spread on the surface of a solid substance when: $\gamma_{sg} > \gamma_{sl} + \gamma_{lg}$, otherwise it has a drop shape. The relation between surface energy γ_{sg}, surface tension γ_{lg} and interfacial tension γ_{sl} is given by the equation: $\gamma_{sg} = \gamma_{sl} + \gamma_{lg} \cdot \cos\theta$, where θ is the wetting angle (angle of contact). If $\theta < 90°$, the liquid wets the solid surface, if the angle is greater, then the solid surface stays unwetted.

The spreadability of liquid A on the surface of another phase B (liquid or solid substance) can be also expressed using Harkins dimensionless spreading coefficient (S), which is the difference between adhesive and cohesive work: $S = w_a + w_c = \gamma_B - \gamma_A - \gamma_{AB}$. Adhesion work ($w_a$) is the work required for rupture of the column of liquid substance A and the phase B, cohesive work (w_c) is the work required to tear the column of liquid substance A of unit cross section ($w_k = 2\gamma_A$). If $S > 0$, the liquid A spreads on the surface of phase B, otherwise it will create a drop (liquids with a negative value of S are not spreadable). The value of S is affected by temperature.

If in the case of two liquids on a solid surface the following equation is valid, $(\gamma_{sl})_A > (\gamma_{sl})_B + \gamma_{ll}$, the liquid substance B forms a film between the solid substance and the liquid substance A and vice versa in the case where $(\gamma_{sl})_B > (\gamma_{sl})_A + \gamma_{ll}$.

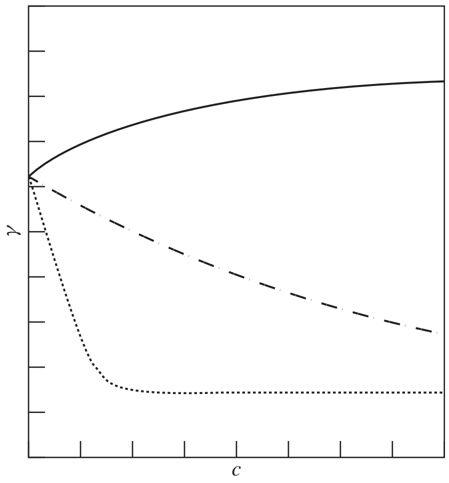

Figure 7.16 Schematic representation of water surface tension depending on the type and amount of dissolved substances: $\gamma =$ surface tension (mN/m), c = concentration, —— = sodium chloride or saccharose, - - - = ethanol or acetic acid (water–air surface tension at 20 °C = 72.8 mN/m), ······· = surfactant.

functional groups. Such substances are called **amphiphilic** or **amphipathic**. In practice, they are used mainly as detergents, emulsifiers, foam-forming substances, solubilisators and wetting agents (Figure 7.16).

The reason that surface tension is influenced by dissolved substances is the fact that the system (aqueous solution of a substance) can bring down its surface energy not only by reducing the phase boundary area as with pure water, but also by changing the concentration of solute at the interphase. Solutes dissolved in a liquid can generally migrate towards the surface or in the opposite direction. The tendency to remove the solute from the solution and concentrate it in the surface is manifested in the case where the mutual interactions of water molecules are stronger than the interactions between water and solute. The surface layer then contains an increased concentration of the solute that reduces the total surface energy (interfacial energy). The phenomenon is called **adsorption**. The substance that is adsorbed is the **adsorbate** and the substance on which another substance adsorbs is the **adsorbent**. Adsorption is a special type of surface aggregation.

Adsorption of liquids and gases can also occur in solid substances. If the liquid or gas does not stay on the surface layer of the solid substance, but penetrates into the interior, the phenomenon is known as absorption (formation of solid solutions). Resolution of both processes (adsorption and absorption) is usually not possible, because it is often a combination of both processes. Therefore, the term often used is sorption.

The forces that cause adsorption at the liquid–gas phase are primarily non-bonding van der Waals forces and hydrophobic interactions. The adsorbed amount increases with the concentration of a substance in the liquid phase and decreases with temperature increase. The action is described by the Gibbs adsorption isotherm.[7]

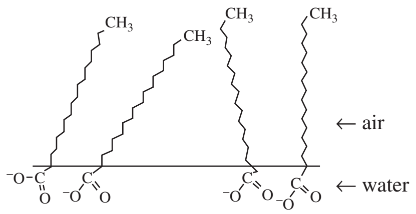

Figure 7.17 Sodium stearate molecules adsorbed on water–air interface at low concentration.

Substances that migrate to the surface and lower the surface tension of liquids are surfactants. The layer in which a significant increase in the concentration of the adsorbing substance occurs, usually has a thickness of only a few molecular diameters, and a film of the surfactant (Figure 7.17) is formed on the water surface.

The formation of films of liquids at surfaces or interfaces is actually a special case of spreading a liquid on the surface of another liquid.[8] If the strong adsorption leads to free spreading of the liquid, the adsorbed substance forms a film one molecule thick, which is called **monomolecular film** (**monomolecular layer**). Monomolecular films also exist in gaseous and solid states. They represent a two-dimensional analogy of the three main three-dimensional states of matter (gaseous, liquid and solid). Molecules of the substance in the surface film are oriented by their polar parts to the liquid (water) and by their non-polar parts to the less polar environment, which is air (Figure 7.18). Monomolecular films have a measurable effect on the mechanical, optical and electrical properties of surfaces and interfaces. The external force, which the film causes during compression, is usually called **surface pressure**.[9] If there is not enough space on the surface, the substance

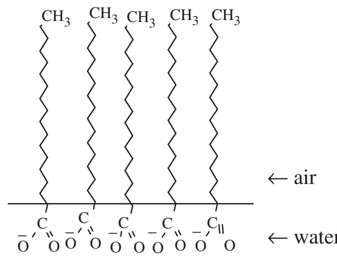

Figure 7.18 Sodium stearate molecules adsorbed in monomolecular film.

[7]Relation between the surface excess of a component (Γ) that migrates to the liquid surface and the change of its surface tension with concentration of adsorbate ($d\gamma/dc$) is expressed by the Gibbs adsorption isotherm, which is valid for ideal adsorption: $-\Gamma = c/RT.d\gamma/dc$, where $c =$ concentration of solute, $R =$ universal gas constant, $T =$ (absolute) thermodynamic temperature (K). In addition to adsorption other phenomena also often occur.

[8]If $(\gamma_{lg})_B > (\gamma_{lg})_A + (\gamma_{ll})_{AB}$, liquid A (surfactant) is spread on the surface of the liquid B (water). Likewise, under certain circumstances, on the surface of the water can be spread a small amount of insoluble and non-volatile substance applied appropriately to the surface.

[9]The surface pressure (π) and surface tension are related by the equation: $\pi = \pi = \gamma - \gamma$ ($\gamma =$ surface tension of pure liquid, $\gamma =$ surface tension of liquid covered with a film). The relationship between surface pressure (π) and surface area (A), which falls on one molecule of a substance is: $\pi = k.T/A = k_B.T/(A-a)$,

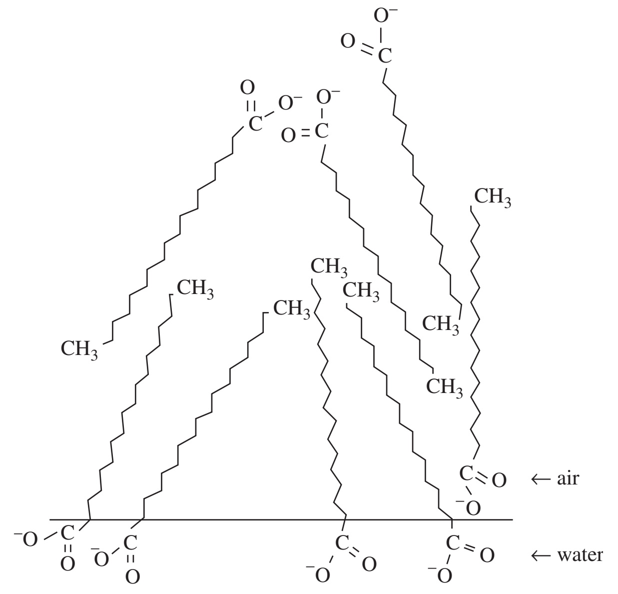

Figure 7.19 Sodium stearate molecules adsorbed on water–air interface at high concentration (multimolecular film).

partly creates a monomolecular film and the excess remains in the form of drops, which are in equilibrium with the film. At higher concentrations of a substance, a multi-molecular film or even a layer of a substance is formed (Figure 7.19).

Substances strongly interacting with water (such as hydrated ions) migrate, unlike surfactants, away from the surface of the liquid as they increase the total surface energy and therefore their interphase concentration decreases.

7.7.2.2 Liquid phase–liquid phase systems

Adsorption at the interface of two liquid phases has the same characteristics as the adsorption at the interface of a liquid phase–gas phase, since it is again a moving interface. Adsorption can be therefore characterised in the same way as adsorption systems in a liquid phase–gas phase (using Gibbs isotherm).

In practice, the most important interfaces are those of the polar phase (water) with a less polar or non-polar phase and a water-immiscible liquid phase (oil). In these systems (e.g. in emulsions) surfactants are employed, whose polar functional groups interact with water molecules (solvation) and the non-polar functional groups interact with the particles of the non-polar phase.

7.7.2.3 Solid phase–gas phase systems

Liquid–gas or liquid–liquid phase interfaces are plain or concave or convex, but the surfaces of solids are almost always non-homogeneous and contain a variety of edges, notches, pores and capillaries. The forces that cause adsorption at the solid–gas interface are, again, primarily non-bonding interactions of van der Waals forces and hydrophobic interactions. This so-called **physical adsorption** takes place on the entire surface, but there is no monomolecular layer, but multiple layers of the adsorbing substance arise. Physical adsorption is very fast, almost instantaneous. The porous solids in the pores can also contain liquid phase. This phenomenon is called **capillary condensation**.

At the same time, in the active centres in solids interactions between solid and liquid phases occur, having the character of chemical bonds. This type of adsorption is therefore called **chemisorption**. The chemisorption process is slower than physical adsorption, as it is preceded by diffusion of the substance to the outer surface of the adsorbent and diffusion through the adsorbent pores to the surface (to the active centres).[10]

Solid–gas phase interfaces are therefore described by other means, such as by the Freundlich, Langmuir and BET isotherm.[11] Heat of adsorption during the physical adsorption is of the same order as heat of condensation. Adsorption heat during chemisorption is of the same order as the reaction heat.[12]

---

where k_B = Boltzmann constant ($k_B = R/N_A$, R = gas constant, N_A = Avogadro constant), T = absolute temperature, a = area occupied by one molecule in a saturated monomolecular film. The value of (a) is practically the same for a number of organic compounds (around 20×10^{-20} m^2, that is 0.2 nm^2).

---

[10] Chemisorption rate constant $k = A.\exp(-E/RT)$, where A = frequency factor, E = activation energy of adsorption of a substance, R = gas constant and T = absolute temperature.

[11] The Gibbs adsorption isotherm is valid generally for each phase boundary, but is used mainly for mobile phase interfaces (gas–liquid and liquid–liquid systems). Solid phase–gas phase systems do not use the variable Γ (as surface energy is not constant), but the amount of gas adsorbed (a), which depends on temperature and pressure. It represents the amount of adsorbate to the amount of solid adsorbent and is expressed mostly in moles or mass units. Adsorption can then be characterised, for example, by an empirical Freundlich isotherm: $a = k.p^{1/n}$ (or in linearised form: $\ln a = \ln k + 1/n.\ln p$), where $a = x/m$, x = amount of adsorbate, m = amount of adsorbent, p = equilibrium pressure, k and n = constants for given adsorbate and adsorbent at a particular temperature.
The Langmuir adsorption isotherm is a good description of processes based on chemisorptions: $a = a_m.b.p/(1 + b.p)$, in linearised form: $p/a = 1/a_m.b + p/a_m$, where b = constant, m = constant (or the amount adsorbed when the adsorbent surface is completely covered with a monomolecular layer of adsorbed substance).
The BET isotherm (named after the authors Brunauer, Emmett and Teller) provides multilayer adsorption, when other layers are created on the first monomolecular layer of particles due to intermolecular attractive forces between particles in the monomolecular layer and particles of the gas phase. A BET isotherm has the form: $a = a_m.C.p/(p^0-p).[1 + (C-1).(p/p^0)]$, where p^0 = saturated vapour pressure, $C = \exp q_k\text{-}q/R.T$, q_k = heat of condensation and q = heat of adsorption. If $C < 1$, the first process is adsorption on the monomolecular layer followed by adsorption on the second and other layers. If $C > 1$, multilayer clusters form instead of the monomolecular layer.

[12] Heat of adsorption is expressed as a differential heat of adsorption (q) or as an integral heat of adsorption (ΔH). Integral heat of adsorption can be determined by calorimetry, differential heat of adsorption (q) is calculated from the measured isosteres: $[\mathrm{dln}\, p/\mathrm{d}T]_a = -q/RT^2$. Differential heat of adsorption heat (q) is defined as heat that is released upon adsorption of 1 mole of gaseous substances in a quantity of the sorbent that the adsorbed amount (a) per unit mass of adsorbent remains constant. Integral heat of adsorption (ΔH) is the heat that is released upon adsorption of 1 mole of a substance in a quantity of the sorbent that the adsorption is just equal to the value of adsorbed amount (a):

$$\Delta H = 1/a \int_0^a q.\mathrm{d}a$$

7.7.2.4 Solid phase–liquid phase systems

Adsorption at the solid–liquid interface is generally similar to the adsorption at the solid phase–gaseous phase interface. Theoretical modelling of the adsorption process is more difficult because, in addition to adsorbing dissolved substances, solvent is present (e.g. water), the molecules of which can also adsorb, and interactions of adsorbed molecules with molecules of the solvent may occur. Molecular adsorptions, when molecules of a substance are adsorbed, and ion adsorptions, in which ions of a substance are adsorbed, can similarly take place. Solid phase–liquid phase interfaces are usually described by empirical equations and theoretically derived equations of the Freundlich and Langmuir type.

7.7.3 Capillary phenomena

The curvature of the surface of the phase boundary creates a number of important so-called **capillary phenomena**. A large curvature of the surface of the phase boundary is characteristic of systems that contain small particles (highly dispersed systems). The result is, for example, an increased pressure (so-called Laplace pressure) inside the droplet of a certain radius due to the change in its size (radius). Another consequence is that the liquid substance in a capillary tube, with one end submerged in a container of liquid, rises so high that the hydrostatic pressure of its column is equal to the Laplace pressure.[13] In other words, adhesion forces between the fluid and the solid inner wall pulls the liquid column until there is a sufficient mass of liquid for gravitational forces to overcome these intermolecular forces.

The free surface of a liquid, the meniscus can be flat or it can have a convex or concave shape, depending on the solid and liquid surface. The forces acting on the molecule of a liquid at the free surface are: the weight of the molecule, the force of adhesion and the force of cohesion that act in various directions, therefore differences in the shape of the meniscus may occur. Pressure on the concave side of the curved surface depends on the radius of curvature and surface tension of a liquid. If the liquid is in a capillary, the radius of curvature of its surface is small and the pressure difference on both sides of the meniscus is large. If it is a liquid substance that wets the capillary walls, the liquid creates a meniscus whose curvature depends on the radius of the capillary and the wetting angle. The meniscus can be concave upwards, and the capillary liquid level rises above the liquid that surrounds it. This phenomenon is called capillary elevation. If the liquid substance does not wet the capillary wall, it creates a meniscus that is convex upwards, and its level is below the surface of the liquid surrounding it. This phenomenon is called capillary depression (Figure 7.20).

Capillary rise of solutions in the pores is of paramount importance for the water supply of plant tissues, and also for the wetting and drying of foods. Capillary phenomena also explain the hysteresis that occurs during adsorption and desorption of water in food. The so-called capillary condensation occurs during adsorption in solid phase–gas phase or solid phase–liquid phase systems.[14]

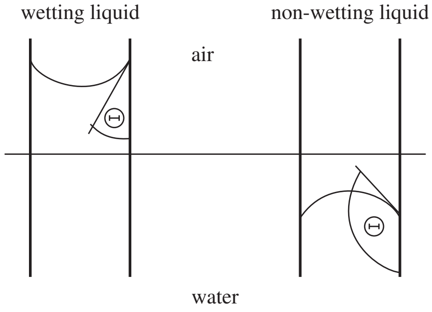

Figure 7.20 Capillary wetting by liquids (θ = contact angle).

7.8 Food dispersed systems

Dispersed systems (dispersions) are mixtures of at least two substances, one of which (dispersed phase or internal phase) is often discontinuous and is distributed in the form of particles throughout another substance (continuous phase also known as external phase or dispersion medium). Dispersions are all systems, which consist of at least two types of particles (molecules of dispersed phase and molecules of continuous phase) or of two different phases (solid, liquid or gaseous).

The dispersion medium of all living cells is water. If liquid water is in contact with its vapour or air, or with another liquid (with which it is not well mixed) or solid, it forms a two-phase or polyphase system. Water is also a dispersion medium for low and high molecular weight chemical components found in food. These components are

---

[13]Relationship is given by the equation: $\Delta p = 2\gamma/r = \rho.g.h = 2\gamma.\cos\theta/R$, where Δp = Laplace pressure, the difference between pressure of the liquid and pressure of the surrounding area, r = radius of curvature = $R/\cos\theta$ (R = radius of capillary, θ = contact angle), $\rho.g.h$ = hydrostatic pressure, h = height of liquid column. The difference of the liquid level in the vessel and capillary $\Delta h = 2\gamma_1/\rho.g.l$, where γ_1 = surface tension of liquid, ρ = its density, g = gravitational acceleration and r = capillary radius.

[14]Vapour pressure over the concave meniscus is lower than over the plane surface. Therefore, the vapour pressure (p) above the liquid that filled the narrow pores of the adsorbent is lower than the vapour pressure of saturated vapour above the liquid with a flat surface (p_0), which is given by the Kelvin equation: $R.T.\ln p/p_0 = -2\gamma.v/r'$, where R = gas constant, T = absolute temperature, γ = surface pressure of liquid, V = molar volume of liquid condensed in the pores, r' = radius of the meniscus ($r' = r/\cos\theta$, where r = pore radius and θ = wetting angle).
The Kelvin equation also shows that the penetration of water into the large pores of relatively large diameter r_2 located inside the food (during water adsorption) that are attached to the surface by a capillary of diameter r_1 depends on the pore radius: $p = p_0 \cdot \exp(-2\gamma.v/r_2.R.T)$. The immediate emptying of pores occurs when the vapour pressure during desorption is equal to $p_d = p_0 \cdot \exp(-2\gamma.v/r_1.R.T)$. According to the theory of the so-called open pores, the mechanisms of adsorption and desorption are different. Adsorption of water within the capillaries takes place on the inner wall where the water is adsorbed in a thin film of thickness D. The water vapour pressure during adsorption (p_a) is then described by the Cohan equation: $p_a = p_0 \cdot \exp[-\gamma.v/(r_1 - D).R.T]$. Desorption (liquid fills the whole capillary and $\cos\theta = 1$) is described by the Kelvin equation. Water vapour pressure during the desorption is $p_d = p_0.\exp(-2\gamma.v/r'.R.T)$. In cases where $r_1 > 2D$, is $p_a > p_d$ and hysteresis occurs, when $r_1 = 2D$ hysteresis does not occur.

water-dispersed (scattered) in the form of ions, neutral molecules or different particles that form the dispersed phase.

Dispersed systems are common aqueous solutions of low molecular weight compounds, salts, amino acids, mono- and oligosaccharides (such as sodium chloride, glycine and saccharose), as they contain at least two types of particles (molecules of the water-dispersion medium and the ions or molecules of the substance-dispersed phase). These systems are **monodispersed systems** because their components contain particles of about the same size with a certain relative molecular weight (in daltons, Da) or molar weight (in kilogram per mole, kg/mol, or gram per mole, g/mol).

Dispersed systems are also solutions of macromolecular compounds, proteins and polysaccharides, which are normally mixtures of polymer homologues containing particles of different sizes (often monomers, dimers, higher oligomers to polymers of the highest molecular weights). They are therefore **polydispersed systems** that do not have exact relative molecular weight. For their characterisation, the mean relative molecular weight or medium polymerisation degree is used (number of bound monomer units). An important point for the characterisation of polydispersed substances is the distribution curve, which indicates the frequency at which the individual particles occur in the dispersed system, depending on their molecular weight. In some polymers, the particles differ not only in size (such as fructans), but also in structure as some of them can be branched in a different way (arabinoxylans) or can have different chemical compositions (alginates). In such cases, their distribution is known as chemical distribution.

7.8.1 Classification of dispersed systems

Dispersed systems are classified according to the number of phases, the shape of dispersed particles, particle size, state (gaseous, liquid or solid) of dispersion medium and state of dispersed phase. In practice, foods can contain all types of dispersed systems.

Depending on the number of phases, dispersed systems are divided into:

- **homogeneous dispersed systems**, where the dispersion medium and dispersed phase form one phase;

- **heterogeneous dispersed systems** in which the dispersion medium and dispersed phase are two different phases separated by a phase interface; if the dispersed phase particles are smaller, the phase interface area is larger and affects the system behaviour more.

Homogeneous dispersed systems arise spontaneously and are stable (such as true solutions). Heterogeneous dispersed systems do not arise spontaneously, but are prepared artificially. They contain a dispersed phase not associated with molecules of solvent (usually water), and they are non-equilibrium dispersed systems, therefore they are unstable and spontaneously disappear.

According to the shape of the dispersed phase particles, dispersed systems are divided into:

- **globular dispersions** (all three dimensions are of the same order, they are isometric);

- **laminar dispersions** (one dimension is smaller by one order of magnitude);

- **fibrillar dispersions** (two dimensions are smaller by one order of magnitude).

Depending on the size of the dispersed phase particles (expressed as a radius, volume or weight), which corresponds to the degree of dispersion of the dispersed phase in the dispersion medium, the dispersed systems are divided into three groups (real dispersed systems, however, form a continuous series without distinct boundaries):

- **molecular dispersions** are characterised by a high degree of dispersability; the dispersed phase particles (molecules or ions) have a size less than 1 nm, are not observable by electron microscopy, easily diffuse and penetrate through membranes (dialysis), show very intense thermal motion (Brownian motion), lead to high osmotic pressures, systems are homogeneous and always form true solutions that arise spontaneously and are stable;

- **colloids** (colloidal dispersions or colloidal systems) are characterised by moderate dispersion; the size of colloidal particles is 1–1000 nm, particles can be observed by electron microscopy, diffuse slowly, penetrate some membranes, perform intense Brownian motion, lead to a measurable osmotic pressure; colloids are often allocated into three categories: **associative colloids** or **micellar colloids** (that form a transition between molecular dispersions and colloids), **lyophilic colloids** (that are homogeneous and form colloidal solutions) and **lyophobic colloids** (that are heterogeneous and consist of two phases or form multiphase dispersed systems);

- **coarse dispersions** (suspensions) are heterogeneous dispersed systems, in which the dispersed phase particles are larger than 1000 nm; systems with a particle size within 1000–50 000 nm are called **micro dispersed systems**; systems with a larger particle size (>50 000 nm) are **macro dispersed systems**, particles of coarse dispersions are observable by optical microscope and are characterised by relatively fast sedimentation due to gravity or other forces, perform Brownian motion only to a maximum particle size of 4000 nm, do not cause osmotic pressure and are always heterogeneous and unstable.

Dispersed systems are often classified according to the state of the dispersion medium and the state of the dispersed phase (gas, liquid and solid) into nine types (Table 7.8). The most common dispersion systems are sols, gels, emulsions and foams.

7.8.1.1 Molecular dispersions

Molecular dispersions are true solutions. They arise, for example, by dissolution of inorganic salts or low molecular weight organic compounds, such as monosaccharides or amino acids. The dispersed phase is dispersed into ions (e.g. sodium chloride) or molecules (such as glucose or air), which are of comparable size to the size of the molecules of the dispersion medium (water). True solutions are

Table 7.8 Types of colloids.

Dispersed phase	Dispersion medium	Name of dispersion	Examples
Solid	Solid	Solid solution or solid sol or solid mixture	Iodised salt (mixture of NaCl and NaI)
Solid	Liquid	Sol (lyosol), true or colloidal solution, suspension	Whey
Solid	Gas	Aerosol (smoke)	Plant protection products (fumigants)
Liquid	Solid	Gel or solid emulsion	Cosmetic products
Liquid	Liquid	Emulsion or solution of liquid in liquid	Milk, mayonnaise, butter, margarine
Liquid	Gas	Aerosol (fog)	Plant protection products
Gas	Solid	Solid foam	Ice cream, foam sweets
Gas	Liquid	Foam or solution of gas in liquid	Whipped cream
Gas	Gas	Mixture of gases	Air

usually kinetically stable (resistant to the effects of the gravitational field) and aggregation (still have the same degree of dispersion).

7.8.1.2 Colloidal dispersions

Colloidal dispersions (colloids) are basically formed in two ways:

- The first possibility is spontaneous reversible association (aggregation) of some low molecular weight unstable organic and inorganic substances in true solutions, as a consequence of attractive forces **associative colloids** or **micellar colloids** appear. An example of micellar colloids is casein micelles in milk.

- The second possibility is dissolution of high molecular weight substances, such as certain proteins, polysaccharides (including nucleic acids or synthetic polymers), which leads to homogeneous dispersion systems called **lyophilic colloids** that arise in various solvents. If the solvent is water then **hydrophilic colloids** are formed. Colloids containing individual molecules of dispersed phase (substance) are sometimes called **molecular dispersions**. Heterogeneous dispersed systems called **lyophobic colloids** or **hydrophobic colloids** are prepared by physical or chemical methods, such as by dispersion of non-polar substances in water. They resemble coarse dispersions and are therefore also called **phase colloids** or **dispersoids**. The common feature of all colloids is their large surface area, which is greater in smaller particles and surface phenomena therefore often determine the properties of colloidal dispersions.

7.8.1.2.1 Micellar colloids

The formation of micellar colloids is mainly a result of hydrophobic interactions (the corresponding entropy change is about 13 kJ/mol) and van der Waals attractive forces between non-polar parts of the molecules. The resulting spherical associates (aggregates) of colloidal dimensions are called micelles. The number of molecules in the micelles depends on the properties of the substances that form the micelles, their concentration and temperature. Micelles contain tens of thousands of molecules of the constituent. Micellar colloids are usually globular or laminar dispersed systems. Micelle formation is typical for all amphiphilic substances. Spherical and ellipsoidal micelles typically consist of fatty acids, glycerophospholipids and also proteins that contain hydrophobic and hydrophilic portion in the molecule (e.g. caseins in milk). Association of molecules occurs only at a concentration that is characteristic of the material, called the critical micelle concentration (dispersions of lower concentration provide true solutions or colloids). For amphiphilic constituents with one hydrophobic end, such as soaps (e.g. salts of stearic acid) and other surfactants (such as dodecyl sulfate), the critical micelle concentration is approximately 1 mmol/l, for amphiphilic substances with two hydrophobic ends (such as glycerophospholipids), the critical micelle concentration is generally 1 mol/l.

Classical examples of micellar colloids are dilute aqueous dispersions of fatty acids (their salts are accordingly known as soaps) and aqueous dispersions of other detergents. At a concentration below the critical micelle concentration, true solutions are formed (Figure 7.21), while at the critical micelle concentration and higher, micellar colloids are formed (Figure 7.22). The interiors of the micelles are filled with concentrically oriented hydrophobic groups, while on the surface are hydrophilic ionised polar groups interacting with counter ions (e.g. Na^+ cations) from the environment. These micelles are called ionic micelles. The arrangement into micelles is advantageous since it eliminates undesirable contact of water with the hydrophobic parts of amphion molecules and allows the polar groups contact with water.

Concentrated solutions of soaps also yield laminar micelles that are formed by non-dissociated molecules. Their shape is similar to the shape of glycerophospholipid micelles. Glycerophospholipids (or sphingolipids) contain two non-polar chains in the molecule and, for steric reasons, tend to form large ellipsoidal micelles, which

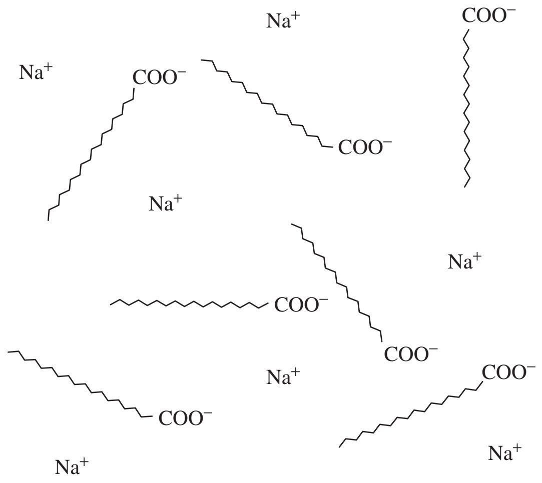

Figure 7.21 True solution of dissociated sodium stearate molecules.

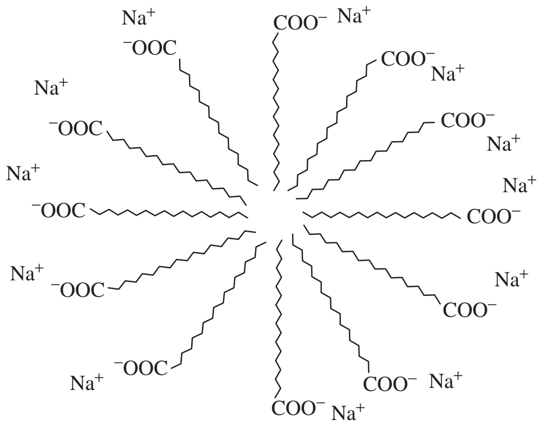

Figure 7.22 Micelle of dissociated sodium stearate molecules.

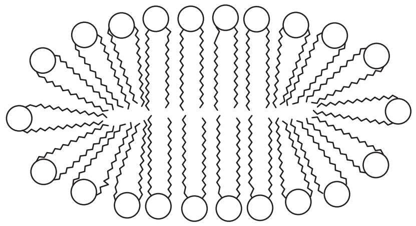

Figure 7.23 Double layers of phospholipids.

are actually a double layer of molecules. They are called bimolecular sheets or bimolecular lamellae or binary films (Figure 7.23). Milk is also a complex micellar colloid containing clusters of casein molecules called submicelles, which are associated to micelles by citric acid molecules and calcium ions.

7.8.1.3 Coarse dispersions

Coarse dispersions contain particles that are not individual chemicals (e.g. particles of food dressings containing particles of vegetables and spices), and are usually strongly polydispersed. The representation of a particle size in a polydispersed system is expressed by various distribution functions, for example, the mean radius of the particles and other particle characteristics can be determined.

7.8.2 Stability of dispersed systems

Colloidal dispersed systems are characterised by high surface energy and high curvature of the surface particles. From a thermodynamic point of view, these systems have low aggregate and kinetic stability. Their aggregate instability manifests by two spontaneous processes:

- slow dissolution of small dispersed particles, while the growth of larger particles is not usually significant (the speed of this process can be regulated in liquid dispersion media by changes in temperature or composition of the dispersion medium);
- **coagulation**, which is clustering of dispersed particles into larger aggregates associated by adhesion forces of the particle surfaces; the process is also called **flocculation**; when aggregation leads to coarse dispersions, sedimentation of aggregates may occur; coagulation, which is often one of the most important processes, can be caused by various interventions.

7.8.3 Important dispersed systems

7.8.3.1 Sols

Dispersions of solids (dispersed phases) in liquids (dispersion media) are called **sols**, or in general **lyosols**. Heterogeneous dispersed systems with only weak interactions between the dispersed phase and dispersion medium are called **lyophobic sols**. Homogeneous dispersed systems with strong interactions between the dispersed phase and the dispersion medium are called **lyophilic sols**. The interaction of particles of lyophilic sols with the dispersion medium leads to **solvation**. If the dispersion medium is water, the preferred terms are **hydrosol**, **hydrophobic sol**, **hydrophilic sol** and **hydration**.

Hydrophobic sols are, like all lyophobic colloids, heterogeneous. The dispersed phase and dispersion medium represent two different phases separated by the phase interface. Hydrophobic sols arise spontaneously, but are unstable. They are difficult to prepare (e.g. by mechanical agitation of solid particles, stirring or condensation of small particles to micelles of colloidal dimensions) and require the presence of surfactants. They are also more stable in the presence of hydrophilic sols.

Hydrophilic sols are homogeneous colloids that give colloidal solutions. They can form spontaneously and are relatively stable. Colloidal solutions of proteins and polysaccharides are typical hydrophilic sols. Hydrophilic sols are prepared by dissolving the solids in water. For example, proteins and polysaccharides are

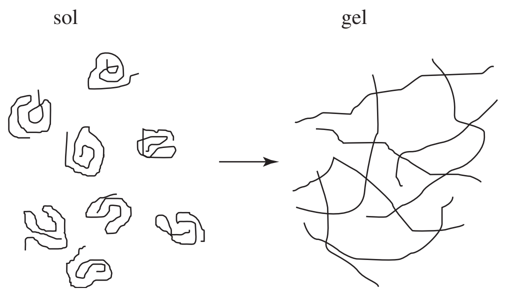

Figure 7.24 Scheme of gelatine gel formation.

suspended in water and the suspension usually requires heating. The sol, the dispersion of the solids (dispersed phase) in an aqueous dispersion medium, forms when there are only weak interactions between the macromolecules. In gelatine sol, individual protein molecules are compact, in the shape of randomly coiled globules. A sol behaves as a liquid (Figure 7.24).

Dissolution of proteins and polysaccharides is not a simple process. The solids often absorb a certain proportion of the liquid (water) with which they are in contact, without losing their shape, which is the most important property of these solids. The process is called **imbibition**. Imbibition occurs, for example, in starch granules at temperatures lower than the gelatinisation temperature (see Section 4.5.6.1.3). Solids can take up even more fluid, which increases their volume and results in **swelling**. The particle volume during swelling does not increase proportionally to the volume of absorbed fluid (water), but the sum of volumes of the substance and absorbed water is always less than the volume of swollen product, which therefore has a higher density than the original material and subjects its surroundings to a certain pressure, **swelling pressure**. Swelling is also accompanied by release of heat and by changes to the mechanical properties, primarily in increased strength and elasticity.

Depending on the mechanism of swelling, the following categories are recognised:

- Capillary swelling, which occurs mainly with the fibrous structure of organic compounds, such as many polysaccharides; solvent (water) penetrates between the individual molecules of the constituents that are solvated and the particles move away from each other during swelling, which increases the degree of dispersal.

- Molecular swelling, during which the particles of the constituent material swell, their volume grows and the degree of dispersal decreases.

According to the degree of swelling, the process can be:

- limited

- unlimited.

Examples of limited swelling are gelatine and agar in warm water (e.g. at 25 °C). Examples of unlimited swelling are gum arabic or soluble starch, which swell in water at any temperature. Gelatine and agar show unlimited swelling in hot water (e.g. at 95 °C).

In gelatine and soluble polysaccharides (such as agar) in an aqueous environment, water molecules penetrate rapidly through the amorphous regions of macromolecules during swelling, and interact with their free binding sites or interrupt the existing intermolecular bonds. Some parts of the macromolecular chains can be fully hydrated easily and, due to thermal motion, recede from each other. This reveals additional binding sites in the chain that are also solvated and solubilised. Swelling is limited only to this stage, as the hydrocolloid absorbs only a certain amount of liquid (usually through capillary swelling); gelatine or agar particles retain their original shape and do not dissolve further. Properties of the swollen material depend on the degree of hydration and the extent of the remaining intermolecular bonds. For example, all soluble polysaccharides go through this transition state during dissolution. Agar is not further hydrated, but other polysaccharides such as gum arabic continue to swell. During further hydration, a layer of water molecules surrounds the molecule of a polysaccharide and the polymer is dispersed in an aqueous environment creating a monodispersed system. With their change in shape, the solid polysaccharide molecules dissolve and form a solution (sol).

Attractive or repulsive forces between particles generally determine the stability of sols. If the particles remain dispersed, their mutual repulsive forces are larger than the attractive forces. The size of these forces is determined by various factors. Important factors in all hydrophobic and hydrophilic sols include the chemical structure of the substances, their particle size, distance between particles, presence of electric charge (particles with the same charge are repelled, while particles with the opposite charge are attracted), other mutual non-bonding interactions of particles (mainly dipole-type interactions of all three types of dipoles), solute concentration, temperature and so on. In hydrophilic sols, interactions of polarised or ionised functional groups with water through hydrogen bonds (hydration) are of great significance.

Water molecules of hydrophilic sols, in the vicinity of dispersed molecules of high molecular weight substances (proteins and polysaccharides), are relatively tightly associated by non-bonding interactions. They are usually in the state of thermodynamic equilibrium and are therefore relatively stable. Their viscosity and surface tension are significantly different (higher) than the viscosity and surface tension of the pure dispersion medium (water).

Coagulation of dispersed particles of sols can be attributed to different factors, such as:

- increased concentration of dispersed phase;

- temperature changes;

- mechanical agitation;

- addition of substances that remove the solvation (hydration) core of the macromolecules;

- addition of a sol whose particles have the opposite electrical charge;

- addition of electrolytes that affect the electric double layer of the particles and change the value of the ζ-potential (zeta potential in the interfacial double layer); all particles of the same substance in the same environment have the same charge sign and in a collision between two particles, electrostatic repulsive forces act against the adhesion forces and no coagulation occurs.

The lowest concentration able to cause coagulation of an electrolyte is called the **coagulation threshold** and its reciprocal is the **electrolyte efficiency in precipitation** (the higher the precipitation value, the less efficient the electrolyte is in the precipitation and vice versa). The value of the ζ-potential at which coagulation occurs is the **critical potential**.

Adding small amounts of inorganic or organic salts to hydrophobic sols causes suppression of the electrical charge on the surface of the colloidal particles or in the vicinity of the particles, which leads to a decrease in the ζ-potential and coagulation. Hydrophilic sols do not coagulate with the addition of small amounts of electrolytes, but their molecules are stabilised, which is manifested by the so-called **salting-in effect**. Precipitation occurs only if the electrolyte is present in excess. The electrolyte then acts as a dehydrating agent, which is manifested by the **salting-out effect**.

The salting-out abilities of ions are different. Multivalent ions are predominantly effective (when they have opposite electric charge signs to the colloidal particles). The coagulation threshold ratios of monovalent, bivalent and trivalent counter-ions are 1 : 0.016 : 0.0015. In accordance with the declining influence of the salting-out ability, the ions of inorganic and organic salts (ions of some dyes, alkaloids, saponins and some neutral organic molecules such as sugars, which eliminate the hydration core of molecules, are effective) belong to the so-called **lyotropic series**, for example:

- anions: citrates^{3-} > tartrates^{3-} > PO_4^{3-} > SO_4^{2-} > CO_3^{2-}> acetates > Cl^- > Br^- > NO_3^- > I^-
- cations: Mg^{2+} > Ca^{2+} > Na^+ > K^+ > NH_4^+
- sugars: saccharose > glucose > xylose
- sugar alcohols (alditols) and other polyols: glucitol > glycerol.

The electric charges of some hydrophilic sols (proteins or colloidal solutions of acid polysaccharides containing carboxyl and sulfate functional groups, such as pectin or agar, respectively) are significantly influenced by the pH value. At the isoelectric point, where the net charge of the molecule is zero, the stability of the colloidal solution is low. The stability of the sol can increase or decrease with a change of pH value as the dissociated functional groups bearing charges of the same sign repel each other and simultaneously interact with additional water molecules.

Electrostatic interactions between dispersed molecules are significantly affected by the dielectric constant of the medium. A decrease in the dielectric constant caused, for example, by the addition of some organic solvents (alcohols or ketones), makes the mutual electrostatic attractive forces stronger and the dispersed particles can form clusters or coagulate. This phenomenon is employed for the isolation of some polysaccharides (such as agar, carrageenan and pectin substances) from aqueous extracts. The stability of hydrophilic sols is also affected by the concentration of the colloidal particles (they have a greater tendency towards coagulation at higher concentration) and temperature. The stability of sols can increase or decrease with increasing temperature and depends on the type of colloid.

The phenomenon known as **coacervation** frequently occurs during coagulation of lyophilic sols. The sol is stratified into two distinct liquid layers that consist of microscopic and macroscopic drops or of a continuous liquid phase.

A concentrated dispersion containing more than about 10% of solids in a liquid dispersion medium is a **paste**. Pastes have the characteristic properties of both sols and gels. For example, dough is a paste, and pastes are similarly formed by some polysaccharides (such as starch).

7.8.3.2 Gels

Gels found in foods are semi-solid materials with varying degrees of elasticity, brittleness and stiffness (rigidity). They represent two-phase dispersed systems consisting of a dispersion medium, which is a solid phase (gelling agent), usually a protein or polysaccharide. The dispersion medium is water located in the spatial (three-dimensional) gel network and associated mainly by hydrogen bonds and weak physical bonds (capillary forces). Gel formation is usually accompanied by small changes in volume, Brownian motion ceases and a certain amount of heat is released (with the exception of thixotropic gels). The mechanical properties of gels (viscosity, elasticity and plasticity) are similar to those of solids.

7.8.3.2.1 Formation

Gels are formed from sufficiently concentrated colloidal sols (solutions), usually due to changes in temperature or by the addition of salts. Most gels are formed by the cooling of sols. In this way, for example, gels of gelatine, agar and other polysaccharides are formed. In exceptional cases, the gels are formed by heating of a sol (e.g. the gel of methyl cellulose).

Protein gels

Gels are formed when partially unfolded proteins form uncoiled polypeptide chains that interact at specific points to form a three-dimensional cross-linked network. For example, a gelatine gel forms by cooling a gelatine sol (even at a concentration of about 1%), when the protein globules uncoil into long fibrous molecules (Figure 7.24), which are mutually connected via non-bonding interactions. This creates an organised three-dimensional cross-linked structure (containing 5–6 crystalline domains per one polypeptide molecule) that binds a number of water molecules. The dispersion medium, unlike in a sol, now becomes the solid phase and water becomes the dispersion medium. The sol thus creates a gel. In the formation of gels, ionic bonds mainly act between amino groups of one polypeptide chain with carboxyl groups of another polypeptide chain. Secondary bonds are hydrogen bonds between the amide hydrogen atoms and the carbonyl groups of peptide

bonds. Polypeptide chains can also be bound by covalent disulfide bonds (Figure 7.25).

Some globular proteins denature on heating, and the denatured molecules aggregate to form gels. In addition to intermolecular ionic and hydrophobic interactions, covalent disulfide bonds also play a part in the formation of these gels. The aggregation of molecules into gels occurs at higher protein concentrations (5–10%) in the solutions. An example is the thermal denaturation of egg white. The aggregation of denatured protein molecules is caused by metal ions in some cases. An example is the formation of soybean curd (tofu) in the presence of calcium ions.

Polysaccharide gels

The mechanism of gel formation in dispersions of polysaccharides is a rather more complex process. In the sol state (at temperatures above the gel melting point), the polymer chains occur (as in gelatine) in the shape of randomly coiled globules, and gel formation on cooling occurs only if an association with neighbouring macromolecules is possible. The ability to form gels depends mainly on the primary structure of the polysaccharide. In perfectly linear unbranched polysaccharides, such as amylose, interactions through hydrogen bonds occur along virtually the entire chain lengths. As a result of this association, dilute solutions of amylose precipitate, and concentrated solutions form rigid gels that are susceptible to retrogradation during further aggregation of molecules. At the other extreme are highly substituted and branched polysaccharides, such as gum arabic, which do not form gels, but only form viscous solutions. Many other polysaccharide molecules have certain parts of the chain unsubstituted or unbranched and in these so-called **binding zones** gelation is due to the formation of intermolecular junction zones between the binding zones of different chains, which leads to the formation of gels. For example, the binding zones of locust gum are the sequences of unsubstituted D-mannose units, while the pectin binding zones are smooth regions composed of D-galacturonic acid units (Figure 7.26).

Gels known as low water activity gels or sugar–acid–pectin gels, formed from highly methoxylated (esterified) pectins that contain more than 50% carboxyl groups esterified with methanol are formed by this mechanism. A prerequisite of the gel formation is the addition of sugar (saccharose), at a concentration of least 500 g/l, which acts as a dehydrating agent. Another condition is a sufficiently acidic medium maintained by adding fruit juice or acids ($pH < 3.5$). Such a gel is considered a three-dimensional network of pectin molecules with immobilised solvent (water), sugar and acid. In this environment, free carboxyl groups are not dissociated, and therefore the otherwise charged chains are not repulsed. The three-dimensional structure formation is based on chain associations stabilised by hydrogen bonding between undissociated carboxyl and secondary hydroxyl groups, and by hydrophobic interaction between methyl esters.

The association of chains and the formation of locust gum gel and the formation of a mixed gel of locust gum with xanthan gum, where the molecules form double helical structures, is shown schematically in Figure 7.27. Like locust gum galactomannan, glucomannan of xanthan gum also forms gels with glucomannan of konjak gum.

Agars and carrageenans (also furcellaran) form gels so that the molecules first associate to double helices that are the gel

building structures. Double helices are transformed by further association to more complex helical aggregates known as superhelices (Figure 7.28). Agars form solid gels at a concentration of about 1% w/w. The average molecular weight of the basic building block of disaccharide agarose is about 150 Da; therefore each polysaccharide molecule binds at least 550 water molecules. Association of basic double-helical structures to more complex helical aggregates also creates gellan gels (Figure 7.29).

Low methoxylated (esterified) pectins can form gels in the presence of divalent cations, usually calcium. The interaction with calcium ions of fragments of two D-galacturonic acid adjacent units in two parallel chains of low methoxylated pectins is shown in Figure 7.30. Molecules of pectin with a low number of methoxyl groups (high content of free carboxyl groups) repel each other, which prevent the association of molecules via hydrogen bonds and hydrophobic interactions and the formation of gels. Therefore, gels are formed only in the presence of calcium ions. The initial strong association of two polymers into a dimer is followed by weak interdimer aggregation, mainly governed by electrostatic forces. Interactions in the entire length of the binding zones of low methoxylated pectin (also of sodium alginate salt) with calcium ions produce structures idealised in the so-called egg box-model (Figure 7.31). Alginates or gellan similarly form gels in the presence of metal ions, particularly calcium. The schematic structure of the alginate gel is shown in Figure 7.32. Binding zones comprising chain segments are mutually linked units of L-guluronic acid joined by calcium ions.

7.8.3.2.2 Properties

The structure of the gel is influenced by temperature, mechanical stress, pH and the presence of electrolytes (salts) and non-electrolytes (sugars). With the increase in temperature, gels become semi-solid materials, pastes or even viscous liquids. In many cases this process is reversible and gelation (e.g. of gelatine or starch gels) occurs again on cooling. Gels of this type are called

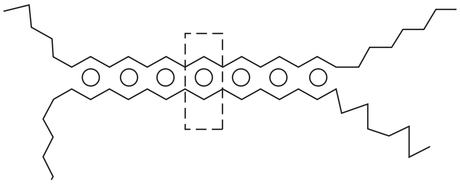

Figure 7.31 Schematic interactions of low methoxylated pectin or sodium alginate with calcium ions: O = calcium ions. Stephen, 1995, fig 10.9. Reproduced by permission of Taylor & Francis – Marcel Dekker.

thermo reversible gels. The process is related to the disappearance and appearance of hydrogen bonds between molecules of gelling agents. The opposite is **thermo irreversible gels**, in which covalent bonds (e.g. disulfide bonds) necessary for gel formation are irreversibly interrupted on heating.

The liquefaction of gels also often appears as a result of mechanical stress (when gels are shaken or agitated). If the gels that undergo liquefaction are then left to stand they rapidly regain their original consistency. This reversible property of some gels is called **thixotropy** (a time-dependent change in viscosity). These gels are called **thixotropic gels**.

Gels usually retain their original volume for a long time, but aging of some gels is manifested by **syneresis**, which is referred to as **retrogradation** if it takes place in starch gels. Aging decreases the gel volume, meaning that gel does not firmly bind all the water, which is partly released and excreted into the environment. Dried out gels are called **xerogels**. The term xerogel is also used for dried compact macromolecular gels such as gelatine gels.

7.8.3.3 Emulsions

Emulsions are heterogeneous dispersed systems (hydrophobic colloids) similar to lyophobic sols. They are the result of dispersions of immiscible liquids. One of the liquids forms a dispersed phase, which is dispersed in the liquid dispersion medium of the second liquid into small particles (drops). Depending on the size of dispersed particles and the associated stability, emulsions can be distinguished as:

- **macro emulsions** with a particle size >100 nm, typically in the range 100–1000 nm (turbid, milky and thermodynamically unstable dispersions of mutually immiscible liquids);

- **micro emulsions** with a particle size of 10–100 nm (clear and thermodynamically stable dispersions).

Emulsions in foods are macro emulsions, mainly mixtures of oil and water. The less polar phase of an emulsion (of lower relative permittivity) is referred to as the oil, while water is the second phase of the emulsion. Emulsions in food are of two types. An oil-in-water (o/w) emulsion (oil is the dispersed phase and water is the dispersion medium) contains small droplets of oil that are dispersed in water. Alternatively, a water-in-oil (w/o) emulsion has small droplets of water (dispersed phase) that are dispersed in oil (dispersion medium). Like all hydrophobic colloids, macro emulsions are unstable, because the dispersed phase tends to **coalescence** (small drops aggregate into larger drops and possibly even into a continuous phase, a layer) and the emulsions can then be divided into two phases, usually irreversibly. According to the density of the dispersion medium, the dispersed phase can be concentrated either on the surface or settle to the bottom of the container.

The stability of emulsions is influenced by many factors, such as the dispersed phase particle size (the smaller the particles, the more stable the emulsion), the amount of dispersed phase (more stable emulsions are formed with small amounts of dispersed phase), the densities of both phases (emulsions are stable when the differences between the densities of both liquids are minimal), the viscosity of the dispersion medium (emulsions with a more viscous dispersion medium are more stable), temperature (extremely high or low temperatures are undesirable), dispersed phase electric charge (stability is influenced by the presence of identical electric charges on the dispersed particles preventing coalescence), the presence of electrolytes (stability is lower in the presence of electrolytes), interfacial tension (low interfacial tension increases emulsion stability) and other factors, including mechanical stress.

Emulsions, as well as other hydrophobic colloids (such as foams), can be stabilised mechanically or by the addition of natural or synthetic surfactants called emulsifiers, which reduce surface tension at the interface of both phases. For example, the surface tension at the interface of oil–water is 20–25 mN/m. In the presence of monoacylglycerol (0.3%), it is reduced to about 80%, and by adding a mixture of lecithin and monoacylglycerol it drops to about 5% of the initial value or less. In the interface, lipophilic groups of the emulsifier molecule interact with the lipophilic (non-polar) molecules of oil and hydrophilic (polar) groups of the emulsifier interact with water. The emulsifier, for example phospholipid or monoacylglycerol, forms a protective barrier that prevents coalescence of oil drops, connects the two liquids (oil and water) and stabilises the emulsion (Figure 7.33).

The stability of emulsions, as well as of other lyophobic colloids in the presence of emulsifiers, is limited. Therefore emulsion stabilisers are often added. These can be low molecular weight hydrophilic substances (such as glycerol) or hydrophilic colloids (proteins or polysaccharides, for example, gelatine, pectin, vegetable gums or modified celluloses, respectively), which either increase the viscosity of the emulsions or interact with particles of hydrophobic colloids and thus allow their association with water.

Examples of oil-in-water emulsions are milk and mayonnaise (where the dispersion medium is water or vinegar, and the dispersed phase is milk fat or vegetable oil, respectively). The emulsifier in milk is casein, but the emulsifiers of mayonnaise are egg yolk phospholipids. An example of a water-in-oil emulsion is butter or margarine (where the dispersion medium is oil and the dispersed phase is water). Emulsifiers of butter are mainly natural phospholipids, while synthetic emulsifiers (monoacylglycerols and their derivatives and other compounds) are used to stabilise margarine.

In cases where the formation of emulsions is an undesirable phenomenon, their destruction can be achieved mechanically or chemically, for example by the addition of electrolytes.

7.8.3.4 Foams

Foam is a heterogeneous dispersed system strictly similar to an emulsion, but with **foaming** as its characteristic property. Foams consist of a gas (dispersed phase) dispersed into small bubbles in the liquid dispersion medium. The individual gas particles are separated by a liquid environment of different thicknesses (a few millimetres to a film thinner than 1 nm). Bubbles are of various shapes, according to the amount of gas located in a dispersion medium and where they occur (in the liquid phase or on the surface), but are typically round or hemispheres (Figure 7.34).

Foams exhibit characteristic elasticity[15] and stiffness. Foam texture is related to the bubble size. A fine textured foam consists of small bubbles, whereas a coarse foam contains larger bubbles. As heterogeneous dispersed systems, foams are thermodynamically unstable. When they collapse, which occurs in systems consisting of only the dispersion medium and dispersed phase (e.g. in air–water or water–carbon dioxide in soda water systems), the liquid phase flows from the liquid film that forms the bubble wall within a few seconds.

The stability of foams is higher in the presence of surfactants, **foaming agents**, which adsorb onto the bubble walls and are arranged in the interphase so that their hydrophilic groups are situated in the water and their hydrophobic groups are directed into the air. They reduce the permeability of bubbles and increase the viscosity of the liquid phase, thus reducing the loss of liquid phase, which flows from the liquid film. In addition to the properties of the dispersed phase, dispersion medium and the presence of surfactants, properties of foams are influenced by other factors, such as the method of foam preparation, the gravitational force, the forces associated with collisions between bubbles, evaporation of the liquid phase and many others.

The dispersed phase of foams in foods is usually air or carbon dioxide. The gas is generally mechanically dispersed in a liquid, for example by whipping or bubbling. Foam texture affects dough and almost all bakery products, creams and whipped creams. Foams form on the surface of non-alcoholic and alcoholic beverages. For example, the properties of beer foam are closely related to the beer constituents such as alcohol, carbohydrates, melanoidins, metal ions, iso-α-acids and proteins. The foam is composed mainly of dispersed bubbles of carbon dioxide in beer (or nitrogen in the case of Velvet beer produced, for example, by Pivovary Staropramen, Czech Republic). A pivotal role in stabilising beer foam is attributed to barley proteins or polypeptides interacting with iso-α-bitter acids derived from hops that are the major contributor to the bitter taste of beer. The bubbling properties of carbon dioxide dissolved in sparkling wines consist of the bubble nucleation on tiny particles stuck on the glass wall, bubble ascent and growth through the liquid and bursting of bubbles which constitutes this most functional and visually appealing step. A foam where the dispersed phase is air is similarly produced when egg white is whipped. The stability of a foam is higher when the protein is partially mechanically denatured as in whipped egg white. Hydrophobic groups of ovalbumin are then directed to the non-polar gaseous medium and hydrophilic functional groups interact with water. Thus oriented partially denatured albumin molecules aggregate and increase the viscosity of the foam. By heating, the whipped egg white proteins coagulate producing a **solid foam**, which are found in some candies. Another example of a solid foam is ice cream, which also contains a considerable amount of air.

The naturally occurring foaming agents in foods are commonly heteroglycosides, known as saponins (that form stable foam at very low concentrations, around 0.005%), some polysaccharides and proteins. Food additives used as foaming agents include polysaccharides (e.g. plant gums) and proteins with concentrations of about 0.5–2% by weight of liquid. Many other compounds are used as food additives, such as glycerol, its ethers, primary alcohols, some saponins and other compounds. Beer, for example, may contain propylene glycol alginate as a foam enhancer.

Foaming is sometimes unwelcomed in syrups, fruit concentrates, soft drinks, vegetable oils, tea and coffee extracts and in many other commodities. Reduction of foaming in these cases can be achieved by adding certain substances to cause the collapse of the foam. Their effect depends on their tendency to form a monomolecular film on the surface, which destabilises the foam. Often these substances reduce the surface tension of the liquid phase to the threshold value at which the bubble walls are so thin that they burst. Commonly used additives are silicone oils in concentrations of 10–100 mg/kg and also primary fatty alcohols, fatty amides, fatty acids and their esters.

[15]The elasticity (E) is related to changes in the surface tension (γ), caused by deformation of bubble walls: $E = 2A.\mathrm{d}\gamma/\mathrm{d}A$, where A = surface area.

7.8.4 Properties of dispersed systems and foods

7.8.4.1 Mechanical properties

A branch of physics that is called **rheology** studies the behaviour of solids and liquids under mechanical stress, which manifests itself by deformation of solids and by flow of liquids under applied forces. The relationship between rheological and organoleptic properties of foods is the subject of **psychorheology**.

From the viewpoint of rheology, foods are very complex materials often composed of solid and liquid components. They are mixtures of various dispersion systems (homogeneous, heterogeneous, molecular, colloidal and coarse dispersions) and are not clear-cut dispersed systems. An example of such a complex material is milk (see Section 2.4.5.2). The behaviour of foods under mechanical stress (rheological behaviour) is closely related to their **texture**. The term texture includes properties of food producing the tactile (haptic) perception of tactile receptors, registered in the oral cavity and often applied by the touch of hands. The consumer assesses, for example, the hardness of fruit according to the deformation resulting from a finger pressure or force that must be employed on chewing. The physical state and physico-chemical properties of foods are very important attributes, as they affect food behaviour during processing, storage and consumption.

The term **consistency** is used to describe the mechanical aspects of the texture associated with the physical properties of food. Important rheological properties of solids are **elasticity** and **plasticity**, while an important feature of fluids is **viscosity**. These phenomena are responsible for the characteristic texture and properties of many foods, since foods often simultaneously exhibit the properties of elastic solids and viscous liquids. Elasticity is the property of a material that enables it to resume its original shape or size when the mechanical stress is removed. Plasticity is the ability of the material to be the subject of a continuous and permanent deformation when exposed to external, usually small forces that exceed the elastic limit of the material (the stress point at which a material subjected to higher stress will no longer return to its original shape and will deform or break). The degree of plasticity depends on various factors such as temperature. By increasing the temperature, an elastic gel, for example, is transferred from the elastic to the plastic (viscoplastic) state. The transition to the plastic state can be realised not only by heating, but also by the addition of water, which acts as a plasticiser. The plastic state of a material has certain characteristic and specific properties that are similar to those of both solids and liquids. Plasticity is to some extent related to viscosity, which is a characteristic property of liquids. Elasticity and viscosity are distinguishing properties of some dispersed systems (such as gels) and many other foods (e.g. dough and bread). Often, therefore, the mechanical properties of foods are described as **viscoelastic properties**. Geometric texture attributes, such as shape and size, are often called **appearance**. The appearance of foods is also closely related to their colour.

Various descriptive terms are used to characterise texture. For example, hardness means resistance to deformation; firmness is essentially identical to the term hardness, and is sometimes used to express the ability to resist deformation caused by the material's own weight. Cohesiveness relates to the strength of internal ties of the material. Flexibility refers to the speed with which the deformed material regains its original shape when it is not subjected to the deforming force (it is associated with a relaxation time of the restoration to the original shape). Related terms are toughness, fragility, brittleness, friability and crispness. Stickiness is the adhesion between the surface material and the adjacent surface. If both surfaces are of the same material, then the correct term is cohesion. The mechanical characteristics are also described by terms such viscosity, pastiness, thinness and other terms. Responsible for foods properties reported by these terms are generally macromolecular food components such as proteins, polysaccharides and products of their mutual interactions and their interactions with other food constituents, first and foremost with water. The water content (amount of dry matter) and fat content in a food are related to the terms dry, watery, greasy and tallow, and to many other synonyms.

7.8.4.1.1 Elasticity

An important property of many materials is their ability to regain their original shape after the load is removed. These materials are called elastic. When an external force acts on a material (external forces are usually much greater than the forces caused by its own weight), it can cause a change in the state of its motion (e.g. change of location or rotation) or deformation, the scope and duration of which depend on a number of factors. When the deforming force is weak (between zero and the elastic limit) and acts for a short time, it generally leads to elastic deformation, which is temporary and the material will regain its initial dimensions. When the deforming force is weak, but acts for a long time or exceeds the elastic limit of the material, the typical result is non-elastic (permanent) deformation. The ratio between elastic and non-elastic deformation is called the degree of elasticity.

The deformation of an ideal solid material under a load is expressed by Hook's law. Deformation can change the material dimensions. For example, the extension (strain) (ε) of a string of the original length (l) caused by stress applied is (Δl). The relative extension of the string $\varepsilon = l/\Delta l$ is in direct proportion to its tensile stress (σ) applied (which is uniaxial) and in indirect proportion to the Young's modulus (E), also known as the modulus of elasticity ($\varepsilon = \sigma/E$, E = stress/strain = σ/ε), which characterises the rigidity of the material. Deformation may be caused not only by pulling or compression, but also by more complex phenomena such as bending and torsion.

A higher value of the modulus of elasticity indicates a rigid material (the E value is about 200 000 MPa for steel), a lower value indicates a more brittle material (such as glass, where E = 50 000–90 000 MPa), and a very low value represents a ductile material (such as rubber with E = 10–100 MPa). The E values of certain foods are, as an illustration, listed in Table 7.9. These values depend on many factors. For example, the modulus of elasticity in bread changes during storage and depends on the type of flour and addition of emulsifiers and a range of other variables.

A similar relationship as for the uniaxial stress caused by pressure is also true for the shear stress (τ) (tension force components

Table 7.9 Modulus of elasticity values of some foods.

Food	Modulus of elasticity (MPa)	Food	Modulus of elasticity (MPa)
Bread (fresh)	0.005	Bananas	0.8–3
Bread (almost fresh)	0.01	Apples, potatoes	6–14
Bread (old)	0.02	Carrots	20–40

act in the tangential direction) and deformation γ of the solid homogeneous isotropic material by the shear stress: $G = \tau/\gamma$, where G = shear modulus or modulus of rigidity is the ratio of shear stress to shear strain. The elastic moduli E and G (measures of stiffness) are correlated by the equation $E = 2G(1 + \nu)$, where ν (Poisson's ratio) is the ratio of relative transverse shortening (contraction) and relative longitudinal extension strains of the material in the direction of stretching force expressing the phenomenon that the material stretched in one direction tends to get thinner in the other two directions.

7.8.4.1.2 Viscosity

The ideal fluid differs from the ideal elastic solid as the shear stress causes irreversible deformation manifested by fluid motion (flow). The liquid is trying to hinder the relative movement of one layer of liquid molecules relative to the other layers. It therefore has some internal friction (internal resistance), which is related to the mutual interaction of liquid molecules. This friction is called shear **viscosity**, often referred to simply as viscosity, which is a measure of a fluid's resistance to flow.

An ideal fluid has constant viscosity when the value of the operating shear stresses changes. When the operating shear stress (σ) is uniaxial, the relationship is analogous to that of solids:

$\lambda = \sigma/\dot{\varepsilon}$, where λ = extensional (elongational) viscosity, a viscosity coefficient when applied stress is extensional stress (σ), $\dot{\varepsilon} = d\varepsilon/dt$ = change of deformation in time or strain rate. This parameter is often used for characterising polymer solutions.

Dynamic (**absolute**) **viscosity**, or the coefficient of absolute viscosity (η), is the measure of internal friction of the liquid (viscosity) at shear stress (τ) between the layers of non-turbulent fluid (Newtonian fluid) moving in straight parallel lines, which is given by the equation:

$$\eta = \tau/\dot{\gamma}$$

where $\dot{\gamma} = d\gamma/dt$ = shear strain rate. Dynamic viscosity of a Newtonian fluid (η) is a constant in the equation (Newton's law of viscosity or Newton's law of friction and motion): $\tau = F/A = \eta.dv/dx$, where τ = shear stress in the direction of the x-axis, caused by the force (F) between two planes (layers) of the liquid, A = area of planes, dv/dx = shear stress or rate gradient between the planes perpendicular to both planes. Specific equations have also been proposed for non-Newtonian fluids.

The reciprocal of the dynamic viscosity, the fraction $1/\eta$, is called **fluidity**. The proportion of dynamic viscosity and fluid density (ρ) is called **kinematic viscosity** (ν): $\nu = \eta/\rho$.

The viscosity of a fluid depends on pressure and temperature. With increasing pressure, viscosity increases, but the effect of pressure (with the exception of high pressures) on the viscosity of a fluid is usually negligible. With increasing temperature the viscosity of a fluid generally decreases substantially. Several equations expressing the dependence of viscosity on temperature have been suggested. Probably the most successful equation is: $\ln\eta = A + B/T$, where A and B = constants and T = absolute temperature.

Most low-molecular weight fluids obey Newton's equation and therefore are called **Newtonian fluids**. Their viscosity is constant at a given concentration of a substance in solution, and at the given temperature does not depend on the shear rate (dv/dx). The only parameter is viscosity, which characterises these liquids completely rheologically. The relationship between viscosity and concentration of dispersed phase for Newtonian fluids can be expressed by a number of equations.[16] The viscosity of fluids decreases exponentially with increasing temperature due to the decrease of interactions of molecules and their greater distance.[17] The dependence of the viscosity of aqueous solutions of saccharose on concentration and temperature is illustrated in Figure 7.35.

The viscosity of polymer dispersions depends, amongst other factors, on the structure of the macromolecules. Dispersions of soluble linear polysaccharides (such as amylose) are more viscous than dispersions of substituted polysaccharides (such as guar gum) and the less viscous dispersions are formed by branched polysaccharides (e.g. amylopectin and gum arabic). Viscosity is generally a function of radius of gyration,[18] Radius of gyration is related to the volume

[16]The viscosity of dispersed systems is different from the dispersion medium viscosity (pure liquid). To establish these deviations in Newtonian liquids, the following relations are used: the relative viscosity $\eta_r = \eta/\eta_0$ (η = viscosity of dispersed system, η_0 = viscosity of pure dispersion medium), the specific viscosity $\eta_{sp} = (\eta - \eta_0)/\eta_0 = 1 - \eta_r$ or viscosity number η_{sp}/c (c = dispersed phase concentration) and limiting viscosity number $[\eta] = \lim_{c\to 0} \eta_{sp}/c$. In dispersed systems, where the dispersed phase particle sizes are comparable to the molecular dimensions of the dispersion medium, the following equation can be used: $\ln\eta = x_1.\ln\eta_1 + x_2.\ln\eta_2$, where η_1 and η_2 = viscosities of components, x_1 and x_2 = their mole fractions.

For the viscosity of diluted dispersed systems with spherical particles, large in comparison with the dispersion medium particles, Einstein's equation was derived: $\eta = \eta_0.(1 + K.\varphi)$, where the constant $K = 2.5$ and φ = dispersed phase volume fraction. Deviations from Einstein's equation (where $K > 2.5$ for non-spherical particles or solvated lyophilic sols) expresses the so-called rheological voluminosity: $k.V_0 = \lim_{\varphi\to 0} \eta_{sp}/2.5{*}\varphi$. For more concentrated dispersed systems other equations are used. The relationship between the relative molecular weight (M_r) and limiting viscosity number is given by the Mark–Houwink equation: $[\eta] = K.M_r^{\,a}$, where K and a = empirical constants. This equation allows the determination of the relative molecular weight of high molecular weight substances, such as proteins and polysaccharides.

[17]The dependence of viscosity on temperature for $T > T_m$ (melting temperature) is the Arrhenius equation: $\eta = A.\exp(E/RT)$, where A = pre-exponential factor (pre-factor), E = activation energy of flow, R = universal gas constant, T = absolute temperature (this relationship does not apply at temperatures $T < T_m$).

[18]The radius of gyration $\sqrt{s^2}$ is the root mean square distance of the individual parts of a macromolecule from its centre of gravity. The relationship between the radius of gyration and the root mean square distance in random balls of linear chains is given by a simple equation: $\sqrt{s^2} = \sqrt{r^2}/\sqrt{6}$.

that the molecules occupy in a dispersion medium under thermal motion. Linear branched molecules of about the same number of monomers have a much larger radius of gyration (Figure 7.12).

Newton's equation is not valid for **non-Newtonian** (non-ideal or real) **fluids** that contain asymmetrical particles, clusters of molecules or macromolecules. Many common food systems, such as suspensions, emulsions and gels, belong to non-Newtonian fluids. Their viscosity depends on the shear rate (dv/dx) or the tangential force. However, Newton's law also applies to certain non-Newtonian fluids at smaller flow rates and to dilute polymer solutions (such as hydrophilic sols) at very low shear stresses. The rheological characterisation of non-Newtonian fluids requires knowledge of the dependence of shear stress on shear rate, which is called the **flow curve**. For example, the real shear strain rate ($\dot{\gamma}$) for spreading butter, margarine or processed cheese on bread is 0–100 s^{-1}, when pouring liquids from bottles 50–200 s^{-1}, when pumping liquid chocolate in a pipe of a diameter of 100 mm and at a flow rate of 50 l/min is 30 s^{-1}.

The non-Newtonian fluids are classified according to behaviour that they show depending on the rate gradient (dv/dx) and the tangential force (Figure 7.36). The following five non-Newtonian fluids (systems) are recognised:

- **plastic** (Bingham plastic)
- **pseudoplastic** (shear thinning)
- **dilatant** (shear thickening)
- **thixotropic**
- **rheopectic**.

Plastic systems initially behave as solid (Bingham) bodies (for $\tau < \tau_0$) and resist deformation until a yield stress (τ_0) is reached. When that stress is exceeded, the shear rate grows. Further stress leads finally to linear (Newtonian) behaviour. Examples of plastic systems are chocolate, butter, cheese, various spreads and ice cream. In pseudoplastic systems the observed viscosity decreases with an increase in shear stress. An example of a pseudoplastic system is pudding. Dilatant systems resist deformation more than in proportion to the applied force. The shear rate is growing much faster than that of Newtonian fluids and viscosity increases with an increase in shear stress. At low applied forces, the system behaves as a Newtonian fluid. Examples of dilatants systems are honey with added dextran and a slurry of wet beach sand. Thixotropic systems become more fluid (they have lower viscosity) with increasing time of an applied force. If the applied force ceases to operate, the original viscosity of the system is restored due to a reversible transformation of the sol–gel type. Examples of thixotropic systems are mayonnaise, ketchup, whipped and hardened fats, butter and processed cheeses. Rheopectic systems exhibit behaviour opposite to that of thixotropic systems. Their viscosity increases with increasing time of applied force. An example is whipped egg white.

7.8.4.1.3 Viscoelasticity

The majority of foods show viscoelastic properties. This means that these foods react, when exposed to applied force, by both the elastic component (which behave as in solids) and the viscous component (which behaves as in liquids). The rheological characterisation of these materials, in addition to flow curves, requires knowledge of other parameters, complex (dynamic) modulus G^*, which is related to the elastic component of the material (storage modulus G') and the viscous component of the material (loss modulus G'') by the following equation: $G^* = (G'^2 + G''^2)^{1/2}$. With the so-called complex dynamic viscosity (η^*), which is analogous to the dynamic viscosity resulting from Newton's law, the complex modulus (G^*) is

related by the equation: $\eta^* = G^*/\omega$, where ω = oscillation frequency or strain rate under dynamic (sinusoidal) material loading.

An example of the mechanical spectra (dependences of G', G'' and η^* on ω; the SI physical unit is the Pascal-second, Pa.s, equivalent to N.s/m^2 or kg/m s) of a polysaccharide gel is shown in Figure 7.37. The gel has a much higher value of the storage modulus G than the value of the loss modulus G$''$ and the gel therefore essentially behaves as a solid. Both modules are independent of strain rate (ω) and the gel is therefore highly elastic. The complex dynamic viscosity (η^*) decreases with increasing strain rate (ω) values as the gel becomes more fluid, which means that it is thixotropic.

Important processes taking place during the formation of a gel, and the influence of temperature and concentration of the gelling agent, are shown in Figure 7.38. After an initial delay during which the system behaves as a liquid, at time t_g the gel formation starts, which is rapid at first and then slower till a certain constant value of the storage modulus G' is achieved, which is a measure of elasticity of the material. The dependence of the storage modulus G' on the polysaccharide concentration in solution (for $t \gg t_g$) shows that the gel formation occurs only at concentrations that are higher than the critical concentration c_0. At concentrations higher than c_0, the gel rigidity grows rapidly, at lower concentrations than c_0 the polysaccharide does not form a gel, and its solution remains just as a viscous liquid.

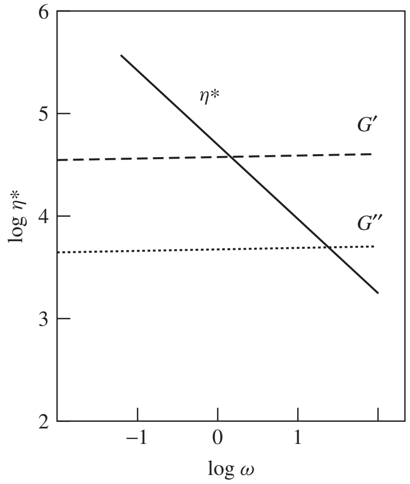

Figure 7.37 Typical mechanical spectra of polysaccharide gels: η^* = complex dynamic viscosity (Pa.s), G' = storage modulus (Pa.s), G'' = loss modulus (Pa.s), ω = oscillation frequency (rad/s). Stephen, 1995, fig 16.1. Reproduced by permission of Taylor & Francis – Marcel Dekker.

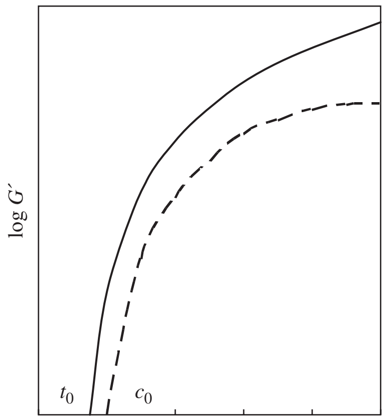

Figure 7.38 Influence of temperature and concentration on polysaccharide gels formation: G' = storage modulus (Pa.s), —— = temperature, – – – – – – = concentration. Stephen, 1995, fig 16.2. Reproduced by permission of Taylor & Francis – Marcel Dekker.

7.8.4.2 Kinetic properties

Kinetic properties of dispersed systems (dispersions) determine the rate of many processes that affect many aspects of food quality.

The dispersed phase particles of the colloidal and coarse dispersions and also of foods are in a permanent random motion called **Brownian motion**.[19] The movement of molecules is caused by bumps of the dispersion medium molecules (mostly by water molecules) that perform the thermal motion. The speed of the particle movement increases with increased temperature and decreases with particle size. At a certain particle size (approximately >4000 nm), their movement is not observable. The thermal motion of dispersed particles is the essence of some phenomena occurring in colloidal dispersion and coarse dispersed systems, and thus also in foods. These phenomena primarily include **diffusivity**, **sedimentation** due to gravitational or centrifugal forces and **osmosis**.

7.8.4.2.1 Diffusivity

In dispersed systems with a dispersed phase or dispersion medium concentration gradient (chemical potential gradient), a spontaneous process occurs to balance the concentration. This kinetic behaviour, the ability of a substance to undergo diffusion, is called **diffusion**. The speed of diffusion is characterised by the diffusion coefficient (D). Its value increases with increasing temperature and decreases with increasing viscosity of the dispersion medium and radius of dispersed particles.[20] The diffusion rate of the dispersed phase is therefore highest in molecular dispersed

[19] Mean translational energy of dispersed particles (ε_{kin}) is given by the equation: $\varepsilon_{kin} = 1/2m.u^2 = 3/2k_B.T$, where m = particle mass, u^2 = mean square speed of movement, k_B = Boltzmann constant and T = absolute temperature. The movement of particles in a certain direction (e.g. along the x-axis) is characterised by the mean shift (Δ): $\Delta=[\Sigma\Delta_i^2/n]^{1/2}$, where Δ_i = projections of individual particle displacements on the given axis and n = number of projections.

[20] One-dimensional diffusion in a stationary liquid medium is described by the first Fick's law. It shows that the diffusion flux of a substance (J) or amount of substance in moles (dS) per area (A) within a certain time (dt) is proportional to the concentration gradient (dc/dx, where dc = change in concentration of a substance at a distance x): J = dS/dt = –$D.A.$dc/dx. The non-stationary diffusion (the concentration gradient changes with time) is described by the second Fick's law as follows: dc/dt = D.$d^2.c$/dt^2. Diffusion coefficient D (in m^2/s) is related to the medium shift (Δ): $\Delta = (2D.\Delta t)^{1/2}$, where Δt = time at which the dispersed particles diffuses to distance Δ. Diffusion coefficient D is related to the friction coefficient f, which counteracts the motion of particles in the dispersion medium: $D = k_B.T/f$ (Einstein relation), where k_B = Boltzmann constant and T = absolute temperature. If the dispersed phase particles are spherical particles

systems, lower in colloidal dispersion systems and immeasurable in coarse dispersions.

The most important process in foods is diffusion of water molecules, which migrate between the non-homogeneous areas of food during storage and processing. Diffusivity determines the rate of drying, the rate of crystallisation of ice during freezing and many other processes. In foods with low moisture content, diffusion of water depends mainly on the water content. The lower the water content, the lower the diffusion coefficient. At the critical water content, which corresponds roughly to the monomolecular layer surrounding the polymers, the diffusion coefficient is zero. In partially crystalline materials such as polysaccharides (starch granules or cellulose), diffusion occurs only in amorphous regions. Another important process is the diffusion of water through food packaging.

7.8.4.2.2 Sedimentation

Sedimentation is the process by which the dispersed phase particles (large molecules or macroscopic particles) are concentrated under the action of gravitational or centrifugal forces in the direction of the force. Friction acts against this movement and diffusion can also be applied. The sedimentation rate is generally inversely proportional to the viscosity of the medium, and directly proportional to the density difference between the dispersed phase and the dispersion medium, and to the square of particle diameter.[21]

Diffusion of particles is immeasurable in coarse dispersions, where only the forces of gravity and friction act. Large particles settle faster than small particles. The movement of particles in the steady state is uniform. Molecular dispersions, on the other hand, do not show any measurable sedimentation, as the sedimentation rate is low, therefore the molecular dispersions are kinetically stable and the rate of diffusion is large. In colloidal dispersions, both processes can be balanced and may establish sedimentation equilibrium in which the sedimentation rate is equal to the diffusion rate in the opposite direction. Such a dispersion system is then kinetically stable.

In practice, the sedimentation of food particles in coarse dispersions (such as some dressings) may be prevented by the increase of the dispersion medium viscosity using suitable polysaccharides, such as carrageenan.

of comparable size with dispersion medium particles, then: $D = k.T/8\pi.\eta.r^3$, where η = dynamic viscosity of the dispersion medium and r = hydrodynamic radius of dispersed particles. Diffusion of large dispersed particles, such as biopolymers, in homogeneous diluted or concentrated solutions is described by the Stokes–Einstein relation for rotational diffusion coefficients: $D = k.T/8\pi.\eta.r^3$ and for translational diffusion coefficients: $D = k.T/6\pi.\eta.r$. From the known value of (D), it is possible to calculate the size of dispersed particles (r) or (after adjusting) their molar weight (M, in kg/mol, which is proportional to the relative molecular weight $M = 0.001.M_r$): $M = 4\pi.N_A/3v.(k.T/6\pi.\eta.D)^3$, where N_A = Avogadro's number (constant) and v = partial specific volume of particles ($1/\rho$). Other relationships are used in gaseous dispersion media.

[21]The sedimentation rate (u) is given by the following relations: $u = V.g/f(\rho-\rho_0) = m.g/f\ \ (1-\rho_0/\rho) = M.g/N_A.f\ \ (1-\rho_0/\rho) = 2r^2.g/9\eta\ \ (\rho-\rho_0)$, where V = volume of sedimentation particles, ρ = their density, ρ_0 = density of dispersion medium, f = friction coefficient, M = molar weigh of particles, N_A = Avogadro's number, η = dynamic viscosity of dispersion medium.

7.8.4.2.3 Osmosis

Osmosis is a process in which dispersion medium (solvent) particles, for example water molecules, migrate from the region of higher concentration (higher chemical potential) to a region of lower concentration (lower chemical potential) through a semi-permeable membrane. This membrane is permeable only to dispersion medium particles and is impermeable to dispersed phase particles. The solvent migration tends to increase the solvent volume of the region of lower concentration and raises the so-called **osmotic pressure** of the solution.[22] Osmotic pressure is the same as the pressure to which the solution would have to be exposed to prevent the solvent penetration through the membrane. It is directly proportional to temperature and inversely proportional to the weight of dispersed particles (their molecular weight and size). Osmotic pressure, for example, decreases if the dispersed phase particles form aggregates or when the particle is present as a polymer.

This is an extremely important phenomenon in living cells. Elastic semi-permeable cell membranes release water, but are selective to solute transport (sugars, organic acids and other substances). Very low concentrations of dissolved substances present in the cells produce high osmotic pressures that are necessary to maintain the internal pressure, called **turgor**, and a state of tension in animal tissues and plant tissues. The cells prevent too great an osmotic pressure by the synthesis of polysaccharides from monosaccharides (e.g. starch from glucose). Osmotic pressure is also an important phenomenon in animal cells post mortem and in the cells of plant tissues at the time of harvest. Higher osmotic pressures are deliberately used for growth control and inhibition of microorganisms in canned products (e.g. brines high in salt or sucrose).

7.8.4.3 Thermal properties

At higher temperatures, in frozen foods and in foods with low water content, macromolecular substances such as proteins and polysaccharides exist mainly in an amorphous state containing unorganised molecules. Amorphous or partially amorphous structures in foods commonly arise during various heat treatment processes such as cooking, concentration, drying and extrusion, where water is removed relatively quickly or concentrated dispersions are rapidly cooled. Amorphous materials are found in a non-equilibrium state and therefore, in relation to time, undergo various changes of their physical and other properties. For example, amorphous lactose crystallises in powdered milk.

When a fluid or melt (such as a sucrose melt) cools, the kinetic energy of the molecules decreases until the motion of the molecules is so small, at a certain temperature $T = T_m$ (melting temperature),

[22]In a sufficiently diluted solution, the osmotic pressure (π) is described by the following equation: $\pi = w.k_B.T/m = w.R.T/M$, where w = weight concentration of dispersed phase particles, k_B = Boltzmann constant, T = absolute temperature, m = average particle weight, R = universal gas constant, M = particle molar weight. Other relationships have been proposed for non-ideal solutions.

Osmotic pressure varies with dispersed phase particle size. Even small differences in particle size result in large differences in osmotic pressures. In two dispersions of the same concentration of particles (w), but differing in particle size, the ratio of osmotic pressures is: $\pi_1/\pi_2 = r_1^3/r_2^3$, where r_1 *and* r_2 are the radii of particles in both systems.

that the molecules can no longer escape from the secondary valence forces of neighbouring molecules, and the liquid or sucrose melt crystallises. The volume of solution or melt changes in a step (usually decreases). If the fluid or sucrose molecules become components of crystals, their spatial position is fixed, the molecules loose the freedom of movement and Brownian motion ceases.

If water, other liquids, sucrose solution or sucrose melt are cooled rapidly, it may be that they do not crystallise for kinetic reasons. Generally, cooling the fluid to a temperature below its melting point ($T < T_m$, the process is known as supercooling) changes its mechanical properties, and its viscosity increases depending on the structure of the substance. The fluid passes the region of the iso phase transition temperature (T_f) to the elastic state, which is the state of fluid with a fixed structure.[23]

Further cooling to temperatures close to T_g (glass transition temperature) results in a dramatic increase in viscosity, and at temperature $T = T_g$ the material passes from the fluid to the glassy state. The process is also called nitrification of fluids. At T_g and lower temperatures, the viscosity of vitreous material remains constant and very high (about 1×10^6 MPa/s). Other properties, such as permittivity, refractive index, diffusivity and elastic modulus are also step changes. Between the elastic state and glassy state (also known as the supercooled or solid melt) there is no difference in the structure, and only the **relaxation time** (the rate of changes of mechanical properties) characteristic for the elastic state is extended. The transition from the elastic to the glassy state is a reversible and kinetic process, since the value of T_g depends on the cooling rate.

The T_g values of food materials range from –135 °C (T_g of water) to values in the tens of °C or more above the melting point of ice (e.g. the T_g of sucrose is about 62 °C). A decrease in T_g values is seen in the presence of water and other low molecular weight compounds that act as plasticisers (e.g. the T_g value of 50% aqueous solution of sucrose is about –100 °C). The T_g value of mixtures of two or more substances lies between the T_g values of pure substances. The changes in the physical state of sucrose solutions at various concentrations and temperatures are described in the state diagram given in Figure 7.39.

Similarly to sucrose, other low molecular weight substances, synthetic polymers and polymeric compounds present in foods (proteins and polysaccharides) may also exist in various physical states, such as crystalline, glassy, elastic or plastic, among which there are iso phase transitions given by temperatures T_m, T_f and T_g. All polymers have similar properties, differing only in the

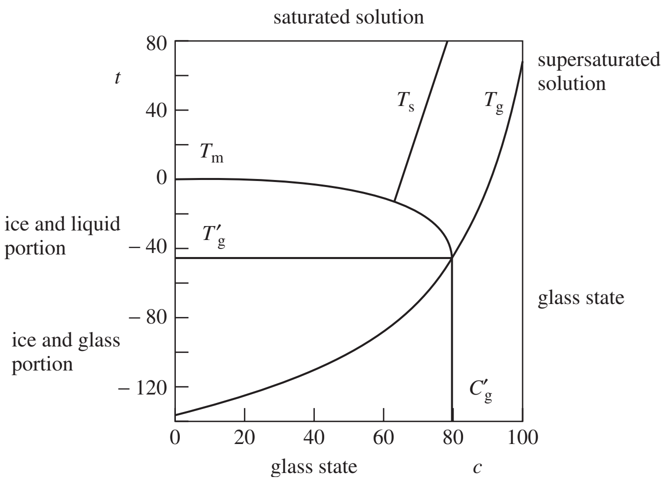

Figure 7.39 Saccharose-water state diagram: t = temperature (°C), c = concentration, T_m = equilibrium: formation-melting of ice (equilibrium melting temperature of ice), T_s = equilibrium: saturated solution-oversaturated solution, T_g = glass transition temperature, T'_g = glass transition temperature of maximum concentrated liquid phase with saccharose content C'_g

temperatures where the iso phase transitions occur. Fully crystalline solids do not have the T_g temperature and amorphous substance does not have the T_f temperature. The T_g value has a great influence on the degree of crystallinity of polymers. The value of T_g of an anhydrous material is significantly reduced in the presence of water (similarly to the synthetic polymers in the presence of plasticisers and solvents). Most biopolymers have similar T_g values. The T_g values of anhydrous substances lie in the range of 200 ± 50 °C (for starches within 151–243 °C). A decrease of the T_g value by 10 ± 5 °C is caused by the addition of 1% w/w of water. Biopolymers containing 20 ± 5% of water have the T_g value at room temperature, while biopolymers with 25–30% of water content have the T_g value at -10 ± 5 °C. Generally, the T_g value increases with increasing relative molecular weight. Up to the relative molecular weight of about 104 Da, the T_g value increases linearly with its reciprocal value.

Knowledge of the T_g values and how T_g changes depending on the water content is important for predicting the shelf life of many foods and ongoing changes related to the organoleptic properties and other quality features. Foods in the T_g region, as well as solutions or melts of sugars, suddenly change many properties, including modulus of elasticity, which increases by several orders of magnitude, and the rate of relaxation of mechanical tension. Glassy material changes to the liquid (melt) or viscoelastic material when heated to a temperature above T_g.

Viscoelastic behaviour is seen in bread, for example, which is actually a rigid foam. Typical bread containing 40% of water is glassy and brittle at temperatures below approximately –15 °C, as it is at temperature $T < T_g$. Bread can be stored at this temperature, with no retrogradation of starch or related consequences (aging and hardening) as there is under storage at normal temperatures. With increasing temperature (or water content, which acts as a

[23]At temperatures $T > T_m$ (melting temperature), the dependence of viscosity on temperature is controlled by the Arrhenius equation. In most materials, in the temperature range from T_m to T_g (glass transition temperature), the temperature decrease results in an increase of activation energy (E), which relates to the fact that molecules do not move as individuals, but in a coordinated manner. At $T > T_g$, viscosity is satisfactorily described by the so-called VTF (Vogel–Fulcher–Tammany) equation: $\eta_T = A.\exp D.T_0/(T–T_0)$ or WLF (Williams–Landel–Ferry) equation: $a_T = \exp [C_{1g}.(T–T_g)]/[C_{2g}(T–T_g)]$, where η_T = viscosity at temperature T, a_T = ratio of viscosities at T and T_g, or the ratio of relaxation times τ and τ_0 at temperatures T and T_0 and A, D, T_0, C_{1g} and C_{2g} are constants. Parameters C_{1g} and C_{2g} are considered universal constants ($C_{1g} = -17$ is for different materials virtually identical).

plasticiser), at $T = T_g$ the elasticity of bread increases rapidly and reaches a value, which remains approximately constant during further rise in temperature (or water content). Bread again becomes a viscoelastic material, but at $T > T_g$ the aging process rapidly accelerates. Some bread types (e.g. crisp bread in the Nordic countries, or German Knäckebrot) are glassy and brittle and durable even under normal temperatures, as they contain less than about 14% of water. Their glass transition temperature is higher than the ambient temperature, and therefore such breads can be stored for a long time without any changes. Wetting associated with the decrease of T_g value below room temperature occurs in extruded products, which results in the loss of crunchiness.

7.8.4.4 Optical properties

When an electromagnetic wave (an incident light ray) passes through an environment where it encounters an obstacle or an area of non-homogeneity, for example scattering particles of dispersed systems (such as in emulsions or sols), the light is scattered.[24] The intensity of light scattering in dilute dispersions on electrically non-conductive spherical particles, which is small in comparison with the wavelength of light ($<\lambda/20$), also depends on the wavelength of the incident light.[25] Light scattering in the visible spectrum region (approximately 400–700 nm) is about ten times more intense for light of shorter wavelengths (violet and blue) than for light of longer wavelengths (yellow and red). The dependence of the scattered light intensity on the wavelength is called **opalescence**. Dispersions composed of very small particles show weak opalescence, while dispersions of large particles do not show opalescence, because the light is reflected.

Opalescence often significantly affects the colour of dispersions. Dispersions exhibit different colours in incident and transmitted lights. These colours are complementary to each other; the blue part of the spectrum predominates in diffuse light and red light predominates in the transmitted light. Therefore, diluted milk is pink as it leads to scattering of light of shorter wavelengths, while light of longer wavelengths passes through the dispersion (milk).

7.8.4.5 Electric properties

Dispersed systems are externally electroneutral as a whole, but show some electric (electrokinetic) properties. Electrical properties of colloidal dispersion systems are associated with the ability to disperse particles that adsorb ions and molecules of the dispersion medium. The important food dispersed systems, lyophilic sols, preferentially adsorb ions resulting from dissociation of electrolytes. Electric charges of the same sign are then accumulated on the surface of colloidal particles as a result of adsorption of the ions that form an inner layer of ions. The electric charges (ions) of opposite sign, which constitutes the outer layer of ions, are in the surrounding part of the dispersion medium. Around the colloidal particles an **electrical double layer** is thus formed that stabilises the sols. Ions of the outer layer are arranged in two different sub-layers. The first section of ions, partially neutralising the electric charge of the inner layer of ions, is bound by adsorption forces and forms a so-called Stern layer. The remainder of the ions of the same sign are bound by electrostatic forces and form a so-called diffusion layer (also known as Gouy–Chapman layer). Their number decreases with increasing distance from the colloidal particle.[26]

During the relative motion of dispersed particles with the electric double layer against the dispersion medium, the Stern layer and part of the diffusion layer move with the particle while the rest of the diffusion layer moves with the fluid. A potential thus arises in the interface with the liquid, which is called the **electrokinetic potential** or ζ-potential (zeta-potential). Its size depends on the type of electrolyte and the ability to adsorb ions. The existence of electrical charge on the dispersed phase particles (the existence of electric double layer) significantly affects the stability of many dispersed systems. It is also associated with the phenomena that occur when one phase moves relative to another (in liquid–gas, liquid–liquid and liquid–solid systems) or with the behaviour of dispersed systems under an external electric potential gradient.

The four possible types of electrokinetic phenomena are streaming (current) potential (electric potential generated by fluid movement relative to another phase), sedimentation potential or Dorn phenomenon or Dorn effect (due to dispersed particles motion relative to the fluid caused by sedimentation) and electrophoresis and electro-osmosis (movement of two phases is caused by an external potential difference).

---

[24] Light (electromagnetic waves) passing through homogeneous environments (e.g. through true solutions) causes polarisation of particles (molecules). The resulting dipoles emit light of the same wavelength and due to the interferences of secondary waves (Huygens' principle), the light spreads only in the direction of the primary light (incident) wave. In heterogeneous environments (e.g. in dispersions), this process leads to a different polarisation of dispersed phase particles and dispersion medium particles. The radiation is not compensated according to the Huygens' principle and is scattered in all directions. The light path through the dispersion system can be seen in a darkened room (Tyndall effect).

[25] Light scattering is expressed by the Rayleigh ratio $R_\theta = I_\theta.r^2/I_0(1 + \cos^2\theta) = \pi^2.\alpha^2.N/2\varepsilon_0.\lambda^4.V$, where I_θ = intensity of light scattered at an angle of θ, I_0 = intensity of incident light, λ = its wavelength, N = number of particles in volume (V) of dispersion, ε_0 = permittivity of a vacuum, $\alpha = \varepsilon_0.V/N.(\varepsilon_r - \varepsilon_r^0)$, where ε_r = relative permittivity of dispersion (for visible light $\varepsilon_r = n^2$), ε_r^0 = relative permittivity of pure solvent (for visible light $\varepsilon_r^0 = n_0^2$), n = dispersion refractive index and n_0 = refractive index of pure solvent. Light scattering measurement (or turbidity measurement, which is the total energy that scatters in all directions from the beam when the light passes through dispersions) can be used to determine the molecular weight and shape of dispersed phase molecules.

[26] The ratio of charges in the inner and outer layer can be calculated using Stern's equation: $-\sigma_1/\sigma_0 = I^{1/2}/k + I^{1/2}$, where σ_1 = charge of the inner layer of ions, σ_0 = charge of the outer layer of ions, I = solution ionic strength and k = constant. Diffusion layer thickness is given by the equation: $[\varepsilon_0.\varepsilon_r.k_B.T/e^2\Sigma(z_i^2.\nu_{i0})]$, where ε_0 = permittivity of vacuum, ε_r = relative permittivity of the medium, e = elementary charge, z_i = number of elementary charges, which the ion I carries, ν_{i0} = number of particles per volume unit, k_B = Boltzmann constant and T = absolute temperature.

Table 7.10 Water activity of selected foods.

Food	Water activity	Food	Water activity
Fresh meat and fish, milk, beer	0.99	Fruit jams, marmalade, jellies	0.75
Eggs, vegetables and fruits	0.98–0.97	Honey, dried fruits, caramel	0.7–0.6
Bread	0.97–0.95	Pasta products (such as noodles)	0.5
Some cheeses (such as Swiss cheese)	0.91	Spices (10% of water)	0.4
Fermented sausages, margarine, aged cheese	0.87–0.85	Biscuits	0.3
Sausages	0.85–0.82	Dried milk and instant coffee	0.2
Condensed milk, legumes (15% of water), flour	0.8	Sugar, dehydrated soups	0.1

7.9 Water activity

The amount of water present in foods has only a very vague relationship with their resistance to microbial attack and biochemical and chemical reactions, which occur in foods. A more important factor than the actual water content is its availability. Water availability is related to interactions of water with food components, with the bond strength of water bound by physical adsorption or chemisorption. Tightly bound water is less available than weakly bound water, which is again less available than free water. The measure of water availability is **water activity**. The water activity of a food is not the same thing as its moisture content.

All interactions of water in food (and also in solutions of electrolytes and non-electrolytes) result in a decrease in entropy, accompanied by a decrease of the vapour pressure of water. It can be inferred that the vapour pressure of water is related to water activity (a_w) by the following formula:

$$a_w = p_w/p_w^0$$

where p_w = partial pressure of water vapour above a solution of solids or liquids or above foods and p_w^0 = partial vapour pressure of pure water at the same temperature. Water activity values therefore range from 0 to 1.

When food is in equilibrium with the ambient air, the water activity of food is equal to the equilibrium relative humidity (φ; lowercase phi), which ranges from 0 to 100%:

$$a_w = \varphi/100$$

The water activity of some selected foods is given in Table 7.10. The water content of many foods and thus their activities vary according to humidity of the ambient air (and thus temperature), as there is a constant sorption or desorption of water. The term water activity should be used only for systems that are in thermodynamic equilibrium. Foods are often multicomponent multiphase systems and only if there is a thermodynamic equilibrium between all phases is the water activity in the whole system equal, which does not happen often. It frequently requires hours, weeks or takes even longer to achieve the equilibrium state. Many food systems may also be in a non-equilibrium metastabile state (e.g. sugar melts).

The water activity of a food increases with increasing temperature at constant moisture content.[27] An increase in temperature of 10 °C causes an increase in water activity value of the food of about 0.03 to 0.2 and may, for example, have a negative effect on the stability of packaged foods, where the water content in the system is constant: undesirable microorganisms may grow or some adverse reactions may occur.

Knowledge of water activity in foods and of the relative humidity of the ambient air allow us to predict under what circumstances the food, in contact with the air of a certain relative humidity, will dry up and when, on the contrary, the food will become moist. However, water activity tells us nothing about how the water is bound in food. If the water activity in food is higher than the ambient humidity, food loses water and dries up until equilibrium is established. In the equilibrium, the water activity in food is equal to the equilibrium relative humidity of the ambient air. On the other hand, if the water activity in food is lower than the relative humidity of the ambient air, food takes water from the ambient air and becomes moist. Prevention of adverse changes in water activity in food during production and storage (drying or wetting) and controlled removal of water by dehydration or drying (the purpose is to reduce weight and extend the food shelf life) is important in many food technologies.[28]

[27] Temperature dependence of water activity is described by the so-called Clausius–Clapeyron equation: $d\ln a_w/d(1/T) = -\Delta H/R$, where R = gas constant, T = absolute temperature and ΔH = integral adsorption heat. The dependence of the a_w logarithm on the temperature (or the $1/T$ value, respectively) in a certain temperature range is linear with the line slope $= -\Delta H/R$).

[28] Water activity in foods is usually determined from knowledge of the equilibrium relative humidity or can be measured using various hygrometers. In some foods it can be calculated from various theoretical and empirical models that take into account the food chemical composition, the content of electrolytes such as sodium chloride and non-electrolytes such as saccharose, respectively. Equations, varying in their levels of complication, are numerous, but their use is limited to certain commodities. One of the simple empirical equations for water activity calculation in jams has the form: $a_w = 1/(1 + 0.27n)$, where n = number of moles of saccharose per 100 g of jam. The following equation was used to calculate water activity in confectionery $a_w = 1.04–0.1\sum s_i.c_i + 0.0045\sum(s_i.c_i)^2$, where c_i = concentration of non-electrolyte (component i), s_i = its equivalent versus saccharose (e.g. the value is 1.0 for saccharose and lactose and 1.3 for invert sugar and gelatine).

Table 7.11 Requirements of selected microorganisms to a minimum water activity.

Bacteria	Yeasts	Molds	a_w	Bacteria	Yeasts	Molds	a_w

	Candida	*Cladosporium*	0.88				
	Torulopsis						

7.9.1 Water activity and microorganisms

Knowledge of water activity is also important to assess the potential susceptibility of foods to spoilage by microorganisms (Table 7.11). Most microorganisms grow well at a_w ranging from 0.91 to 0.99. Common bacteria need at least a water activity value of 0.94 for their growth, yeasts 0.90 and fungi around 0.75 (Figure 7.40). Bacteria *Clostridium botulinum* will grow and produce the deadly botulism toxin if the water activity is above 0.85 and the pH value is above 4.6. Most halophilic bacteria and mycotoxigenic aspergilli can reproduce in media where the water activity value is at least 0.75. Xerophilous fungi grow at water activity of 0.60 and osmophilic yeasts are adapted to the environment of about the same water activity (0.65 or 0.60), which causes problems even in otherwise stable foods such as dried fruits and honey. This property of microorganisms is related to their chemical composition, the presence of polyols (glycerol and ribitol) in fungi and the higher content of proline and glutamic acid in bacteria.

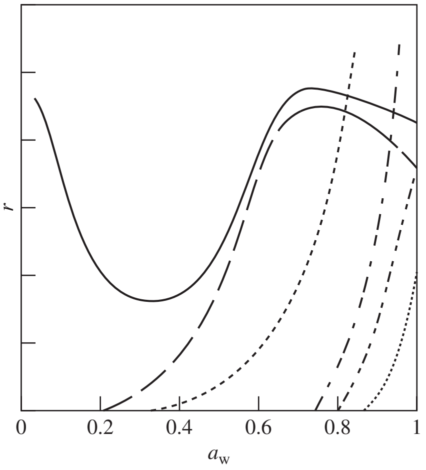

Figure 7.40 Influence of water activity on microorganisms and important reactions in foods: r = relative reaction rate, a_w = water activity, —·—·—· = molds, —· · —·· = yeasts, ~ · ~ · ~ = bacteria, ·········· = enzymatic activity, — — — = Maillard reaction, —— = lipid autoxidation.

7.9.2 Water activity and reactions

In addition to microbial activity, water activity also affects many important enzymatic and non-enzymatic reactions that proceed in foods during processing and storage (Figure 7.40).

For example, the enzymatic hydrolysis of lipids in dried meat is a negligible process up to the point where water activity decreases below 0.4. Although lipid autoxidation rate decreases with decreasing water activity (up to about 0.3–0.5, because a certain amount of water inhibits the decomposition of lipid hydroperoxides), it then increases again with decreasing water activity with a maximum reaction rate in water activity close to zero. This odd behaviour

is explained by the removal of water from the hydrophilic sites of the material, therefore more lipid molecules are thus exposed to atmospheric oxygen.

The Maillard reaction rate increases with gradually decreasing water activity and the maximum reaction rate is at a water activity of about 0.7–0.8, which is attributed to the increase in the concentration of reactants (amino compounds and reducing sugars). With further decrease of water activity, the reaction rate decreases. The Maillard reaction does not proceed at all when the water activity decreases to less than 0.2–0.3, because the mobility of reactants is too low.[29]

7.9.3 Water activity and food organoleptic properties

Water activity is also related to the organoleptic properties of foods, especially foods with low or medium water content. At water activity values 0.35–0.50, some foods show desirable organoleptic properties such as crispness and crunchiness (e.g. potato crisps and extruded cereal products) that are mostly lost when the food becomes moist. In this range of water activities, instant beverages also become moist and, as a result, undesirable changes may occur, such as crystallisation of amorphous sugars, wetting and dissolution of their crystals, stickiness and colour changes.

7.9.4 Free and bound water

Water contained in foods was previously classified as **bound water** and **free water**, or as **movable water** and **immobilised water**. Such a classification takes into account the strength of water bonds in food and is related to how easily water can be mechanically removed from the food (e.g. by pressing) or by physical processes (such as drying). These terms are very vague, however, often poorly understood and mostly incorrectly used. According to some opinions, all the water contained in foods can be classified as bound water. In common foods with high water content (more than 90%), **bound water** exists at water activities ranging from 0.0 to 0.7, and is often divided into the following categories.

- The very tightly bound water is present as **constitutional water**, which is an integral part of hydrates (<0.03% of total water). About 0–1% of the total water is found in the immediate vicinity of molecules of organic substances in foods, and has the following attributes: it has a lower mobility in comparison with the bulk water in the same food, is bound mainly by chemisorption, particularly by the hydrophilic polar groups of proteins and polysaccharides (by water–ion and water–dipole associations), it can form a continuous layer surrounding hydrophilic molecules (proteins and polysaccharides) or their hydrophilic sites, it does not have the function of a solvent and does not freeze even at –40 °C. This proportion of water (generally 0.5 ± 0.4% of the total water) is referred to as **vicinal water**. At this water content, which roughly corresponds to the monomolecular layer, no chemical reactions proceed. For example, the water content corresponding to the monomolecular layer is reportedly 11% in gelatine and starches, 6% in dried potatoes, 3% in whey powder and in crystalline saccharose 0.4% of the total water content.

- Another proportion of bound water (3 ± 2% of the total water content) exists at water activities ranging from 0.2 to 0.7. This water occupies the remaining first-layer sites and forms several layers around the monomolecular layer. In these layers mutual hydrogen bonds between water molecules already dominate, but there are also interactions between water molecules and ions or dipoles. Some water molecules penetrate into the capillary pores in the food structures by physical sorption. This water has the limited function of a solvent and the main proportion of this water does not freeze at –40 °C. The boundary between the first and second category water is the value of water activity of about 0.25. This water is known as **multilayer water**.

- The water activities ranging from 0.7 to 1.0 amounts approximately 90–96% of the total water content. Water occurs more or less as **free water**, which has similar properties as water in diluted salt solutions, or has all the attributes of pure water. It mainly acts as a solvent of inorganic and organic substances. This water does not come out of foods freely, as it is bound exclusively by physical sorption (capillary forces), but can be released from foods using suitably small forces (such as the gravitation force). The boundary between the water of the second and third category is at a water activity value of around 0.7 and higher. Sometimes, this category of water is known as **condensed water**; two types are also recognised, these being **trapped water** and **free water**.

Classification of water is also possible on the basis of thermodynamic properties. The binding enthalpy of water of the first category (vicinal water) is about −4 to −6 kJ/mol, of the second category of water (multilayer water) approximately 1–3 kJ/mol and of the third category of water (condensed water) around –0.3 kJ/mol.

7.9.5 Sorption isotherms

The relationship between water content in food (or equilibrium relative humidity of ambient air) and water activity is not simple. It is best described by the **sorption isotherm** of a particular food, which is the dependence of its water content on water activity.[30]

[29]In foods with low or medium water content the limiting factor is mobility and especially diffusivity of the reacting molecules. For example, the rate of reaction A + B = C is normally given by the rate constant (k). If the reaction rate is limited by diffusion, the rate constant $k'=k/1 + (k/\alpha.D)$, where α=constant independent of temperature and (D) is diffusion coefficient, $D = D_A + D_B$ (k and D are dependent on temperature). According to the Stokes–Einstein equation (D) value depends on the hydrodynamic radii of reactants and the viscosity of environment and therefore depends on water content. The influence of temperature on reaction rate is a function of the environment viscosity (η) in the diffusion-controlled reactions as it is given, according to the temperature at which the reaction takes place, by the Arrhenius equation or WLF equation.

[30]Physical chemistry phenomena at the interface describe by the name adsorption isotherm the relationship between the amount of substance present in the

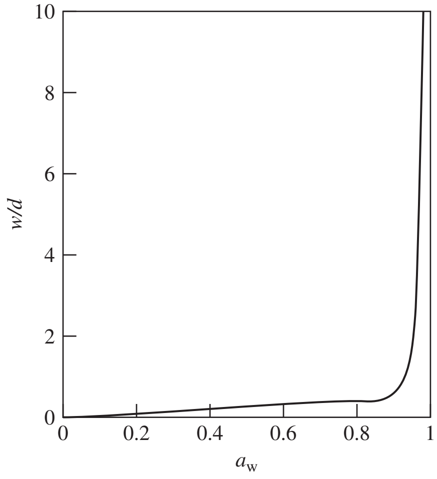

Figure 7.41 General sorption isotherm of food in a wide range of water contents: *w/d* = grams of water per gram of dry matter, a_w = water activity.

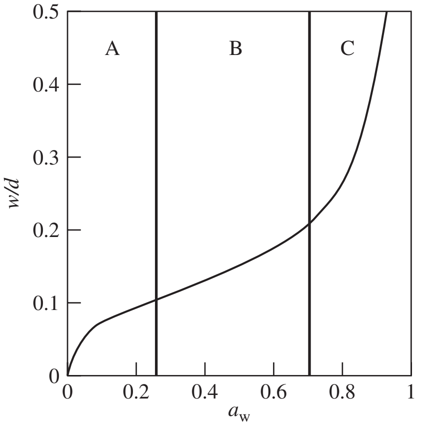

Figure 7.42 Detail of general sorption isotherm: *w/d* = grams of water per gram of dry matter, a_w = water activity, A = vicinal water, B = multilayer water, C = condensed water.

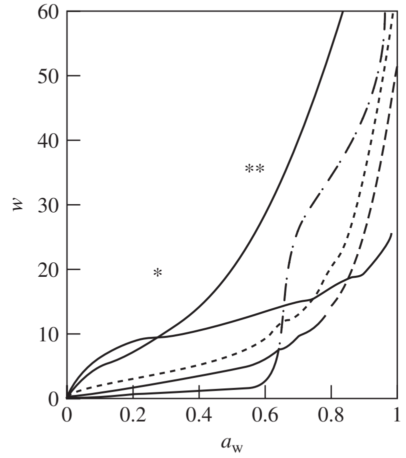

Figure 7.43 Various types of sorption isotherms: *w* = water amount (%), a_w = water activity, —— = dry hydrolysed vegetable protein, ┈┈┈ = dry whey, –·–·–· = ground roasted coffee, – – – = wheat flour, –· · –· · = saccharose.

The sorption isotherm of a hypothetical food with high water content is shown in Figure 7.41, while the same isotherm over a narrow range of water contents and indicating the existence of vicinal water, multilayer water and condensed water is shown in Figure 7.42.

Various foods have different sorption isotherm shapes (Figure 7.43) depending on their physical microstructure and macrostructure, qualitative and quantitative chemical composition and distribution of chemical components. Attempts have been made to explain the shape of isotherms of food of different chemical composition, but their importance lies more in practical application than in theoretical interpretation. From the sorption isotherms of dried acid protein hydrolysate (Figure 7.43), which is strongly hygroscopic, it can be seen that even a very small change in water activity (or the humidity of the ambient air) causes a significant increase in water content in the hydrolysate. In the point marked *, the visible changes in the hydrolysate water content are beginning, as originally powdery particles stick together and change their colour from light brown to dark brown. At the point marked **, the hydrolysates become a viscous sticky mass.[31] An example of a moderately hygroscopic material is saccharose, and a non-hygroscopic material is ground coffee.

The sorption isotherms of foods are only valid at the particular temperature at which the results were obtained. Many materials (such as fibrous proteins, cellulose and most foods) have different water activity at the same water content, depending on whether the system absorbs or desorbs water. The corresponding isotherms then have a different shape, and therefore the absorption isotherms and desorption isotherms are recognised. The phenomenon is called a **hysteresis** (Figure 7.44). In general, the water activity is higher when the food absorbs water. If it loses water, then the water activity

surface layer (the surface excess) and the change of surface tension with concentration (Gibbs adsorption isotherm). In chemistry the Langmuir adsorption isotherm is often used, which is a very simplified description of adsorption. It is sometimes similarly applied to describe the sorption of water in foods. More often, however, the BET isotherm is used, which provides information on the nature and extent of interactions of water in foods. The importance lies in the fact that it is possible to calculate the amount of water corresponding to the monomolecular layer (v_m) from the linearised equation: $a_w/(1-a_w).v = a_w.(c-1)/v_m.c + 1/v_m.c$ (a_w = water activity, V = volume of water adsorbed in 1 g of dry food, c = constant related to the adsorption heat). This allows estimation of the water content in the food at which the dry product has maximal stability.

[31] Agglomeration of particles of initially powdery material, between which the liquid forms a film that agglutinates them, depends on surface tension and viscosity of the film. This agglomeration can be, for example, described by the equation: $t = 2R\eta/3\gamma(r/R)^2$, where t = time of contact of material particles, R = initial radius of particle, r = radius of liquid film between particles, η = film viscosity and γ = film surface tension. The critical viscosity range is 1×10^5 to 1×10^8 Pa s.

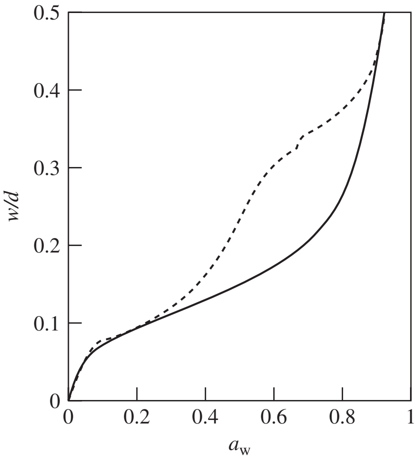

Figure 7.44 Hysteresis during water absorption and desorption: w/d = grams of water per gram of dry matter, a_w = water activity, —— = absorption, − − − − = desorption.

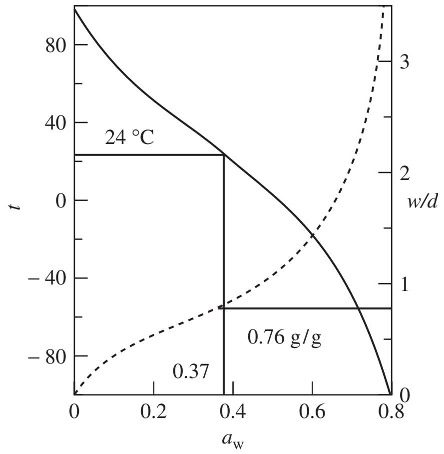

Figure 7.45 Sorption isotherm of powdered milk in association with glass transition temperature: t = temperature (°C), w/d = grams of water per gram of dry matter, a_w = water activity, − − − − = sorption isotherm —— = glass transition temperature (T_g in °C).

is lower. The physical nature of the hysteresis appears to be related to capillary phenomena in foods and their eventual collapse. The practical significance of the existence of a hysteresis is that, when adjusting the water content in food to a water activity value at which a certain reaction does not take place, it is better to reach this value by absorption, because the material then binds water more tightly than the material of the same activity that has been achieved by desorption.

The importance of sorption isotherms is generally in the evaluation of the water content in food at which the adverse effects on the food quality can be minimised. This is usually the moment when other layers are formed around the monomolecular layer of water (vicinal water), which is the instant when the multilayer water arises. Most adverse events in storage of foods with medium and low water content, such as crystallisation of amorphous sugars (e.g. lactose in powdered or condensed milk), agglomeration of powder materials, stickiness or re-crystallisation of water and formation of large crystals in frozen products (e.g. in ice cream) relates to water content, its activity and storage temperature, and are therefore closely related to the glass transition temperature of the material.

Figure 7.45 illustrates, together with the sorption isotherm, the glass transition temperature of dried milk (virtually identical to the glass transition temperature of lactose), depending on the activity of water. This dependence allows the prediction of the influence of water activity (a_w) or equilibrium relative humidity (φ) on glass transition temperature (T_g) and allows evaluation of product stability or localisation of critical values of water activity. The critical value at 24 °C is the value $a_w = 0.37$ at which the (T_g) value is the same as the storage temperature (24 °C). Under such conditions, the stored dried milk contains 0.76 g of water in 1 g of dry matter, which leads to agglomeration of particles of milk and also to the crystallisation of amorphous lactose, which causes a sandy consistency of the product. The rate of these changes is determined by the difference between storage and glass transition temperatures ($T - T_g$). Minor changes occur during storage at lower temperatures (at $T < T_g$).

8

Flavour-active Compounds

8.1 Introduction

The most important psychological factor in human nutrition is the sensory quality of food, which significantly affects the type and quantity of food consumed and its utility. Sensory quality of food depends on the presence of **sensory-active substances** that are perceived by chemical sensors and which determine the **sensory value** of foods by inducing **olfactory**, **gustative** and other sensations (such as visual, haptic or tactile and auditorial; see Chapter 1). The **organoleptic properties** of foods are usually more important to the consumer than other attributes, such as the vitamin content, because this information is observed first, and thus contributes significantly to the overall impression of the food raw materials and foods. Many foods and dishes are therefore aromatised, flavoured, coloured or their texture is improved, while many others are consumed solely for their sensory value for example, various delicatessen items (delicacies, gourmet or fine foods), such as caviar or truffles.

Olfactory sensation results when olfactory receptors in the nose are stimulated by a particular substance in gaseous form called an **odorant**, which is capable of being translated into the subjective responses of neural brain stimulation that we term **odour**, **smell, aroma**, **flavour** or **scent**. Gustatory sensation that determines the **taste** is a sensation elicited by substances acting on taste receptors in taste cells in the mouth.

Depending on their origin, the odour- and taste-active substances can be divided into two basic groups:

- Those that are already present in food raw materials or foods, as products of the secondary metabolism. These secondary metabolites are produced by intracellular processes and their quality and quantity depend mainly on the genetic predisposition of the organism (plant or animal species). In plants, animals and other organisms, there is a variability within certain limits that is caused by some external factors. In plants, it may be location, age, degree of maturity (vegetative stage), harvest time, various environmental factors (the amount of moisture, nutrients, temperature and light) and conditions during post-harvest storage. These flavour-active substances are also known as **primary flavour-active substances**.

- Many odour- and taste-active substances occur in foods in a bound, sensorially inactive form, mainly as glycosides or esters. These compounds release the sensorially active substances by the action of enzymes, glycosidases and hydrolases of carboxylic acid esters, for example, during tissue disintegration. Sensorially active substances also result during storage and processing of food as products of enzymatic and non-enzymatic reactions from proteins, carbohydrates and lipids (the primary products of the metabolism), or from other chemical substances, such as vitamins and various pigments. Fermentation processes and thermal processing of foods (during cooking, baking, frying, smoking and drying) are the main processes in which these substances are formed from their precursors. Autoxidation, the Maillard reaction (non-enzymatic browning reactions) and enzymatic browning reactions are the major reactions that lead to the formation of these flavour-active substances during storage, industrial and culinary processing of foods. Sensorially active substances generated during these processes are often referred to as **secondary flavour-active substances**.

The resulting sensations of smell and taste, but also the sensation of colour and texture of food, are due to substances that are usually complex mixtures of several compounds. Odoriferous (odour-active) substances (odorants) are compounds that act on the olfactory receptors and give the impression of odour. They can also affect the taste receptors, in which case they are also taste-active substances. An example of such a compound is acetic acid, which has a penetrating odour resembling vinegar, and a sharp sour taste. Odoriferous substances are predominantly low-polar or non-polar (water insoluble to slightly soluble) compounds, producing a wide variety of sensory perceptions. Taste substances are those that act on taste receptors and give the impression of taste in the mouth.

Gustatory sensation includes five basic tastes: **sweet**, **salty**, **sour**, **bitter** and **umami**.

Common sweet substances are monosaccharides and disaccharides, such as saccharose (sucrose, table sugar), while the best known salty substance is sodium chloride (table salt). A sour taste is found in the previously mentioned acetic acid found in vinegar and pickled vegetables, and bitter tasting compounds are caffeine in coffee and quinine in tonic water. The umami taste was officially recognised as a legitimate fifth taste in the 1980s because it complements the conventional taste categories of sweet, sour, salty and bitter. Opinions vary as to the precise translation of the word umami, but the best approximation is something like 'savoury deliciousness'.

The oral cavity also responds to other sensations, such as those described as astringent taste, pungent (hot, burning) taste or some others. There is an increasingly popular belief that taste is more complicated than was originally believed as it is related to a combination of sensations such as smell, colour, texture and the sound of foods when chewing, and even to the emotional circumstances of the consumer when eating.

Taste-active substances are usually water-soluble polar and non-volatile substances. Some taste-active substances may additionally be odour-active substances, but not necessarily. The complex (uniform) sensory perception of taste and smell is called flavour; a strong pleasant smell, usually from food or drink is called aroma, and aromatic food or drink is that which has a pleasant smell. However, the term 'aromatic substance' has a completely different meaning in organic chemistry. An aromatic substance, put simply, is a benzene derivative. The unwanted, altered, modified, unnatural or unpleasant odour, taste and flavour are called **off-odour** and **off-taste** or **off-flavour**, respectively.

Substances influencing **colour** (such as dyes and pigments) are also important sensory-active substances present in foods. They determine not only the characteristic colour of the food, but also affect the taste threshold concentrations of substances and the ability to identify smells. Food that has a satisfactory nutritional and hygienic-toxicological quality or excellent odour, taste and texture will still not be accepted by consumers unless the characteristic colour corresponds to the standard product.

The properties included under the heading **texture** are found mainly in macromolecular food components, especially proteins and polysaccharides, as well as products of their interactions and associations with other food ingredients, first and foremost with water. Texture implies those characteristics of foods that cause tactile or haptic sensations registered by receptors in the oral cavity. Touch by hands is very important. Auditorial perceptions such as crispness are related to a range of textural characteristics. Geometric attributes of texture that simultaneously cause visual and haptic sensations, often referred to as shape and appearance (such as particle size or size of the whole food), are closely related to food colour. The term **consistency** describes the texture aspects related to physical (mechanical) properties of food, which are also called rheological properties (see Section 7.8.4.1).

This relatively extensive chapter is devoted to components that affect food odour and taste. Also included are a number of organic compounds of plant origin, which, although not affecting the odour or taste of foods, are structurally similar to the sensory-active substances and also have important biological effects, for which they are at the forefront of medicine and pharmacy. In the first section, the aromatic compounds are classified into their common groups, so hydrocarbons, and their oxidation products that include alcohols, aldehydes, ketones, carboxylic acids and functional derivatives of carboxylic acids (esters, lactones and nitriles) are described. Other groups of organic compounds discussed are phenols, sulfur- and nitrogen-containing compounds, including heterocyclic compounds. Each section presents the structure of individual compounds, their properties, occurrence and important reactions that occur in food. Another part of the chapter is devoted to odour-active substances in individual food commodities (meat and meat products, poultry, fish, milk and dairy products, eggs, cereal products, fruits, vegetables, alcoholic beverages, tea, coffee, cacao and chocolate, nuts, honey, mushrooms and spices). Next, the importance of aromatic compounds in the diet, their organoleptic properties, biological effects, production and use are dealt with. The last part is devoted to substances that affect the taste of foods. These substances are categorised into groups according to the basic and also other tastes: sweet, salty, sour, bitter, astringent and pungent (sharp, burning), and commodities in which they are found. The structure of these compounds, their occurrence, properties, quality of taste perception, reactions, significance in nutrition, physiology and technology and practical use are all described.

8.2 Odour-active substances

The aroma of food is often a very complex phenomenon caused by a large number of odour-active substances. The total number of odorants identified in foods is estimated to be about 10 000, and each food commonly contains several hundred different aromatic compounds. Some compounds are not involved in the characteristic odour of a particular food at all, some contribute very little, but others are of fundamental importance for various reasons, such as their odour character, low threshold concentration of perception or high concentration. The resulting odour impression is thus caused by several compounds. The intensity and quality of odour, however, depends not only on the odoriferous substances present, but also on other food components, especially proteins, carbohydrates and lipids, with which the odorants interact. These non-bonding interactions influence the concentration of aromatic substances in the gaseous phase. Typical examples are allyl mercaptan, diallyl disulfide, methyl mercaptan and allyl methyl sulfide, responsible for the smell of crushed garlic and the so-called garlic breath, while the smells of oranges and roasted coffee result from about two dozen different compounds. In only a limited number of cases are the typical smells associated with a single substance or a few compounds, which are called **key components**. An example is vanillin, which is practically the only substance responsible for the typical smell of dry vanilla beans. Some other examples are listed in Table 8.1.

Volatile flavour-active components of foods include virtually all groups of organic compounds, hydrocarbons and their oxygen derivatives (such as alcohols, aldehydes, acetals, ketones, carboxylic

Table 8.1 Characteristic (key) odorous components of foods.

Compound[a]	Descriptor	Occurrence
(−)-(*R*)-Oct-1-en-3-ol	Mushroom-like	Mushrooms, molds
(−)-Geosmin	Earthy	Red (garden, table) beet root
Anethole	Anise-like	Anise seeds
Cinnamaldehyde	Cinnamon-like	Cinnamon bark
Vanillin	Vanilla-like	Dry vanilla beans
Eugenol	Clove-like	Clove plant fruits
(*E*)-Citral (geranial, citral a) and (*Z*)-citral (neral, citral b)	Lemon-like	Lemons
(2*E*,6*Z*)-Nona-2,6-dienal	Cucumber-like	Fresh cucumbers
Benzaldehyde	Bitter almond	Bitter almonds, sour cherries
(+)-(2*E*,5*S*)- and (−)-(2*E*,5*R*)-5-methylhept-2-en-4-one[b]	Hazelnut-like	Roasted hazelnuts
4-(4-Hydroxyphenyl)butan-2-one (raspberry ketone)	Raspberry-like	Raspberries
(+)-(*S*)-Carvone	Caraway-like	Caraway and dill seeds
(2*E*,4*Z*)-Ethyl deca-2,4-dienoate	Pear-like	Pears
5-Ethyl-3-hydroxy-4-methyl-5*H*-furan-2-one (abhexon)	Hydrolysate-like	Acid protein hydrolysates
(+)-(*R*)-*p*-Menth-1-ene-8-thiol	Grapefruit-like	Grapefruits
Diallyl disulfide	Garlic-like	Garlic
Maltol and isomaltol	Caramel-like	Caramel
2-Acetyl-1-pyrroline	Crust-like	Bread crust, aromatic rice
2-Isobutylthiazole	Tomato-like	Tomato leaves, fresh fruits

[a] The structures of compounds are given further in the text.
[b] Trade name of the mixture of (*E*)-isomers is filbertone.

acids, their esters and other derivatives), amino derivatives (amines, nitrogen heterocyclic compounds), sulfur derivatives (such as thiols, sulfides and sulfur heterocyclic compounds) and many more. Particularly important primary flavour-active substances are **terpenes** and **terpenoids**. Terpenes are naturally occurring hydrocarbons derived biosynthetically from units of isoprene (2-methylbuta-1,3-diene) linked together head to tail (or, more rarely, head to head) to form linear chains, or they may be arranged to form rings. Terpenes modified chemically, such as by oxidation or rearrangement of the carbon skeleton, are terpenoids, sometimes referred to as **isoprenoids**. Terpenoids are the largest class of plant secondary metabolites with over 20 000 known compounds, produced primarily by a wide variety of plants, where they serve a range of different functions in basic and specialised metabolism. Depending on the number of isoprene units, isoprenoids acting as odour-active substances are divided into:

- **hemiterpenes** and **hemiterpenoids** (C_5 compounds containing one isoprene unit)
- **monoterpenes** and **monoterpenoids** (C_{10} compounds containing two isoprene units)
- **sesquiterpenes** and **sesquiterpenoids** (C_{15} compounds containing three isoprene units).

The main volatile components in essential oils are monoterpenes and monoterpenoids. Historically they have been used in the food, perfume and pharmaceutical industries because of their culinary, fragrant and antimicrobial properties. In fruits and vegetables, herbs and spices, and in wines, they express a wide spectrum of odours, most of which are perceived as very pleasant. Sesquiterpenes and sesquiterpenoids are among the most widely occurring odorants. Numerous sesquiterpenic hydrocarbons, alcohols and derived metabolites found in plant essential oils are highly valued for their desirable flavour characteristics. They also display a broad range of physiological properties, including antibiotic, antiviral, antifungal, antitumour and hormonal activities. Synthetic variations and derivatives of natural terpenes and terpenoids are additionally used to greatly expand the variety of aromas used in perfumery and flavours used in food additives.

Secondary flavour-active substances arise in particular:

- as metabolic products of microorganisms in fermentation processes

- by oxidation and degradation of labile constituents (such as lipids and carotenoids)
- in thermal processes, especially from proteins and carbohydrates in the Maillard reaction.

For completeness, this chapter also includes some non-volatile substances that do not have the potency of odour-active compounds. However, these substances may frequently be precursors of volatile compounds or have other important properties.

8.2.1 Hydrocarbons

Hydrocarbons are common components of many foods often occurring as constituents of essential oils and food lipids. They are either natural components of food raw materials and foods (primary substances) or form during food processing and storage by enzymatic and chemical reactions as secondary substances (e.g. as lipid oxidation products and degradation products of carotenoids). Some hydrocarbons may be present in food as endogenous or exogenous contaminants (e.g. polycyclic aromatic hydrocarbons).

For food flavouring, hydrocarbons are used relatively rarely, but they are used as the starting material for the synthesis of other volatiles. Some aliphatic hydrocarbons (such as hexane) or in a mixture (e.g. petroleum ether and gasoline) are also used as solvents in the flavour and fragrance industry and in oleochemistry. Residues of these hydrocarbons may therefore be present in essential oils, oilseed meals and other materials obtained by extraction with hydrocarbons.

8.2.1.1 Classification, structure, terminology and occurrence

Depending on their structure, hydrocarbons occurring in foods can be divided into three basic groups: aliphatic, alicyclic and aromatic hydrocarbons. The most important flavour-active substances (in addition to natural dyes) are terpenic hydrocarbons (terpenes).

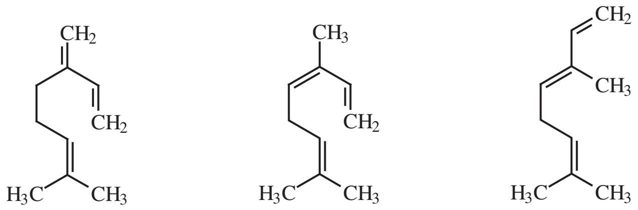
8.2.1.1.1 Terpenic hydrocarbons

Compounds with the formula $(C_5H_8)_n$, which includes monoterpenes ($C_{10}H_{16}$) and sesquiterpenes ($C_{15}H_{24}$) can be active as odorous substances. Higher terpenic hydrocarbons, starting from diterpenes ($C_{20}H_{32}$), are indifferent as flavouring materials, but may act as taste-active substances or precursors of flavour-active substances. Terpenic hydrocarbons occur in almost all fruits, vegetables and spices. For example, about 90–99% of orange fruit volatiles and about 80% of carrot root volatiles are terpenic hydrocarbons. About 70–80% of black pepper volatiles are monoterpenic hydrocarbons and 20–30% are sesquiterpenic hydrocarbons. However, terpenic hydrocarbons are usually not very important compounds in defining the typical aroma of food commodities. More important are various monoterpenoids and sesquiterpenoids, alcohols, aldehydes, ketones, esters and other compounds. In pepper, for example, an important compound with peppery and spicy flavour is sesquiterpenoid (−)-rotundone (see **8-200**, later). About 1000 monoterpenoids, more than 300 distinct sesquiterpene carbon skeletons and more than 7000 oxidised or otherwise modified sesquiterpenic derivatives have been identified in nature. Most of these terpenoids are optically active compounds. Individual enantiomers and diastereoisomers may occur in different organisms or just in a single organism, but often they are as mixtures.

Terpenes are synthesised in organisms by complex mechanisms from isoprene units, isopentenyl phosphate and dimethylallyl diphosphate (pyrophosphate). The first product is geranyl diphosphate, which is the universal precursor of monoterpenoids. The reaction of geranyl diphosphate with another molecule of isopentenyl diphosphate yields farnesyl diphosphate, which is the precursor of sesquiterpenoids. Further reaction with isopentenyl diphosphate gives geranylgeranyl diphosphate, the precursor of diterpenoids (see Figure 3.10).

Monoterpenes

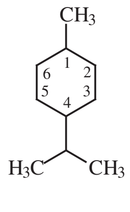
Monoterpenic hydrocarbons found in foods are linear (acyclic), monocyclic, bicyclic and tricyclic compounds. Linear monoterpenes are mainly present in fruits and essential oils. Examples of common hydrocarbons are myrcene (β-myrcene, **8-1**) and ocimene (β-ocimene, **8-1**), which occurs in two stereoisomers, as *trans*-isomer (*E*)-ocimene and as *cis*-isomer (*Z*)-ocimene.



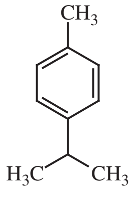
myrcene (*Z*)-β-ocimene (*E*)-β-ocimene

8-1, linear monoterpenic hydrocarbons

Monocyclic monoterpenic hydrocarbons are derived predominantly from the optically active hydrocarbon 4-isopropyl-1-methylcyclohexane, known as *p*-menthane (**8-2**). An exception is *p*-cymene also known as cymene (1-isopropyl-4-methylbenzene, **8-3**), which is an aromatic hydrocarbon. Cymene is a common component of many essential oils, especially the essential oils of cumin (the seed of the herb *Cuminum cyminum* of the parsley family Apiaceae) and common thyme (*Thymus vulgaris*, from the mint family Lamiaceae) listed in Table 8.32 (see later).

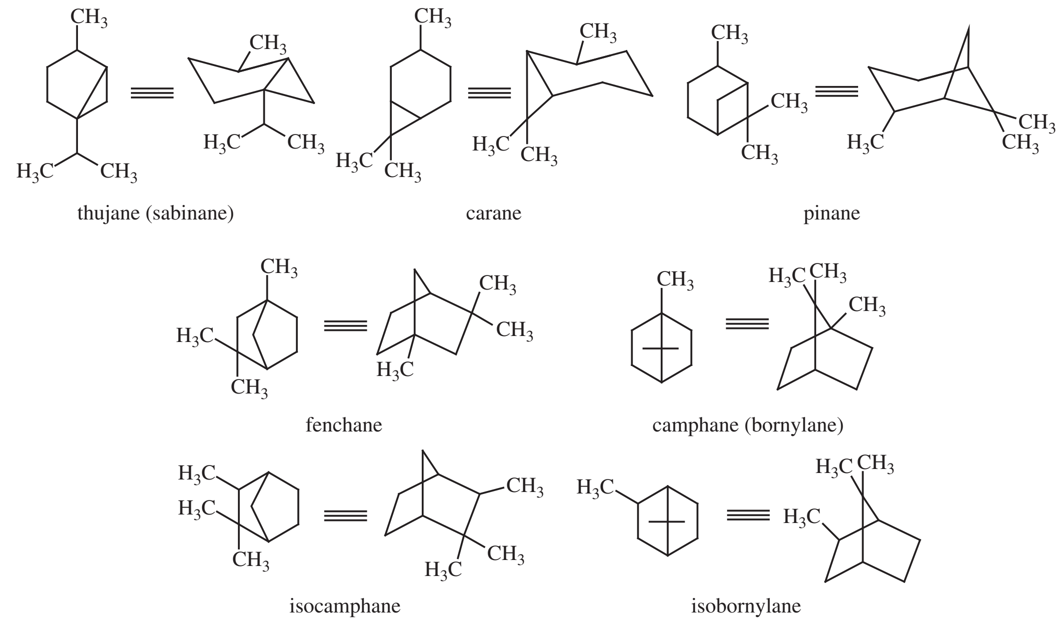


8-2, *p*-menthane



8-3, *p*-cymene

Bicyclic hydrocarbons can be divided into seven structural types. These systems are combinations of three- and five-membered rings



8-4, bicyclic monoterpenic hydrocarbons

(thujane, also known as sabinane), three- and six-membered rings (carane), six- and four-membered rings (pinane) or two five-membered rings (fenchane, camphane, also known as bornylane, and isocamphane and isobornylane) (**8-4**).

The most important compounds are menthadienes, derived from *p*-menthane, which differ in the positions of the double bonds (**8-5**). A common hydrocarbon is limonene (*p*-mentha-1,8-diene), which typically occurs in many essential oils (such as essential oils of citruses, mints and conifers) and turpentine. For example, the (+)-limonene isomer is the major component (>90%) of essential oils of citrus peels, (−)-limonene is a component of essential oils of different types of mint (*Mentha* spp., Lamiaceae) and conifers. Racemate, which is trivially known as dipentene, occurs in many essential oils. Other important menthadienes include α-terpinene (*p*-mentha-1,3-diene), γ-terpinene (*p*-mentha-1,4-diene), α-phellandrene (*p*-mentha-1,5-diene) and β-phellandrene, also known as *p*-mentha-1(7),2-diene.

A number of bicyclic hydrocarbons are present in turpentine, and also as components of fruits, vegetables and spices (**8-6**). A frequently occurring compound is sabinene, also known as thujene or 4(10)-thujene (which is found in higher concentrations in the essential oil of black pepper), car-3-ene (Δ^3-carene), α-pinene (2-pinene), β-pinene, also known as 2(10)-pinene, nopinene or pseudopinene and camphene. Trivial and systematic names of the main compounds are listed in Table 8.2.

Sesquiterpenes

About 300 different basic structures are found in nature, from which sesquiterpenes and sesquiterpenoids are derived. Often

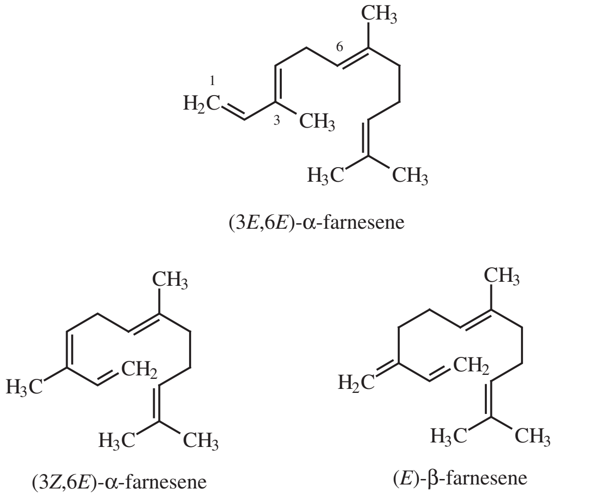
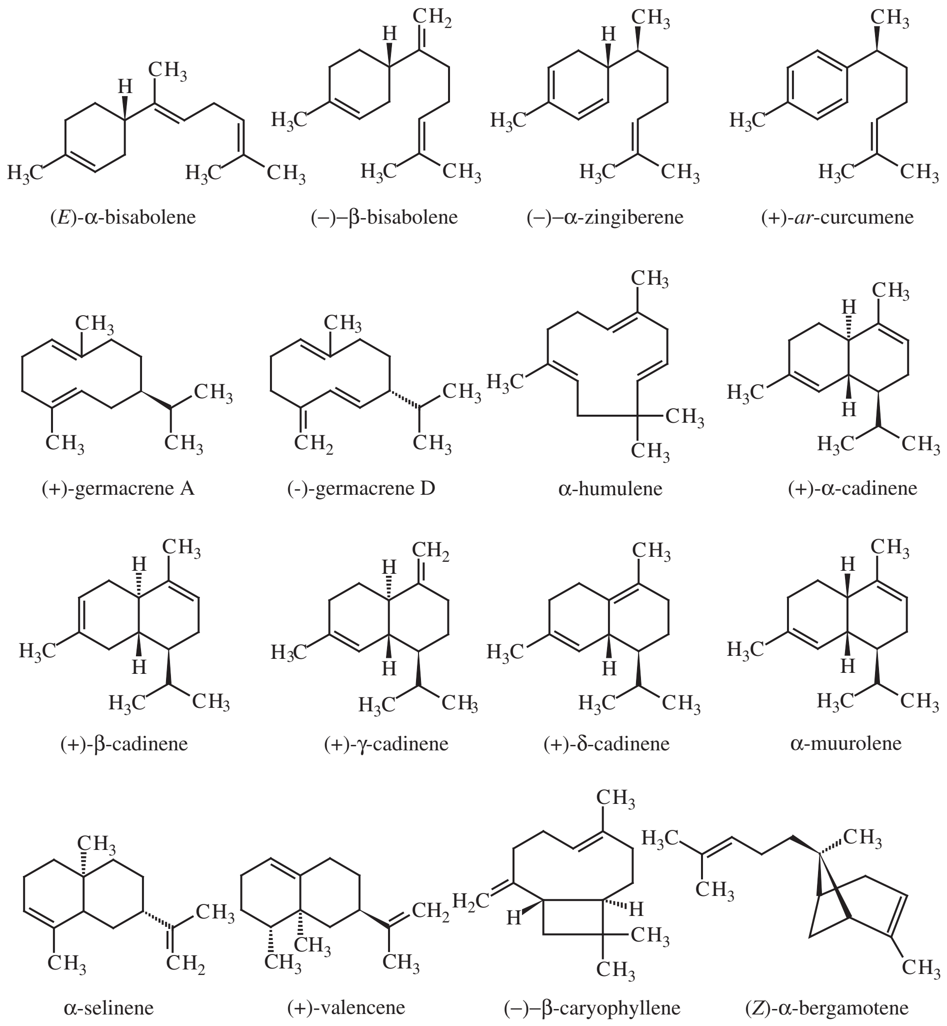
present in foods are stereoisomeric acyclic sesquiterpenic hydrocarbons called farnesenes, which include α-farnesene and β-farnesene. α-Farnesene exists as four stereoisomers that differ in the geometry of two (C-3 and C-6) of its three internal double bonds. The most common isomers are (3*E*,6*E*)-α-farnesene known as *trans*,*trans*-α-farnesene and (3*Z*,6*E*)-α-farnesene known as *cis*,*trans*-α-farnesene (**8-7**). (3*E*,6*E*)-α-Farnesene, which represents about 90% of the α-farnesene isomers in some apple and pear cultivars, accumulates in the surface wax of fruits during low-temperature storage. Conjugated trienes, such as (7*E*,9*E*)-2,6,10-trimethyldodeca-2,7,9,11-tetraen-6-ol, resulting from its oxidation, have been linked with the development of a serious physiological storage disorder known as superficial scald, which leds to injury of cell membranes. Scald manifests as brown or black patches on the fruit skin and in a bitter taste in the fruit. (3*Z*,6*E*)-α-Farnesene has been isolated from the perilla oil (*Perilla frutescens*, Lamiaceae) that dries faster than linseed oil; therefore it is used in the production of varnishes. The herb is used in Chinese medicine, either alone or in combination with other herbs, especially as a remedy for coughs and asthma. Both isomers act as insect pheromones. β-Farnesene can exist as two stereoisomers about the geometry of its central (C-6) double bond. The (6*E*)-isomer, known as *trans*-β-farnesene (**8-7**), is a constituent of various essentials oils, such as ginger oil. It is also released by aphids as an alarm pheromone upon death to warn away other aphids. Several plants have been shown to synthesise this pheromone as a natural insect repellent.



8-7, linear sesquiterpenic farnesenes

Cyclic sesquiterpenes (**8-8**) are found in large numbers in food volatiles and essential oils. The representatives of monocyclic hydrocarbons with six-membered cycle are α-bisabolene and β-bisabolene, α-zingiberene and *ar*-curcumene. Representatives of macrocyclic hydrocarbons are germacrene A, germacrene D and α-humulene. Bicyclic hydrocarbons with two six-membered rings are α-selinene, valencene, α-, β-, γ- and δ-cadinene. Muurolenes are isomeric with cadinenes,[1] while examples of other structures are β-caryophyllene and α-bergamotene. Some sesquiterpene hydrocarbons are precursors for the biosynthesis of other important compounds. For example, germacrene D is the precursor of two

[1]The name cadinene is sometimes used to refer to all sesquiterpenes having the structure of cadalane (4-isopropyl-1,6-dimethyldecahydronaphthalene). However, a large number of isomers exist with different positions and stereochemistry of the double bonds. These compounds are divided into four subgroups according to the stereochemistry of the isopropyl group at C-1 and hydrogen atoms on C-4a and C-8a. Cadinenes (1*S*,4a*R*,8a*R*), muurolenes (1*S*,4a*S*,8a*R*), amorphenes (1*S*,4a*R*,8a*S*) and bulgarenes (1*S*,4a*S*,8a*S*) have been identified.



8-8, cyclic sesquiterpenic hydrocarbons

major odour-active components of grapefruit peel, valencene and nootkatone. Valencene is the main volatile emitted by flowers of the vine (*Vitis vinifera*, Vitaceae) and a precursor of ketone nootkatone in grapefruits. (−)-δ-Cadinene is a precursor of the dimeric sesquiterpenoid pigment of cotton plants (*Gossypium hirsutum* and other species, Malvaceae) called gossypol.

β-Caryophyllene is a common component of many essential oils. For example, the essential oil of black pepper (see Table 8.32, later) contains about 20% of β-caryophyllene. Its α-isomer humulene (also known as α-caryophyllene) occurs in the hops essential oil (*Humulus lupulus*, Cannabaceae); both compounds are often present in the mixture. Common components of essential oils are also bisabolenes. Higher quantities of β-bisabolene (10–15%) and also α-zingiberene (22–30%), *ar*-curcumene (20%), α-selinene and β-farnesene are found in ginger essential oil. The essential oil of white sandalwood (*Santalum album*, Santalaceae) contains, in addition to sesquiterpenic alcohols as major components, many sesquiterpenic hydrocarbons, including α-bergamotene *ar*-curcumene, β-bisabolene and many others. Trivial and systematic names of the main sesquiterpenic hydrocarbons are listed in Table 8.3.

Diterpenes

Although not directly involved as odour-active food components, diterpenes are widespread in the plant kingdom, where they mainly occur as components of resins of conifers and juices of the aster (sunflower) family (Asteraceae) and spurge family (Euphorbiaceae) plants. Diterpenic hydrocarbons are precursors of numerous diterpenoids, many of which are biologically active substances. More than 3000 different diterpenoid structures have been defined, all of which appear to be derived from geranylgeranyl diphosphate. Like monoterpenes and sesquiterpenes, diterpenes are mostly cyclic compounds. Examples of diterpenoid hydrocarbons (**8-9**) are tricyclic hydrocarbon (−)-*ent*-kaur-16-ene, tetracyclic hydrocarbon (−)-abieta-7(8),13(14)-diene and macrocyclic compounds cembrene, casbene and taxa-4,11-diene.

All of these structures are central to a wide variety of natural products found both in plants and in animals. For example, cembrene is a pheromone of termites; casbene occurs in castor beans (*Ricinus communis*, Euphorbiaceae) as an antifungal substance and is a precursor of other biologically active diterpenoids, such as phorbol (see **8-25**, later) of the same plant family. Many species of the *Euphorbiaceae* family are regarded as toxic because their

latex can cause poisoning in humans and animals, skin dermatitis, cell proliferation and tumour promotion. Most of the biological effects are due to the fatty acid esters of phorbol, such as 13-acetyl-12-myristoyl phorbol. The principal toxin of common yew (*Taxes baccarat*, Fabaceae) has been shown to be a mixture of at least 11 alkaloids based on the taxa-4,11-diene skeleton, *ent*-caurene is a precursor of plant hormones gibberellins, flavour-active diterpenoid alcohols cafestol and kahweol (see **8-25**, later) found in unroasted coffee beans, diterpenoid antioxidants, such as carnosic acid and bitter carnosol (see **10-181**) occurring in a medical herb rosemary (*Rosmarinus officinalis*, Lamiaceae) and sweet stevioside (see Section 11.3.2.1.3) in the leaves of South American stevia

(*Stevia rebaudiana*, Asteraceae), known as sweet leaf. Abietadiene is a precursor of abietic acid (see **3-156**) in resins in coniferous trees.

8.2.1.1.2 Other hydrocarbons

Aliphatic and alicyclic hydrocarbons

Saturated and unsaturated hydrocarbons with odd and even numbers of carbon atoms in the molecule (about C11–C35) are present as the primary substances in all vegetable oils and animal fats. Alkanes, alkenes, alkadienes and alkatrienes also arise as oxidation products of unsaturated fatty acids, catalysed by lipoxygenases or by autoxidation of fatty acids during food storage and processing. Only the lower hydrocarbons can play a role as odour-active substances. The main hydrocarbons resulting from oxidation of unsaturated fatty acids are ethane from linolenic acid, pentane and butane from linoleic acid and hexane and octane from oleic acid. The immediate precursors of hydrocarbons are the fatty acid hydroperoxides (Table 8.4). The unsaturated hydrocarbons are predominantly (*Z*)-isomers. Numerous other hydrocarbons, including alicyclic hydrocarbons, appear as secondary lipid oxidation products.

Some aliphatic, alicyclic and aromatic hydrocarbons may be products of oxidation and degradation of substances other than lipids; for example, penta-1,3-diene arises by decarboxylation of sorbic acid (see Section 11.2.1.1.2), which is used as a preservative.

Aromatic hydrocarbons

Aromatic hydrocarbons are relatively rare natural components of foods. An important natural component of essential oils of many spices and vegetables is *p*-cymene (1-isopropyl-4-methylbenzene, **8-3**). Together with the related hydrocarbon α,*p*-dimethylstyrene (**8-10**), *p*-cymene is also formed by degradation of citral. Various alkyl benzenes and alkyl xylenes (**8-10**) are found in small

amounts in olive oil. The degradation products of carotenoids are, for example, 1,2-dihydro-1,1,6-trimethylnaphthalene (**8-10**), which is an odorant of tomatoes (see Section 9.9.5.2.1) and (*E*)-1-(2,3,6-trimethylphenyl)buta-1,3-diene, present as a potent odorant in wines.

Undesirable contaminants include monocyclic aromatic hydrocarbons (MAHs), toluene, xylenes and ethyl benzene, which may be present in small quantities in foods as exogenous contaminants, along with polycyclic aromatic hydrocarbons (PAHs, see Section 12.2.5.1). Together with benzene and styrene (vinyl benzene), these hydrocarbons are also formed as processing contaminants (see Section 12.2.6).

8.2.1.2 Properties and reactions

Terpenic hydrocarbons are stable in the absence of air, but are easily oxidised in air, especially at higher temperatures. Their autoxidation proceeds by similar mechanisms as autoxidation of unsaturated fatty acids and depends greatly on the hydrocarbon structure. The primary autoxidation products are hydroperoxides. In branched hydrocarbons, the hydroperoxyl group mainly occurs in the secondary or tertiary carbon adjacent to the quaternary carbon of the double bond. The final autoxidation products are usually epoxides, alcohols and ketones. The primary site of attack in olefins is the carbon adjacent to the double bond, as in monounsaturated fatty acids. Hydroperoxides can also be formed by the addition of singlet oxygen to the olefin double bond.

An example is the oxidation of limonene, the (+)-(*R*)-isomer of which is the major component of essential oils from the peel of citrus fruits. The oxidation products are the alcohols (2*R*,4*S*)-carveol, known as (+)-(*E*)-carveol, and (1*S*,4*S*)-carveol, known as (+)-(*Z*)-carveol, ketone (+)-(*S*)-carvone (see **8-50**, later), which is an important component of caraway essential oil, and isomeric limonene-1,2-epoxides, also known as limonene oxides. The reaction mechanism, including the hydroperoxide intermediates, is shown in Figure 8.1. Analogous (+)-limonene products also result from oxidation of some microorganisms, which is used in their biosynthetic production. Grapefruit peel oil aroma, a strange, extraneous type of aroma normally not present in oranges, may arise as an off-flavour through metal-catalysed oxidation or photooxidation of the hydrocarbon (+)-valencene (**8-8**) to ketone (+)-nootkatone via hydroxylation to the corresponding alcohol (+)-β-nootkatol (see **8-23**, later) and its oxidation in orange juices. Cyclisation of β-ionone to 1,1,6-trimethyl-1,2-dihydronaphthalene (**8-10**) in fruits containing carotenoid pigments causes off-flavour in fruit juices and wines (see Section 9.9.5.2.1).

Autoxidation of saturated hydrocarbons is, like autoxidation of saturated fatty acids, important at higher temperatures (around 150 °C). The final odorous products formed are mainly fatty acids, their lactones, alcohols and ketones with fewer carbon atoms in the

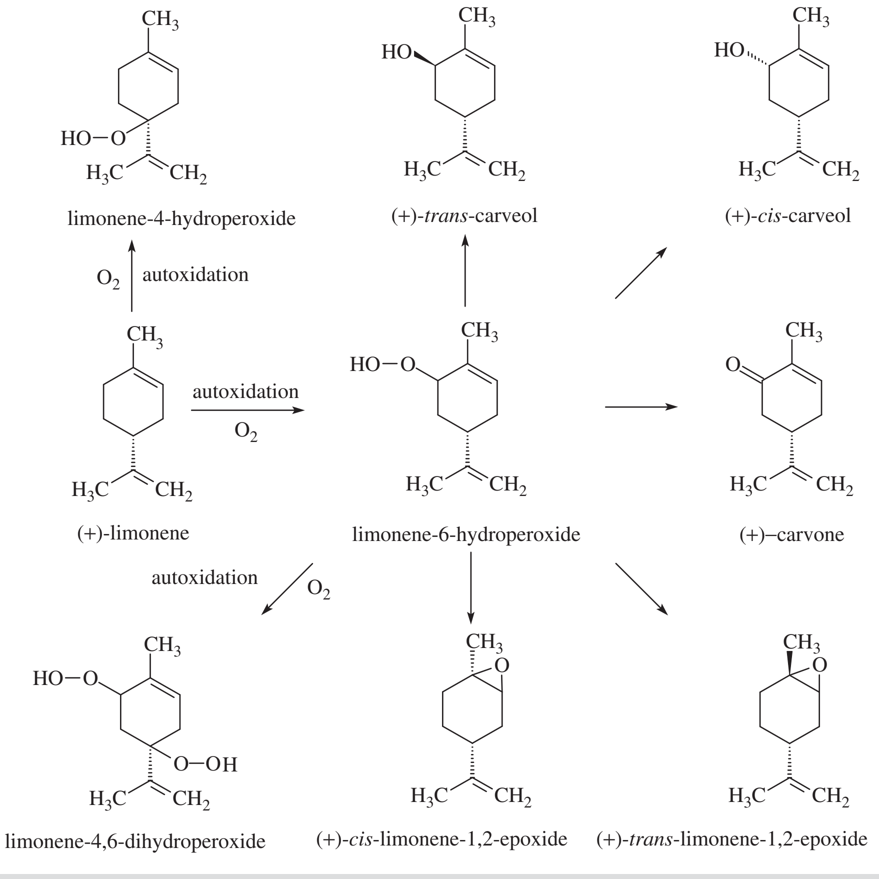

Figure 8.1 Main products of (+)-limonene oxidation.

molecule. The oxidation also occurs in aromatic and condensed aromatic hydrocarbons. The oxidation products formed chemically or *in vivo* are regarded as the carriers of the carcinogenic effects of these hydrocarbons (see Section 12.2.5).

8.2.2 Alcohols

Alcohols and phenols can be formally considered as the primary oxidation products of hydrocarbons. Alcohols are primary and secondary odour- and taste-active substances of plant and animal origin. Typical compounds are primary, secondary and tertiary aliphatic, alicyclic, aromatic and heterocyclic alcohols and alcohols containing more hydroxyl groups (diols, triols and higher polyols). Free primary alcohols and their esters mainly act as odour-active compounds, especially in fruits and alcoholic beverages. Lower aliphatic saturated and unsaturated alcohols are natural odour-active substances, especially monoterpenic and sesquiterpenic alcohols. Higher terpenoids can play roles as odour-active substances through their degradation products. Slight or no odour-activity is shown by higher aliphatic alcohols (such as the fatty alcohols, which are components of waxes), polar aliphatic and alicyclic diols, triols, other polyols, diterpenic, triterpenic alcohols and sterols, which accompany lipids, amino alcohols, such as 2-aminoethanol and choline, that are present as part of the phospholipids, hydroxycarboxylic acids and other polar hydroxy derivatives. Some substances, such as glycerol, sugar alcohols (exhibiting a sweet taste) and hydroxycarboxylic acids (sour taste), however, are important taste-active substances.

Alcohols (especially terpenic alcohols) that have less than 15–18 carbon atoms in the molecule are used for food flavouring. The use of higher alcohols is an exception. Lower alcohols are used for the production of esters, acetals and other flavour-active compounds or are used as food additives (e.g. as solvents).

8.2.2.1 *Classification structure, terminology and occurrence*

8.2.2.1.1 *Aliphatic and alicyclic alcohols*

Methanol

Methanol (**8-11**) is a member of the homologous series of saturated aliphatic alcohols found in plants in the form of various esters, most often in pectins and esters of aromatic carboxylic acids (benzoic, salicylic, cinnamic and others). Free methanol results mainly by hydrolysis of pectin catalysed by plant pectin esterases: therefore, it occurs regularly in small amounts as a component of all natural fruit juices and is present in larger amounts in wines and fruit distillates.

The methanol content in citrus juices ranges from 24 to 47 mg/l, its content in ciders is 36–88 mg/l, and in blackcurrant juices reaches 70–176 mg/l. The methanol content of fruit wines is higher; usually ranges from 20 to 240 mg/l, but, exceptionally, it may reach even more than 600 mg/l, because a further portion of the pectin is hydrolysed during the fermentation process. The amount of methanol formed in wines depends on many factors. Red wines have about twice as high a methanol content as white wines. Vodka has

8-11, aliphatic alcohols

methanol, R = H
ethanol, R = CH_3
propan-1-ol, R = CH_2CH_3
butan-1-ol, R = $CH_2CH_2CH_3$

hexan-1-ol, R = $[CH_2]_4CH_3$
heptan-1-ol, R = $[CH_2]_5CH_3$

a very small amount of methanol (79–158 mg/l). Spirits produced by distilling wine (such as brandy or cognac) have methanol contents similar to those of wines (320–400 mg/l). Fruit brandies (distilled from fermented stone fruits) tend to have much higher methanol contents. The content of methanol in cherry brandy is usually 0.48–0.95% (4800–9500 mg/l) and in plum brandy around 1.2% (12 000 mg/l).

Ethanol

Ethanol is a natural metabolite and a small amount of ethyl alcohol (0.003–0.015% in blood) is necessarily present in our bodies, even if we do not drink alcohol. Ethanol (**8-11**) is generally not considered an important flavouring, but still has a significant impact on the flavour and energy value of many beverages. The energy value of ethanol is 29 kJ/g (7 kcal/g). Ethanol, bound in various esters, for example in essential oils, is a common volatile component of many foods (in small amounts). Free ethanol, together with carbon dioxide and many minority substances, is formed as the main product of anaerobic degradation of sugars by yeast, the so-called alcoholic fermentation or alcoholic glycolysis. Therefore, ethanol is present in variable amounts in alcoholic beverages and is also present in batter, bread and all fermented milk products. For example, yoghurt and other dairy products contain ethanol in quantities ranging from 0.04 to 0.05%. Alcoholic fermentation is a sequence of reactions, which generates pyruvic acid from sugars as the key intermediate (Figure 8.2). The decarboxylation of pyruvic acid by pyruvate decarboxylase yields acetaldehyde (ethanal), which is reduced to ethanol by alcohol dehydrogenase. The amount of ethanol depends on the amount of fermentable sugars in the raw material, type and strain of yeast used, the fermentation temperature, nutrient content in the medium and other factors. The same reaction also takes place in plants when there is a reduced oxygen level. For the industrial production of ethanol, certain strains of *Saccharomyces cerevisiae* yeast are employed, which are able to ferment glucose, mannose, fructose, saccharose, xylulose and raffinose. The ability to ferment galactose, maltose and melibiose is variable; trehalose, lactose and xylose are not fermented at all. Glucose, fructose and saccharose can enter yeast cells directly (after cleavage of saccharose by invertase); maltose requires specific permeases to enter the yeast cells.

To produce ethanol from starchy materials, such as cereal grains, the starch must first be converted into fermentable sugars, which are formed by starch degradation by amylases and maltases (see Section 4.5.6.1.3). For the production of beer, for example, yeast strains are selected that metabolise maltose and maltotriose (which

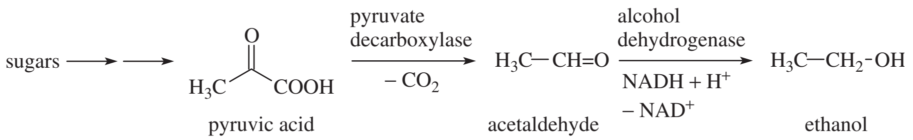

Figure 8.2 Formation of ethanol in alcoholic fermentation of sugars.

is fermented to varying degrees), the two sugars that prevail in the wort. According to the type of yeast used in the fermentation process, beers are differentiated into ales and lagers. Ales use yeast strains active at warmer temperatures and rise to the top of the wort (top-fermenting type of *S. cerevisiae*), while lagers use strains of yeast that are active at cooler temperatures and the yeast resides settle at the bottom of the tank (bottom-fermenting type). Some bacteria and fungi also produce ethanol from sugars. For example, the natural fermentative agent in anaerobic ethanol production from glucose is the gram-negative bacterium *Zymomonas mobilis*. Recent efforts have concentrated on natural renewable and relatively low cost lignocellulose waste that can be fermented to give ethanol by either bacteria (such as strains of the wood-decaying bacteria of the genus *Paenibacillus* that can break down and digest hemicelluloses containing xylose as the main sugar or thermophilic bacteria *Clostridium thermohydrosulfuricum* strains) or yeasts (such as *Candida utilis*, *C. tropicalis* and *Rhodotorula glacilis*). Starchy materials can similarly be fermented by mixed cultures of yeasts and molds (such as *Aspergillus niger* and *Saccharomyces cerevisiae*).

The ethanol content of beers varies over a relatively wide range. According to the original concentration of the extract in the wort before fermentation,[2] beers produced in the Czech Republic are classified as **light** if they have up to 7% m/m extract, **standard** (**table**) **beers** with an extract of 8–10% m/m, **lagers** with an extract of 11–12% m/m, **special beers** with a minimum extract of 13% m/m and **porters** with a minimum extract of 18% m/m. In the packaging and accompanying commercial documents, the original wort content is rounded down to the nearest whole number. For example, beer with an extract of 10.2% m/m is regarded as standard beer.

Instead of the original extract declaration, the packaging often declares ethanol content in per cent by volume (alcoholic strength or alcohol by volume, in short ABV), usually recognised as a long-term average value, for example 5.0%. Designation according to the ethanol content is also mandatory for beers with reduced alcohol content (from 0.5 to 1.2% by volume) and **non-alcoholic beers**, which contain up to 0.5% alcohol by volume. Similar classification of beers is also used in other EU countries. For example, the Pilsner type of beer known as Pilsner Urquell, produced by bottom-fermentation technology in the Czech Republic, has an original wort concentration of 11–12% and ethanol content of about 3.6% w/w. Beers for diabetics are low carbohydrate beers with higher alcohol content. Dark beers have an original wort content that is generally higher (13–20% w/w). The dark beers Stout, Porter and Guinness, produced in the United Kingdom, are usually bottom fermented and have high ethanol contents (up to 6.8% w/w).

Ethanol content in wines varies from 8–9% to 18–18.5% by volume, depending on the content of sugars in the must (see Section 4.2.2.6). Normal table wines contain 10–14% ethanol by volume, while dessert wines of the sherry type contain 17–24% ethanol by volume. The ethanol content in grape brandy, spirits and other spirits is around 40% by volume, and a number of special products have lower alcohol content, but some spirits have also higher alcohol content. In the United States, the proof of an alcoholic beverage is twice its alcohol content expressed as percentage by volume at 60 °F (15.6 °C). So an 80-proof whiskey (whisky) is 40% ethanol.

Milk contains a small amount of ethanol, about 0.003% on average, yoghurts and other dairy products obtained by fermentation contain ethanol at levels not exceeding 0.04–0.05%. Of the dairy products, only fermented mare's milk (called kumiss or kumys) has higher alcohol content (1–3%).

Higher alcohols

In addition to ethanol, alcoholic fermentation produces a series of higher aliphatic alcohols (**8-11**) with a strong aroma, which are collectively known as the **fusel oil alcohols**. These alcohols accompany ethanol in beer, wine and other spirits, but also in dough and fermented dairy products (Table 8.5). Fusel oil alcohols are produced either by catabolic processes (some aminocarboxylic acids are their precursors) or anabolic processes (they are formed from sugars in the synthesis of aminocarboxylic acids). The immediate precursors of fusel oil alcohols are aldehydes generated as byproducts of metabolism. Alcohol dehydrogenases reduce these aldehydes to the corresponding alcohols. Formation of fusel oil alcohols is described in Section 2.5.1.3.2, which deals with transamination and oxidative deamination of aminocarboxylic acids. The level of fusel oil alcohols in alcoholic beverages depends on the raw materials processed. In wines, for example, important variables are the grape variety (red wines contain somewhat higher amounts of fusel oil alcohols than white wines), conditions during fermentation and yeast strains used.

[2] A slurry of germinated barley seeds (barley malt) and brewing water (called mash) is heated at a temperature around 60 °C to allow the malt enzymes, mainly amylases but also proteases, to degrade starch and proteins. In general, a few hundreds of grams of are used for 1 l of beer. The process is stopped by heating and the solution obtained by filtration is the wort. Using the Balling's formula, the original wort extract p (% m/m) can be calculated from the ethanol content A (% m/m) and real extract E (% m/m; determined from the beer density after evaporation of ethanol and made up to original weight with water):

$$p = \frac{100\,(E + 2.0665A)}{100 + 1.0665A}$$

Table 8.5 Fusel oil and other higher alcohols in some alcoholic beverages (mg/l).

Alcohol	Beer	Wine	Whisky	Alcohol	Beer	Wine	Whisky
Fusel oil alcohols				2-Phenylethanol	4–102	5–138	0.6–131
Propan-1-ol	4–60	11–93	20–187	Tyrosol	0.6–29	5–45	-
Butan-1-ol	-	3–9	-	Tryptophol	0.2–12	0–1.6	-
2-Methylpropan-1-ol	2–98	15–184	110–670	***Other alcohols***			
(*S*)-2-Methylbutan-1-ol	3–41	12–311	60–1390	Butan-2,3-diol[a]	40–250	165–1615	-
3-Methylbutan-1-ol	19–160	40–523	150–1465	Glycerol	1100–3 200	1400–26 700	-

[a]Butan-2,3-diol is a mixture of isomers of which (2*R*,3*R*)-butan-2,3-diol, also known as (−)-D-butan-2,3-diol, prevails.

2-Methylpropan-1-ol, known as isobutyl alcohol or isobutanol (resulting from valine via 2-oxoisovalerate) and 3-methyl-1-ol, known as isoamyl alcohol (created from leucine via 2-oxoisocaproate) are the main alcohols found in fusel oils in relatively large amounts. Both alcohols have considerable influence on the aroma of alcoholic beverages. Fusel oils contain some other alcohols in smaller quantities, such as (−)-(*S*)-2-methyl-1-ol known as optically active amyl alcohol (produced from isoleucine via 2-oxo-3-methylvaleric acid), propane-1-ol (which is produced from threonine via 2-oxobutyric acid) and butane-1-ol (created as a byproduct of isoleucine biosynthesis from threonine, by decarboxylation of 2-oxovaleric acid and reduction of butanal that is formed as the decarboxylation product, Figure 8.3). In the butanol fermentation method employed in industrial

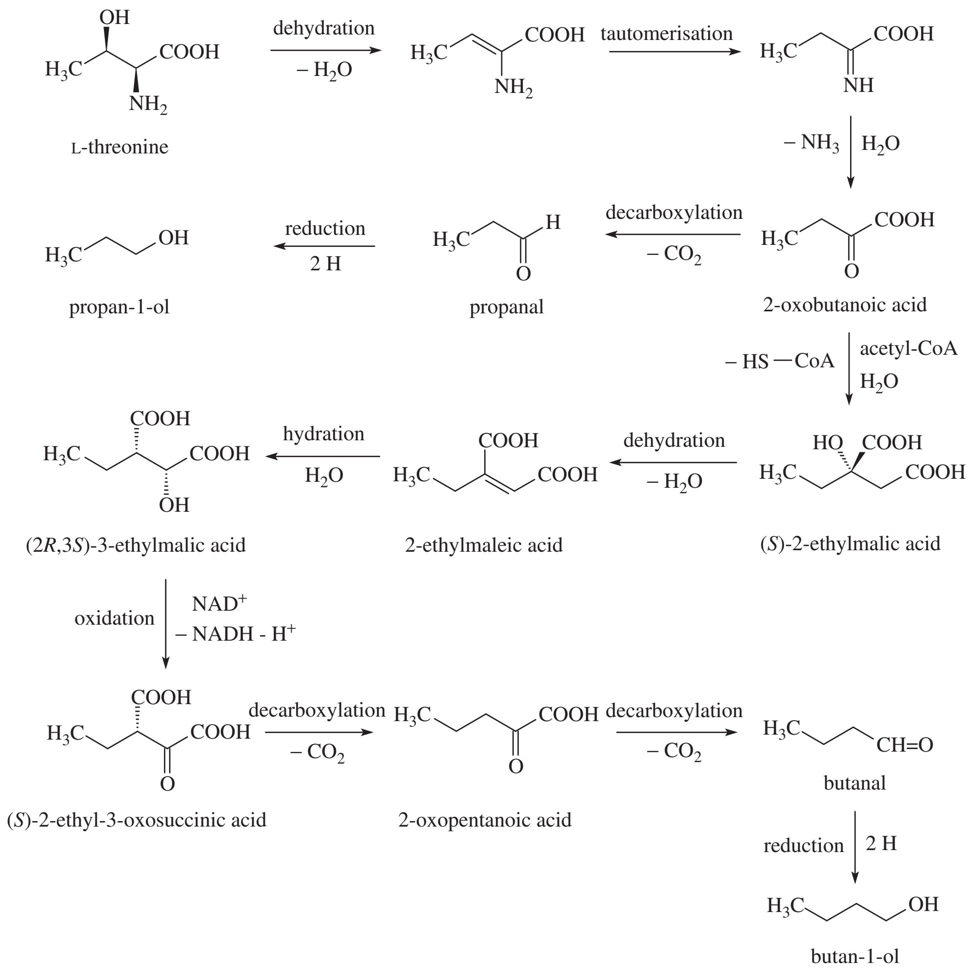

Figure 8.3 Formation of propan-1-ol and butan-1-ol from threonine.

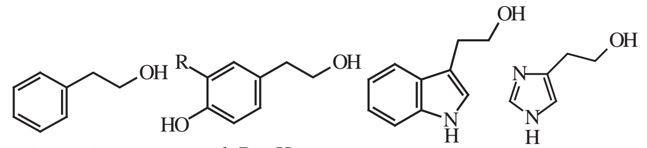
processes (also known as acetone–butanol fermentation) with bacteria of the genus *Amylobacter*, butan-1-ol is the main product, followed by acetone, propan-2-ol (isopropyl alcohol) and ethanol. During fermentation processes, the aromatic aminocarboxylic acid phenylalanine forms 2-phenylethanol, also known as 2-phenylethyl alcohol (**8-12**), tyrosine yields non-volatile alcohol tyrosol (**8-12**), 3,4-dihydroxyphenylalanine (DOPA) yields 3-hydroxytyrosol (**8-12**) and tryptophol (**8-12**) is produced from tryptophan. Some mycobacteria, such as *Mycobacterium diernhoferi*, *M. fortuitum* and *M. chelonei* and some yeast strains (*Saccharomyces rouxii*) are known to oxidise histamine to give histaminol (**8-12**). Histaminol has also been found in red and white wines at concentrations of 0.3–1.1 mg/l.



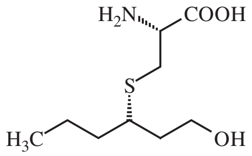
2-phenylethanol; tyrosol, R = H; hydroxytyrosol, R = OH; tryptophol; histaminol

8-12, aromatic and heterocyclic alcohols derived from amino acids

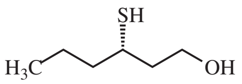
Sulfur aminocarboxylic acids also yield some sulfur-containing aromatic and heterocyclic alcohols. Methional is formed from methionine and reduced to the corresponding alcohol methionol (**8-13**) in beers and wines. Important sulfur-containing alcohols formed in wines, including 3-mercapto-3-methyl-1-ol, 4-mercapto-4-methylpentan-2-ol and 3-mercaptohexan-1-ol, are formed as degradation products of cysteine conjugates (**8-14**) with sulfur-containing alcohols under the action of CS lyases. These sulfur-containing alcohols are characteristic components of wine aroma. For example, (+)-(*S*)-3-mercaptohexan-1-ol (**8-15**) has (on dilution) an interesting tropical fruit aroma, reminiscent of passion fruit (*Passiflora edulis*, Passifloraceae). The (−)-(*R*)-isomer has a fruitier aroma, reminiscent of grapefruit.

Some higher alcohols present in alcoholic beverages at low concentrations are even present in certain amounts in the raw materials. For example, pentan-1-ol, hexan-1-ol, heptan-1-ol (8-11), octan-1-ol and other higher alcohols are present in grape musts. They are formed by oxidation of essential fatty acids by lipoxygenases and by cleavage of fatty acid hydroperoxides by lyases, which are followed by reduction of the saturated or unsaturated aldehydes through the action of alcohol dehydrogenases (Figure 8.4) from the raw material and with the action of yeast alcohol dehydrogenases during fermentation. Detailed mechanisms of these reactions are given in Section 3.8.1.8.5.

8-13, methionol



8-14, 3-mercaptohexan-1-ol cysteine conjugate



8-15, (*S*)-3-mercaptohexan-1-ol

For example, reduction of propanal yields propan-1-ol, butan-1-ol is produced from but-2-enal or butanal, pentanal gives rise to pentan-1-ol, which is present in wines at levels of about 0.1 mg/l. Hexan-1-ol (the amount in wines is usually 0.3–12 mg/l) arises mainly by reduction of hexanal (Figure 8.5) and (*E*)-hex-2-enal (Figure 8.6) by alcohol dehydrogenases. It has a faint green and tallowy odour (see below). Hexanal forms by decomposition of linoleic acid (13*S*)-hydroperoxide with hydroperoxide lyase, (*E*)-hex-2-enal is formed by enzymatic cleavage of linolenic acid (13*S*)-hydroperoxide and isomerisation of the thus formed (*Z*)-hex-3-enal catalysed by enal isomerase. Reduction of methylketones produced by oxidation of fatty acids generates alkan-2-ols.

Alcohol dehydrogenases are quite specific to the substrate and reduce higher aldehydes (>C_5) very slowly. For this reason, the content of higher (fatty) alcohols in alcoholic beverages, as well as in fruits and vegetables, is relatively low and the main products of fatty acid oxidation are aldehydes and not alcohols.

In addition to aminocarboxylic and fatty acids, the precursors of higher alcohols may likewise become other food components. For example, minor degradation products of β-carotene, in addition to other compounds, are butan-1-ol, 2-methylpropan-1-ol and pentan-1-ol.

Unsaturated alcohols

The simplest aliphatic unsaturated alcohol, allyl alcohol (prop-2-en-1-ol), is formed from alliin during high temperature processing of garlic. Allyl alcohol was found to be one of the major degradation

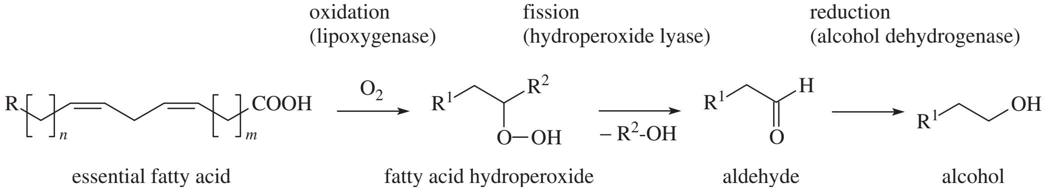


Figure 8.4 Formation of alcohols from fatty acids.

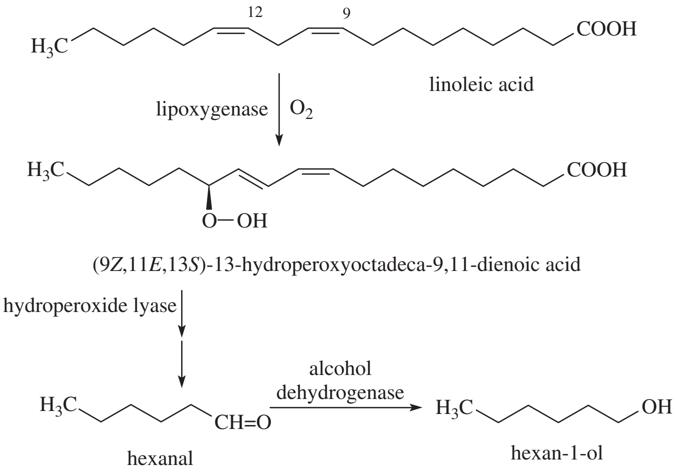

Figure 8.5 Formation of hexan-1-ol from linoleic acid.

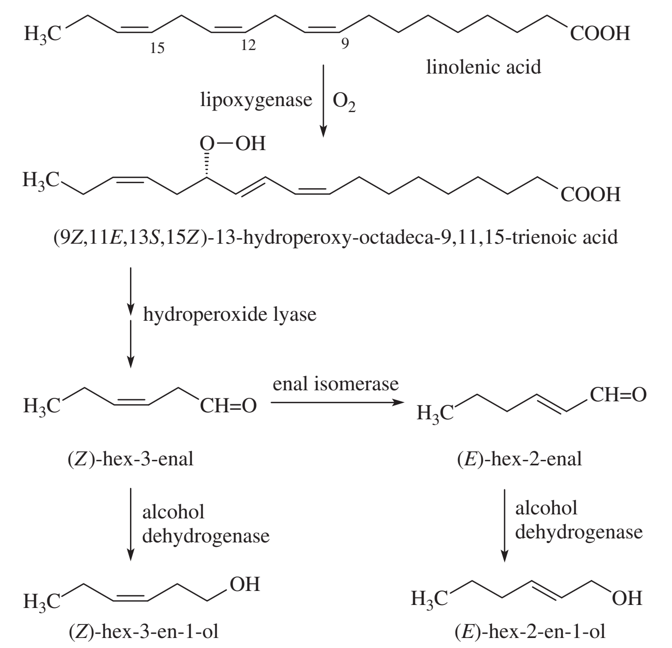

Figure 8.6 Formation of hex-2-en-1-ol and hex-3-en-1-ol from linolenic acid.

products of alliin heated at 80–200 °C in the presence of variable amounts of water. Its amount increased with the amount of added water and was the highest at 140 °C (37 mg/g amino acid). Allyl alcohol at a level of 1.1 mg/kg was also found in Boursin Ail cheese flavoured with garlic. It is proposed that allyl alcohol is formed either through [2,3]-sigmatropic rearrangement of alliin to the corresponding sulfenate, which decomposes to allyl alcohol and cysteine (Figure 8.7) or by transformation of alliin via thiosulfonium ion (see Section 8.2.9.1.4). Cysteine then decomposes further into acetaldehyde, hydrogen sulfide and ammonia.

Some unsaturated aliphatic alcohols arising from essential fatty acids are important flavour-active components of fresh fruits, vegetables and mushrooms. Hydroperoxides of fatty acids resulting

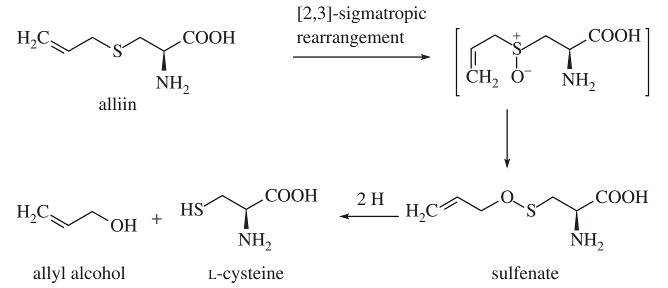

Figure 8.7 Formation of allyl alcohol from alliin.

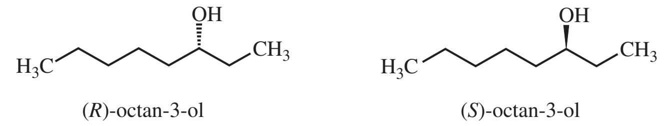
from regioselective and stereospecific oxidation by lipoxygenases are broken down in different ways. In animal tissues, hydroperoxides are reduced to non-volatile hydroxycarboxylic acids by the enzyme glutathione peroxidase. In plants and fungi, hydroperoxides decompose by lyases, dehydrases, epoxygenases and hydroperoxide hydrolases. Differences in sensory quality of active products are related to the substrate and reaction specificity of these enzymes. The main products formed in plants are aldehydes, while mushrooms produce allyl alcohols.

Cleavage of 13- and 9-hydroperoxides of linoleic acid and, in particular, α-linolenic acid, which is the main fatty acid of green plants, by hydroperoxide lyases provides a range of aldehydes, significantly contributing to the fresh, herbal odour, called green odour, of fruits and vegetables (apples, plums, olives, leafy vegetables, tomatoes, peppers and other products). Decomposition of α-linolenic acid (13*S*)-hydroperoxide by hydroperoxide lyase yields (*Z*)-hex-3-enal that has pure green odour (Figure 8.6). Cleavage of (9*S*)-hydroperoxide of the same fatty acid provides (3*Z*,6*Z*)-nona-3,6-dienal with an oily and green odour (Table 8.6). (*Z*)-Alkenals can be subsequently transformed into (*E*)-alkenals by enal isomerases and reduced to (*Z*)- or (*E*)-alkanols by alcohol dehydrogenases (Figure 8.6). These products often have a characteristic smell of fruits and vegetables. For example, isomerisation of (*Z*)-hex-3-enal yields (*E*)-hex-2-enal, known as leaf aldehyde, on reduction this gives (*Z*)-hex-3-en-1-ol, which is trivially called leaf alcohol. Isomerisation of (3*Z*,6*Z*)-nona-3,6-dienal provides (2*E*,6*Z*)-nona-2,6-dienal with a typical aroma of fresh cucumbers. Hexanal (Figure 8.5) and some other aldehydes (Table 8.6) also contribute to the green odour.

The aroma of fresh mushrooms contains (−)-(*R*)-oct-1-en-3-ol, which arises in a similar way from linoleic acid (Figure 8.8). The formation of (10*S*)-hydroperoxide is catalysed by a specific lipoxygenase. Oct-1-en-3-ol is accompanied by oct-1-en-3-one, octan-1-ol and (*R*)-octan-3-ol (**8-16**). Other compounds also have the mushroom-like smell, such as (3*R*,5*Z*)-octa-1,5-dien-3-ol (**8-17**), which is produced analogously by decomposition of linolenic acid (10*S*)-hydroperoxide.

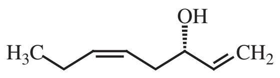


8-16, octan-3-ol isomers

Table 8.6 Trivial and systematic names of monoterpenic alcohols.[a]

Trivial name	Systematic name (IUPAC)
(+)-Borneol	(1*R*,2*S*,4*R*)-1,7,7-Trimethylbicyclo[2.2.1]heptan-2-ol
(+)-Citronellol	(*R*)-3,7-Dimethyloct-6-en-1-ol
(+)-Fenchol	(*R*)-1,5,5-Trimethylbicyclo[2.2.1]heptan-6-ol
Geraniol	(*E*)-3,7-Dimethylocta-2,6-dien-1-ol
(−)-(*E*)-Hotrienol	(3*R*,5*E*)-3,7-Dimethylocta-1,5,7-trien-3-ol
(+)-Isomenthol	(1*S*,2*R*,5*R*)-5-Methyl-2-propan-2-ylcyclohexan-1-ol
(+)-(*E*)-Carveol	(1*R*,5*S*)-2-Methyl-5-prop-1-en-2-ylcyclohex-2-en-1-ol
(−)-(*E*)-Carveol	(1*S*,5*R*)-2-Methyl-5-prop-1-en-2-ylcyclohex-2-en-1-ol
(−)-Lavandulol	(*R*)-5-Methyl-2-prop-1-en-2-ylhex-4-en-1-ol
(+)-Linalool	(*S*)-3,7-Dimethylocta-1,6-dien-3-ol
(−)-Menthol	(1*R*,2*S*,5*R*)-5-Methyl-2-propan-2-ylcyclohexan-1-ol
(−)-2-Methylisoborneol	(1*R*-exo)-1,2,7,7-Tetramethylbicyclo[2.2.1]heptan-2-ol
(+)-Neomenthol	(1*S*,2*S*,5*R*)-5-Methyl-2-propan-2-ylcyclohexan-1-ol
Nerol	(*Z*)-3,7-Dimethylocta-2,6-dien-1-ol
(−)-Perillyl alcohol	[(*S*)-4-Prop-1-en-2-ylcyclohex-1-en-1-yl]methanol
(+)-(Z)-Sabinene hydrate	(1β,2β,5α)-4-Methyl-1-propan-2-ylbicyclo[3.1.0]hexan-4-ol
(+)-Terpinen-4-ol	(*S*)-4-Methyl-1-propan-2-ylcyclohex-3-en-1-ol
(+)-α-Terpineol	(*R*)-2-(4-Methyl-1-cyclohex-3-en-1-yl)propan-2-ol

[a]Numbers in the trivial names derived from *p*-menthane (4-isopropyl-1-methylcyclohexane) differ from the numbers of the names recommended by IUPAC. For example, (+)-(*E*)-dihydrocarvone is (1*S*,4*S*)-dihydrocarvone or (2*S*,5*S*)-2-methyl-5-prop-1-en-2-ylcyclohexanone; (+)-(*E*)-carveol is (2*R*,4*S*)-carveol or (1*R*,5*S*)-2-methyl-5-prop-1-en-2-ylcyclohex-2-en-1-ol.



8-17, (3*R*,5*Z*)-octa-1,5-dien-3-ol

In meat, oct-1-en-3-ol and oct-1-en-3-one are produced analogously by decomposition of 12-hydroperoxy-5,8,10,14-eicosatetraenoic acid, which is one of the arachidonic acid autoxidation products. When this decomposition occurs, it may cause an off-flavour.

Terpenic alcohols

Monoterpenic alcohols Monoterpenic alcohols, together with terpenic hydrocarbons and other terpenoids, are widespread components characteristic of various essential oils from flowers and other plant parts that are often used in perfumery. Many monoterpenic alcohols are also odour-active components of spices, fruits and vegetables. They exhibit frequently a sweet, heavy floral odour in different shades.

The most important monoterpenic acyclic alcohol with one double bond is citronellol. Alcohols with two double bonds include linalool, geraniol and nerol, and an example of an alcohol with three double bonds is hotrienol (**8-18**). (+)-Citronellol (β-citronellol) is a major component of essential oils of *Zieria citriodora* (syn. *Boronia citriodora*, Rutaceae, about 80%), a plant native to Australia and known as lemon-scented zieria. It also occurs in *Corymbia citriodora* (syn. *Eucalyptus citriodora*, Myrtaceae; 15–20%), an Australian tree known as lemon-scented gum or lemon eucalyptus. (−)-Citronellol isolated from natural sources is often called rhodinol. It is the predominant enantiomer in geranium (*Pelargonium graveolens* and other species, Geraniaceae) and Bulgarian Damask rose essential oils (*Rosa damascena* var. *bulgaria*, Rosaceae), which contain up to 50% citronellol. A mixture of both enantiomers is present in many essential oils, for example in the essential oil of aromatic citronella grass *Cymbopogon nardus* and *C. winterianus* (Poaceae) native to tropical Asia. (+)-Linalool (coriandrol) is found at a

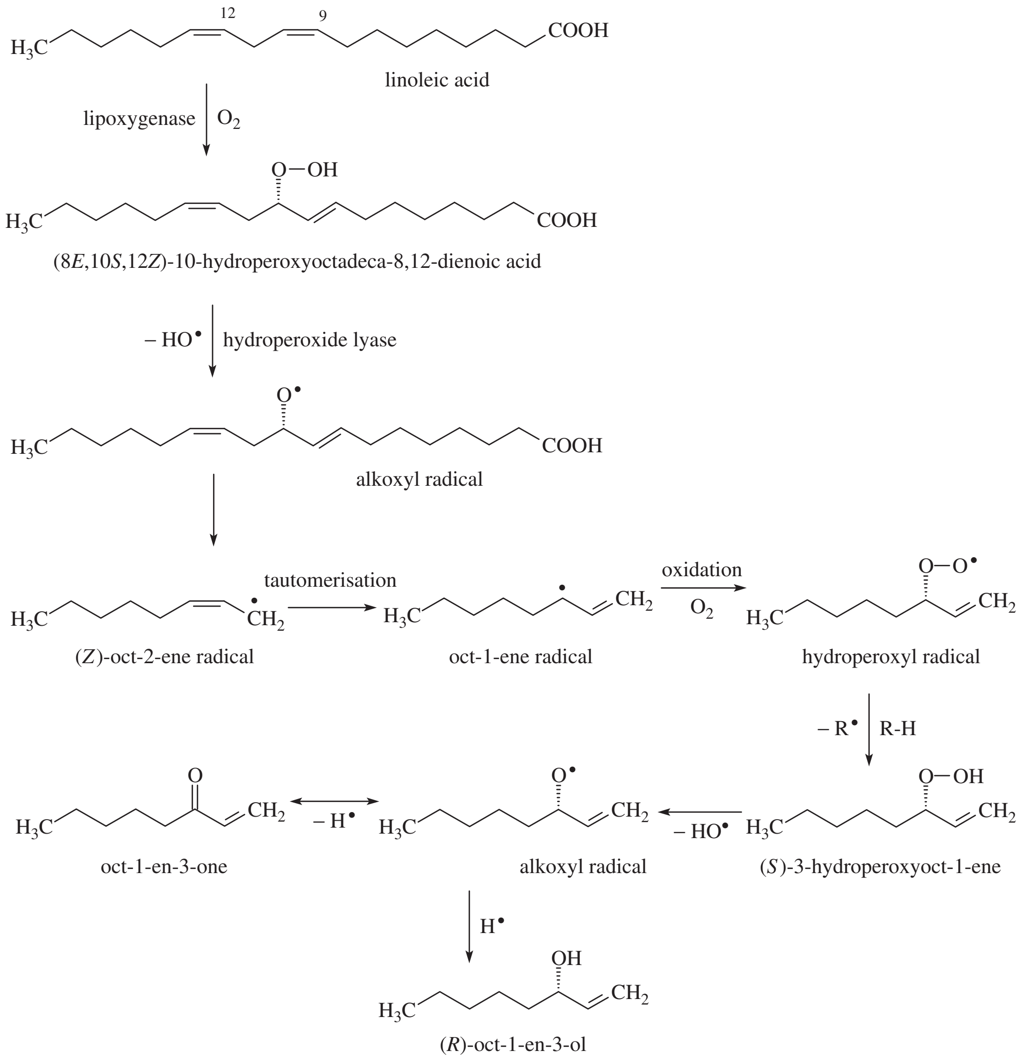


Figure 8.8 Formation of oct-1-en-3-ol and oct-1-en-3-one from linoleic acid.

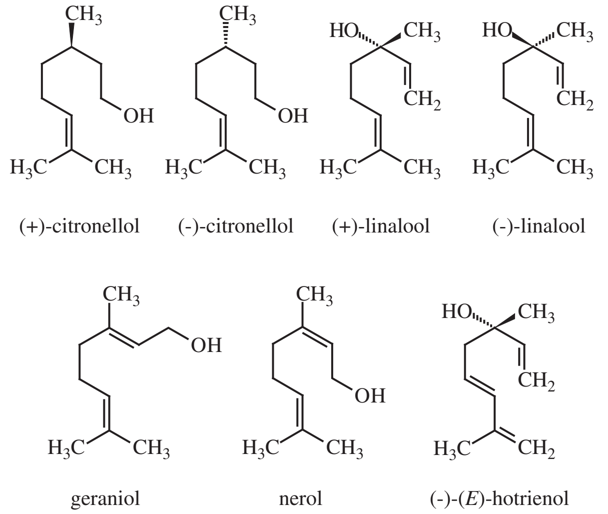
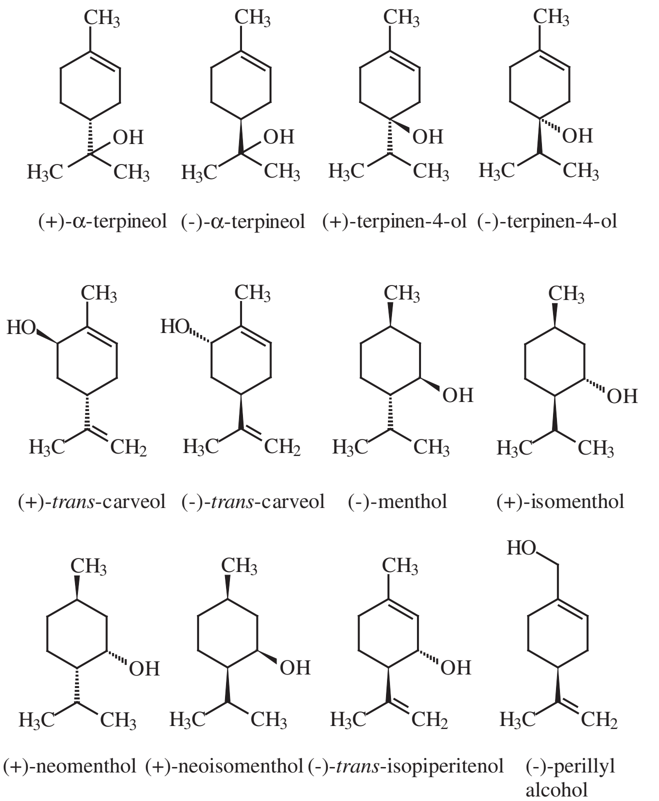


8-18, acyclic monoterpenic alcohols

level of 60–80% in coriander essential oil (see Table 8.32, later), (−)-linalool (licareol) is the major component (80–85%) of cinnamon essential oil. Geraniol is, at about 8%, a component of geranium oil, its *cis*-isomer, known as nerol, occurs in Bulgarian rose oil together with citronellol. Hotrienol is the product of linalool oxidation and further transformation of linalool oxidation products, as well as linalool oxides, lilac aldehyde and lilac alcohol. Hotrienol occurs in many essential oils, for example it is an odorous component of some aromatic wines and of the essential oil of elderberry flowers (*Sambucus nigra*, Adoxaceae).

Other common components of essential oils are the monoterpenic monocyclic alcohols α-terpineol (found in lilac, marjoram, cardamom, star anise oil and other oils), terpinen-4-ol (4-terpineol), also known as 4-carvomenthenol, is a component of the essential oils of pine (*Pinus* spp., Pinaceae), eucalyptus (*Eucalyptus* spp. Myrtaceae), marjoram and thyme (see Table 8.32, later). It is also the main component of the antiseptic essential oil of the Australian tree *Melaleuca alternifolia* (Myrtaceae), known as tea tree oil. It often occurs as a racemate. (+)-Terpinen-4-ol occurs at about

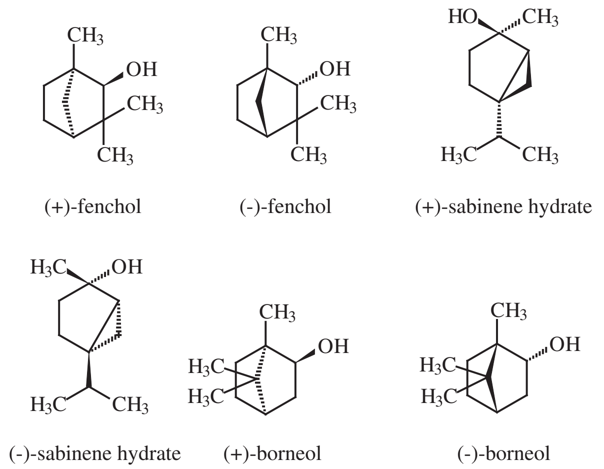
10% in the essential oil of lavender (*Lavandula* spp., Lamiaceae), (−)-terpinen-4-ol is a component of orange essential oil, (+)-(*E*)-carveol is an intermediate in the biosynthesis of the characteristic caraway oil component (see Table 8.32, later) (+)-carvone (see **8-50**, later) from (+)-limonene, while its isomer (−)-(*E*)-carveol (**8-19**) is an intermediate of biosynthesis of (−)-carvone from (−)-limonene. (−)-Carvone (see **8-50**, later) is an important component of spearmint essential oil (see Table 8.32, later).



8-19, monocyclic monoterpenic alcohols

(−)-Menthol, which evokes coolness through stimulation of the somatosensory system, is, along with its isomers (+)-isomenthol, (+)-neomenthol and (+)-neoisomenthol (**8-19**), a key component of peppermint essential oil (see Table 8.32, later). The starting compound for the biosynthesis of these alcohols is (−)-limonene, while one of the menthol precursors is (−)-(*E*)-isopiperitenol. Good-quality peppermint essential oil has a high menthol content, moderately high content of menthone and low content of (+)-(*R*)-pulegone and (+)-(*R*)-menthofuran. The (−)-(*S*)-enantiomers are found rarely in essential oils. Pulegone and menthofuran are undesirable because of their hepatotoxicity, and therefore appeared in the list of substances under Regulation (EC) No. 1334/2008, which should not be added to foods as flavouring. Their natural amount in foods is restricted to 2000 and 3000 mg/kg in micro breath freshening confectionery, to 250 and 500 mg/kg in other peppermint-containing confectionery, to 350 and 1000 mg/kg in chewing gums and to 100 and 200 mg/kg in peppermint-containing alcoholic beverages, respectively. The level of pulegone is restricted to 20 mg/kg in peppermint-containing non-alcoholic beverages.

An important precursor of (−)-perrillyl aldehyde (perillal) is (−)-perillyl alcohol. Fenchol (also known as α-fenchyl alcohol or fenchan-2-ol, **8-20**) is a bicyclic monoterpenic alcohol occurring as a minor component in citrus, fennel and sage essential oils. Another common compound is the bicyclic alcohol thujan-4-ol (sabinene hydrate), which occurs at a high level in the marjoram essential oil (see Table 8.32, later). Borneol (bornan-2-ol) is a component of camphor oils (*Cinnamomum camphora*, Lauraceae). Trivial and systematic names of selected monoterpenic alcohols are listed in Table 8.6.



8-20, bicyclic monoterpenic alcohols

Monoterpenic alcohols are found in the flowers of plants, fruits and other plant materials mainly as sensorially inactive glycosides. The predominant glycosides are β-D-glucopyranosides substituted with L-rhamnose, L-arabinose, D-apiose and acylated with malonic acid. Examples of these glycosides are α-L-arabinofuranosyl-(1→6)-β-D-glucopyranosides, α-L-rhamnopyranosyl-(1→6)-β-D-glucopyranosides (β-rutinosides) and β-D-apiofuranosyl-(1→6)-β-D-glucopyranosides; less common glycosides are unsubstituted β-D-glucopyranosides. α-L-Arabinofuranosyl-(1→6)-β-D-glucopyranosides and β-D-apiofuranosyl-(1→6)-β-D-glucopyranosides of geraniol, β-D-glucopyranosides of geraniol, nerol, citronellol and β-D-glucopyranosyl-(1→2)-β-D-glucopyranoside (β-sophoroside) of citronellol occur, for example, as precursors of the corresponding alcohols in Bulgarian Damask rose flowers. In apricots and grapes, glycosides are mainly localised in the skin. Linalool, nerol and α-terpineol are present as β-D-glucosides, geraniol occurs in the form of β-rutinoside and linalool and α-terpineol as 6-*O*-α-L-arabinofuranosyl-(1→6)-β-D-glucopyranosides. Glycosides of diols and other polyols have also been identified.

Complex enzymatic and non-enzymatic transformations of glycosides of monoterpenic alcohols and free alcohols during the development of flowers, fruit ripening or fermentation provide a range of new oxygenated monoterpenoids, which are often characteristic constituents of flowers, fruits and alcoholic beverages (wine and spirits). For example, a glycoside of terpenic alcohol can be enzymatically oxidised, or the free alcohol formed by hydrolysis can be oxidised, which is then transformed into other products.

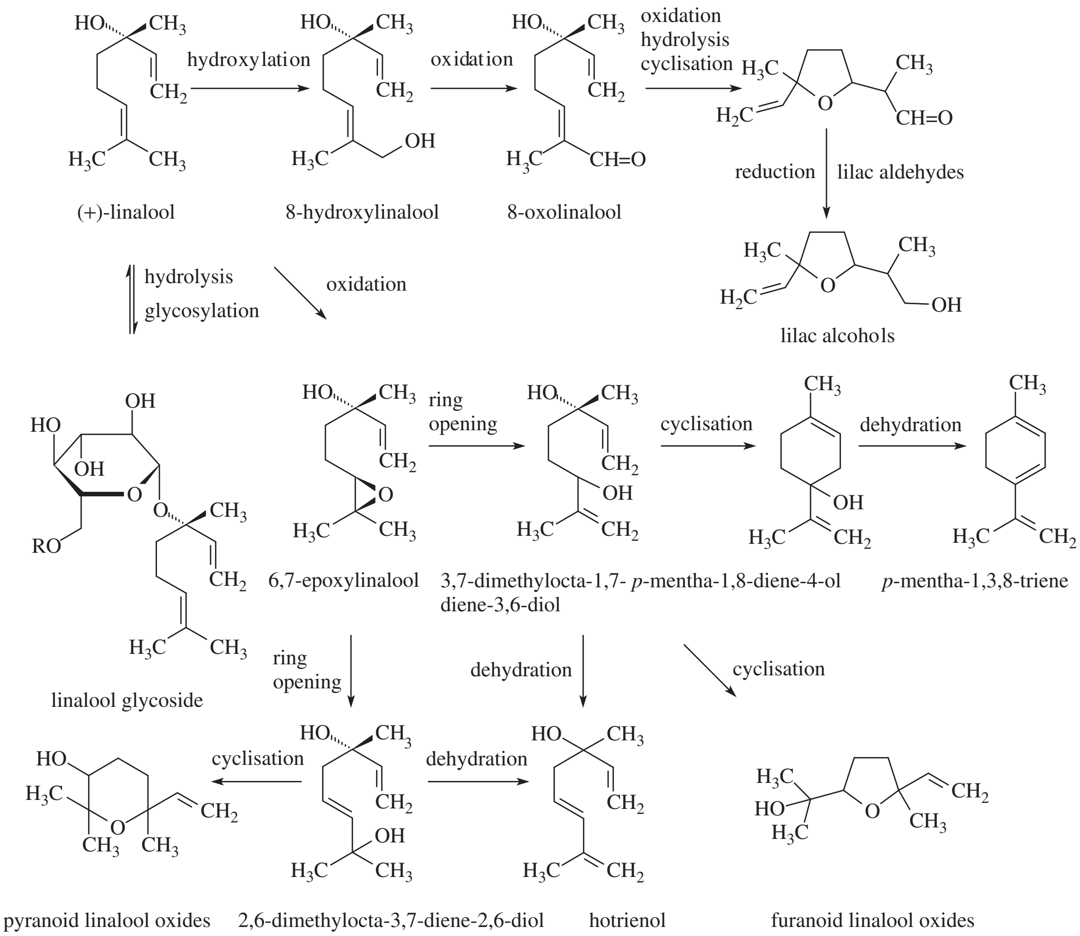


Figure 8.9 Reactions of linalool and formation of lilac alcohol, linalool oxides and hotrienol.

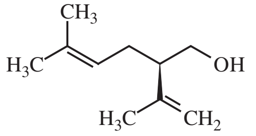
These transformations are shown in Figure 8.9 for the example of (+)-linalool and its glucoside. Linalool in lilac flowers (*Syringa vulgaris*, Oleaceae) is oxidised to 8-hydroxylinalool, which is the precursor of four (5'*S*)-isomers of lilac aldehydes, reduction of which yields lilac alcohols that are typical components of the odour of lilac flowers and honey from citrus flowers. Linalool glucoside can be oxidised analogously to 8-hydroxylinalool glucoside, hydrolysis of which provides free 8-hydroxylinalool. Under the acidic conditions in musts, especially during heating, glycosides are easily hydrolysed non-enzymatically to monoterpenic alcohols or their oxidation products, such as 6,7-epoxylinalool. Enzymatic ring opening of this epoxide yields either 3,7-dimethyl-1,7-octadien-3,6-diol or 2,6-dimethyl-3,7-octadien-2,6-diol. The former compound then becomes the precursor (after cyclisation and dehydration) of *p*-mentha-1,3,8-triene, which is the main flavour-active component of parsley essential oil. Its dehydration yields (−)-(*E*)-hotrienol, which is a component of many fruit aromas. In acidic solutions, spontaneous cyclisation of the mentioned diols yields furanoid and pyranoid linalool oxides. Linalool oxides are also present as glycosides.

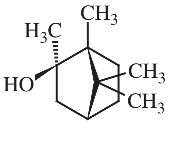
Illustrative of monoterpenic alcohols biosynthesised from two molecules of dimethylallyl diphosphate linked together head to head is (−)-lavandulol (**8-21**). Along with its acetate, lavandulol occurs



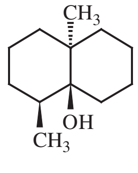
8-21, lavandulol

in the essential oil of common lavender (*Lavandula angustifolia*, syn. *L. officinalis*, Lamiaceae).

The characteristic odour of raw, wet land is caused by the presence of two terpenoids, monoterpenic alcohol (−)-2-methylisoborneol (**8-22**) and the sesquiterpenoid (−)-geosmin (**8-23**) produced by streptomycetes, myxobacteria and cyanobacteria. Both compounds cause an unpleasant odour in drinking water and some foods, such as canned mushrooms, wheat, coffee and meat of freshwater fish



8-22, 2-methylisoborneol



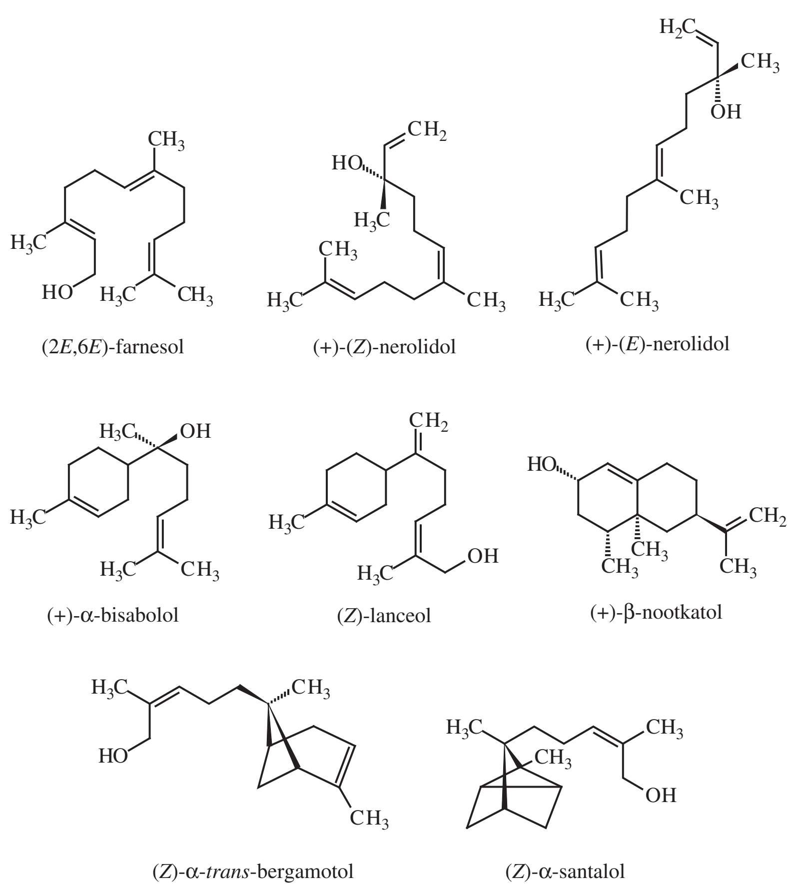
8-23, geosmin

(such as carp) that depend on the nutrients from benthos, animal (zoobenthos) and vegetable (phytobenthos) organisms inhabiting the bottom waters. 2-Methylisoborneol has been reported to occur in soil in quantities of about 4 μg/kg, which is more than 100-fold above its threshold value. Its reported occurrence in the green coffee beans (80–420 ng/kg in Arabica and 740–1280 ng/kg in Robusta green coffee) is most likely of microbial origin.

Sesquiterpenic alcohols Examples of sesquiterpenic alicyclic alcohols (**8-24**) are farnesol and nerolidol (also known as peruviol). Both alcohols, smelling of flowers, are components of many essential oils used in perfumery. Of the four possible geometric isomers, the (2*E*,6*E*)-isomer of farnesol, is the most common in nature and occurs, for example, in basil oil and ambrette (*Abelmoschus moschatus*; Malvaceae) seed oil. The (2*Z*,6*E*)-isomer occurs in the petit grain oil bigarade, which is derived from the bitter orange tree leaves (*Citrus aurantium* var. *amara*, Rutaceae). Farnesol is a natural pesticide for mites and a pheromone for several species of insects. Nerolidol with a double bond at C-6 occurs in the form of (*Z*)- and (*E*)-isomers, each of which can exist as an enantiomeric pair (chiral carbon C-3). The individual enantiomers and their mixtures are found in many essential oils. For example, the essential oil known as cabreuva oil that is used in perfumery is obtained from the bark of the South American tree *Myrocarpus frondosus* (Fabaceae) and contains the (+)-(*E*)-isomer of nerolidol (3*S*,6*E*)-nerolidol. (*S*)-Nerolidol (in some plants) and in part (*R*)-nerolidol are precursors of acyclic hydrocarbons (*E*)-4,8-dimethylnona-1,3,7-triene and (3*E*,7*E*)-4,8,12-trimethyltrideca-1,3,7,12-tetraene, which are formed by oxidative degradation. These hydrocarbons are released from the damaged leaves of many plants, but they are also typical components of the scent emitted by some plants (belonging to the Orchidaceae, Cactaceae, Magnoliaceae and Liliaceae families) that bloom at night.

An example of monocyclic sesquiterpenic alcohols is (+)-α-bisabolol (**8-24**). It occurs in citrus essential oils along with other sesquiterpenic alcohols, and represents the major component of the essential oil of chamomile flowers (*Matricaria chamomilla*, Asteraceae). α-Bisabolol (0.26%) and other sesquiterpenoids, such as monocyclic sesquiterpenic alcohol (*Z*)-lanceol (1.7%), bicyclic sesquiterpenic alcohol (*Z*)-α-*trans*-bergamotol (3.7%), (−)-(*Z*)-β-santalol (about 21%) and its isomers are the major and essential components of white sandalwood oil (*Santalum album*, Santalaceae) used in perfumery, cosmetics and aromatherapy. (*Z*)-Lanceol is also a component of sage species (*Salvia* spp., Lamiaceae) essential oil. Sesquiterpenic bicyclic alcohol (+)-β-nootkatol is the precursor of ketone (+)-nootkatone, an important component of grapefruit essential oil. Trivial and systematic names of the main sesquiterpenic alcohols are listed in Table 8.7.

Many sesquiterpenoids have antimicrobial and insecticidal properties. For example, germacrene A is the precursor of capsidiol (see



8-24, sesquiterpenic alcohols

Table 8.7 Trivial and systematic names of selected sesquiterpenic alcohols.

Trivial name	Systematic name (IUPAC)

(+)-Nootkatol	(2*R*,4*S*,4a*S*,6*R*)-4,4a-Dimethyl-6-prop-1-en-2-yl-2,3,4,5,6,7,8-heptahydronaphthalen-2-ol
(−)-(*Z*)-β-Santalol	(1*S*,2*Z*,4*R*,6*R*)-2-Methyl-5-[6-methyl-5-methylidene-6-bicyclo[2.2.1]heptanyl]pent-2-en-1-ol

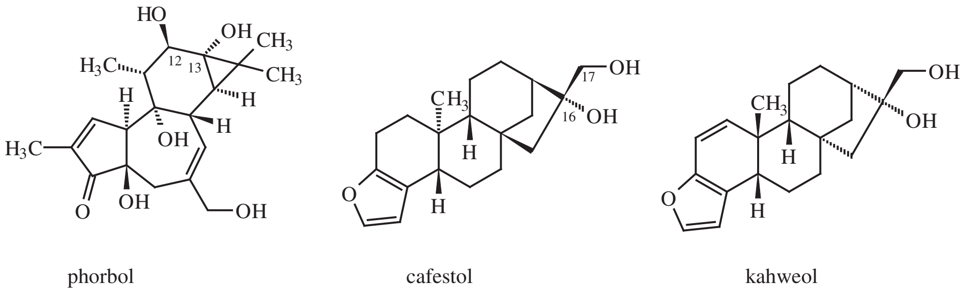
10-155), which is the main phytoalexin that forms in bell peppers and tobacco plants, when attacked by pathogenic fungi. Unusual sesquiterpenoids are sweet hydroxy ketones (+)-hernandulcin and (+)-4β-hydroxyhernandulcin (see **11-35**). Many other sesquiterpenoids have a bitter taste (see Section 8.3.4).

An unusual sesquiterpenoid (though it has only 12 carbon atoms) is (−)-geosmin (**8-23**), produced by some microorganisms, including cyanobacteria and actinobacteria, especially species of the genus *Streptomyces*. Geosmin causes off-flavour in drinking water and some foods. For example, it is responsible for the characteristic earthy flavour of beetroot (cultivars of *Beta vulgaris*, Amaranthaceae, formerly Chenopodiaceae) during cooking. Biosynthesis of alcohol geosmin starts from the sesquiterpenic hydrocarbon germacrene D, but during the biosynthesis three carbon atoms are eliminated as acetone. A similar off-flavour may be caused by monoterpenic alcohol (−)-2-methylisoborneol (**8-22**).

Diterpenic alcohols Diterpenic alcohols are present in nature as free compounds or bound in fatty acid esters and glycosides. They have no significance as flavourings, but may be precursors of flavour-active products. A number of diterpenoids are biologically active substances. Diterpenic alcohols known as gibberellins are found universally in plant tissues, and act as plant hormones.

An important representative of diterpenoid alcohols is phytol (2*E*,3,7*R*,11*R*,15)-3,7,11,15-tetramethylhexadec-2-en-1-ol, a constituent of chlorophylls, tocopherols and K group vitamins. Free phytol arises during chlorophyll hydrolysis by chlorophyllase as an integral part of plant catabolism in fruit ripening and yellowing of leaves. Microbial decomposition of phytol creates some unusual branched fatty acids, such as pristanic and phytanic acids (see Section 3.2.3.3.2). Acyclic diterpenic alcohol is also retinol (vitamin A_1) (see Section 5.2.1).

Many diterpenoid alcohols are cyclic compounds occurring as free substances, but also as fatty acid esters or glycosides. The toxicity of latex of many plant species from the spurge family (Euphorbiaceae) is caused by the presence of phorbol esters such as 13-acetyl-12-myristoyl-phorbol. Cafestol, kahweol (**8-25**) and related diterpenoids (16-*O*-methylcafestol, 16-*O*-methylkahweol and other compounds) are found in green coffee (*Coffea* spp., Rubiaceae) beans (mainly esterified to fatty acids at the C-16 or C-17 position) and unfiltered coffee prepared from roasted coffee seeds, such as Turkish coffee. Kahweol is specific to *C. arabica* coffee, where it occurs in concentrations of about 5890 mg/kg of fresh weight and 5200 mg/kg in the endosperm and perisperm, respectively, while 16-*O*-methylcafestol occurs only in robusta coffee (*C. canephora*). The amount of cafestol in *C. arabica* is about



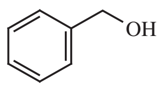
8-25, diterpenic alcohols

3000 mg/kg in the endosperm and 1300 mg/kg in the perisperm and in *C. canephora* the amounts are about 940 mg/kg and 1100 mg/kg, respectively. Cafestol (and also to some extent kahweol) increases the cholesterol level in the blood serum as a result of interaction of palmitate with biological membranes. Furthermore, anticarcinogenic, antioxidant and anti-inflammatory properties as well as hepatoprotective effects have been reported. During roasting of green coffee seeds, these alcohols partially dehydrate to dehydroalcohols (dehydrocafestol and dehydrokahweol) and are oxidised to the corresponding aldehydes (cafestal and kahweal).

Teucrin A is the major component of the so-called *neo*-clerodane diterpenoids (**8-26**) from the plant known as wall germander (*Teucrium chamaedrys*, Lamiaceae), native to Europe and the Near East and used in the form of alcoholic extracts for the aromatisation (bittering) of wines and aperitifs (as it contains a number of odour-active mono- and sesquiterpenoids), and in folk medicine for its antiseptic (anti-inflammatory) and choleretic (increased bile excretion) properties. Teucrin A also occurs in some other species of the genus *Teucrium* and is accompanied by further diterpenoids, such as teuscorolide, teuquin, teuflin (**8-26**) and their glycosides. Because of its hepatotoxicity, teukrin A is in the list of substances of Regulation (EC) No. 1334/2008, which must not be added to foods as flavourings. Its natural content is restricted to 5 mg/kg in bitter-tasting spirit drinks or bitters and to 2 mg/kg in other alcoholic beverages.

8.2.2.1.2 Aromatic and heterocyclic alcohols

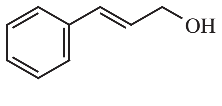
Aromatic alcohols are natural constituents of many essential oils. They arise as secondary compounds in fermentation and thermal processes. The simplest alcohol in this group is benzyl alcohol (**8-27**). It is assumed that benzyl alcohol results from the gradual reduction of benzoic acid by dehydrogenase enzymes via benzaldehyde. In alcoholic beverages it is produced by reduction of benzaldehyde, which is a product of cyanogenic glycosides decomposition and a byproduct of Strecker degradation of phenylalanine. In fruit brandies produced from fermenting fruits with stones (such as cherry, apricot and plum brandies), larger quantities amounting to 20–70 mg/l of benzyl alcohol are found. Benzyl alcohol also occurs in the form of esters in some essential oils. The most common compounds are benzyl acetate and benzyl benzoate.



8-27, benzyl alcohol

Common non-volatile components of plants are hydroxy derivatives of benzyl alcohol that mainly occur in nature in the bound form as glycosides, esters of aromatic carboxylic acids (caffeic, protocatechuic, 4-hydroxybenzoic and vanillic acids) or glycosides of these esters. For example, 4-hydroxybenzyl alcohol was first isolated from muskmelon seedlings (*Cucurbita moschata*). The compound acts as a cofactor for indoleacetic acid oxidase. The glycoside of its ester with protocatechuic acid, 4-(3,4-dihydroxybenzoyloxymethyl)phenyl-*O*-β-D-glucopyranoside occurs in oregano (*Origanum vulgare*), which has been reported to possess antithrombin, anti-*Helicobacter pylori*, antibiotic, antihyperglycaemic and antioxidation effects.

During fermentation processes, phenylalanine produces the higher homologue of benzyl alcohol 2-phenylethanol, also known as phenylethyl alcohol (**8-12**). Analogously, tyrosol results from tyrosine (**8-12**), hydroxytyrosol from 3,4-dihydroxyphenylalanine (DOPA; **8-12**) and tryptophol from tryptophan (**8-12**), but these aldehydes are non-volatile compounds. 2-Phenylethanol formed by reduction of phenylacetaldehyde is one of the main components of rose oil and occurs in small quantities in many other essential oils. One component of cinnamon oil (see Table 8.32, later), fruit brandies and other materials is the *trans*-isomer of cinnamyl alcohol, (*E*)-cinnamyl alcohol (**8-28**), which is produced by the reduction of cinnamic acid via cinnamic acid aldehyde (cinnamaldehyde). In the form of various esters, cinnamyl alcohol is found in the leaves and bark of evergreen aromatic trees and shrubs of the genus *Cinnamomum* (Lauraceae), growing in tropical and subtropical regions of America, Asia and Australia, and in Peru balsam, secretion of trees of the *Myroxylon balsamum* (Fabaceae)



8-28, (*E*)-cinnamyl alcohol

8-26, *neo*-clerodane diterpenoids

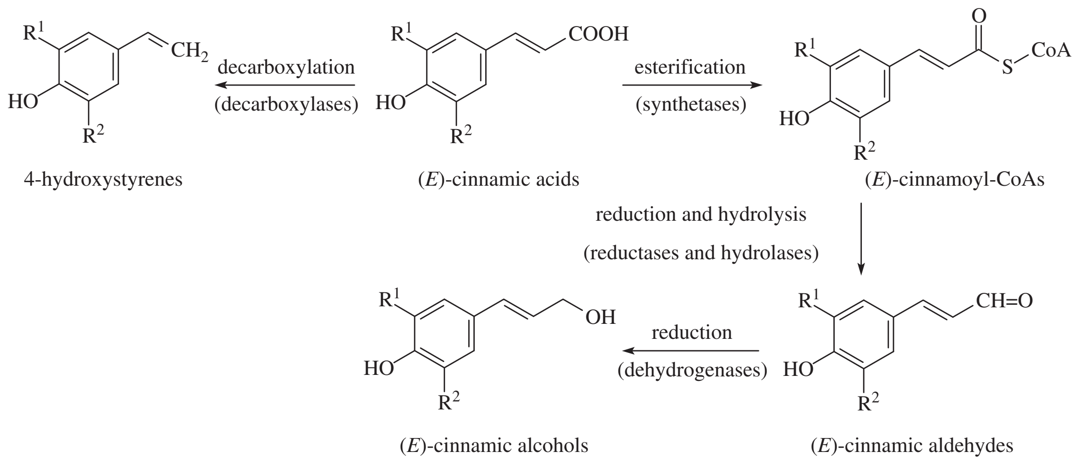

Figure 8.10 Biosynthesis of cinnamyl alcohol from cinnamic acid.

native to Central and South America, which is used in perfumery. A number of related substituted alcohols derived from substituted cinnamic acids, such as 4-coumaryl, caffeoyl, coniferyl (feruloyl) and 5-hydroxyconiferyl (sinapoyl or sinapyl) alcohol, and the corresponding aldehydes, are building units of lignin (Figure 8.10).

The most common oxygen-containing heterocyclic alcohol is furfuryl alcohol, which is a degradation product of sugars. Furfuryl alcohol results primarily from furan-2-carbaldehyde by reduction or a Cannizzaro reaction. A large number of other alcohols derived from furan, pyran and other heterocyclic compounds are products of the Maillard reaction.

8.2.2.1.3 Glycols and polyols

Glycols and polyols are non-volatile compounds that are formed in foods as secondary products of fermentation processes and of the Maillard reaction, or may be used as food additives. Frequently occurring polyols present in foods are sugar alcohols, which act as taste-active substances.

The lowest member of the homologous series of glycols is ethylene glycol. It may be released to the environment as a contaminant, with the major source being the disposal of used antifreeze and deicing solutions. It is also used in hydraulic brake fluids, inks in stamp pads and ball point pens. Another two-carbon compound is the oxidation product of ethylene glycol glycolaldehyde that is produced as a degradation product of sugars in the Maillard reaction.

The three-carbon compound methylglyoxal is the byproduct of fermentation processes and of the Maillard reaction. Products of its reduction, namely acetol (hydroxyacetone), (*R*)-propane-1,2-diol (D-propane-1,2-diol) and (*R*)-lactaldehyde (D-lactic acid aldehyde or D-lactaldehyde) are relatively common compounds present in small amounts in foods (Figure 8.11). Under anaerobic conditions, some microorganisms (such as *Bacillus amaracrylus*, *Citrobacter freundii* or *Klebsiella pneumoniae*) can ferment glycerol as the sole substrate and transform it into 1,3-dihydroxyacetone (which is then involved in metabolic pathways) or 3-hydroxypropionaldehyde (by a coenzyme B_{12}-dependent glycerol dehydratase), which was first discovered in wine spoiled by *B. amaracrylus*. It is further reduced to propane-1,3-diol. 3-Hydroxypropionaldehyde dimer (see Section 4.7.1.2.3) was patented under the name reuterin and is thought to be responsible for the probiotic effects of lactic acid bacteria *Lactobacillus reuteri*. Accordingly, the food industry has begun industrial applications with *L. reuteri* to enhance the quality and value of milk products. Bacteria *L. brevis* can produce propane-1,3-diol from glycerol as a product of sugar and lactic acid co-fermentation.

Commercial propane-1,2-diol (propylene glycol) is a racemic mixture of both stereoisomers. It is used to absorb excess water, if used as a humectant, and to maintain moisture in some medicines, cosmetics and foods, and as a solvent for food colourings and stabilisers of carbonyl compounds in food flavours. It is also used in antifreeze and de-icing solutions and as a solvent in the paint and plastic industries.

The most important diols occurring in alcoholic beverages and fermented dairy products are butane-2,3-diol and pentane-2,3-diol that are not, however, odour-active substances. These diols are produced as byproducts due to the activity of certain microorganisms, along with the corresponding acyloins (acetoin and 3-hydroxypentane-2-one) and sensory active α-diketones (biacetyl and pentane-2,3-dione).

In fermented dairy products, such as yoghurt and butter, all these four-carbon compounds are produced from pyruvic acid, which is

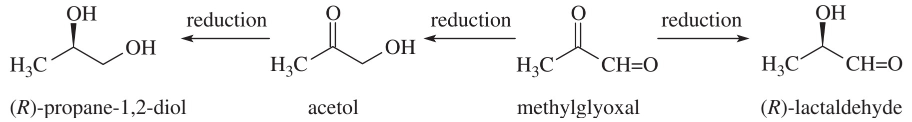

Figure 8.11 Formation of acetol, lactaldehyde and propane-1,2-diol.

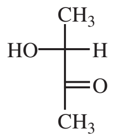
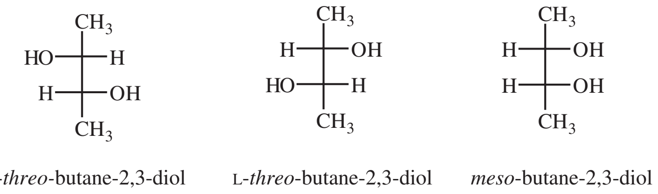
formed from citric acid. In the so-called malolactic fermentation of wine, pyruvic acid arises mainly by decarboxylation of (*S*)-malic (L-malic) acid. The conversion of pyruvic acid into lactic acid (catalysed by L-lactate dehydrogenase and D-lactate dehydrogenase) requires NADH (nicotinamide adenine dinucleotide, see Section 5.8.2). If NADH is not available, some lactic acid bacteria (such as *Streptococcus*, *Leuconostoc*, *Lactobacillus*, *Pediococcus* and *Oenococcus*; in fermented dairy products lactic acid bacteria *Streptococcus diacetylactis* are important and in wines, bacteria *Oenococcus oeni*) transform most of the pyruvic acid and acetaldehyde, which is generated by its decarboxylation, to an unstable intermediate (*S*)-2-hydroxy-2-methyl-3-oxobutanoic acid, also known as (*S*)-2-acetolactic acid (Figure 8.12). Decarboxylation and oxidation of 2-acetolactic yields provides butane-2,3-dione (biacetyl), while decarboxylation yields (*R*)-3-hydroxybutan-2-one (acetoin, **8-29**), and reduction of acetoin gives (2*R*,3*R*)-butane-2,3-diol, also known as (−)-D-*threo*-butane-2,3-diol (**8-30**). In small quantities, it is accompanied by (2*S*,3*S*)-butane-2,3-diol, also known as (+)-L-*threo*-butane-2,3-diol, and *meso*-butane-2,3-diol (**8-30**). The amount of the *meso* isomer is 20–38% of the total amount of butane-2,3-diol. Not all lactic acid bacteria produce all of these compounds, and in some cases the reaction stops earlier and some intermediates accumulate. Acetic acid is also a fermentation product.



8-29, acetoin



8-30, butane-2,3-diol isomers

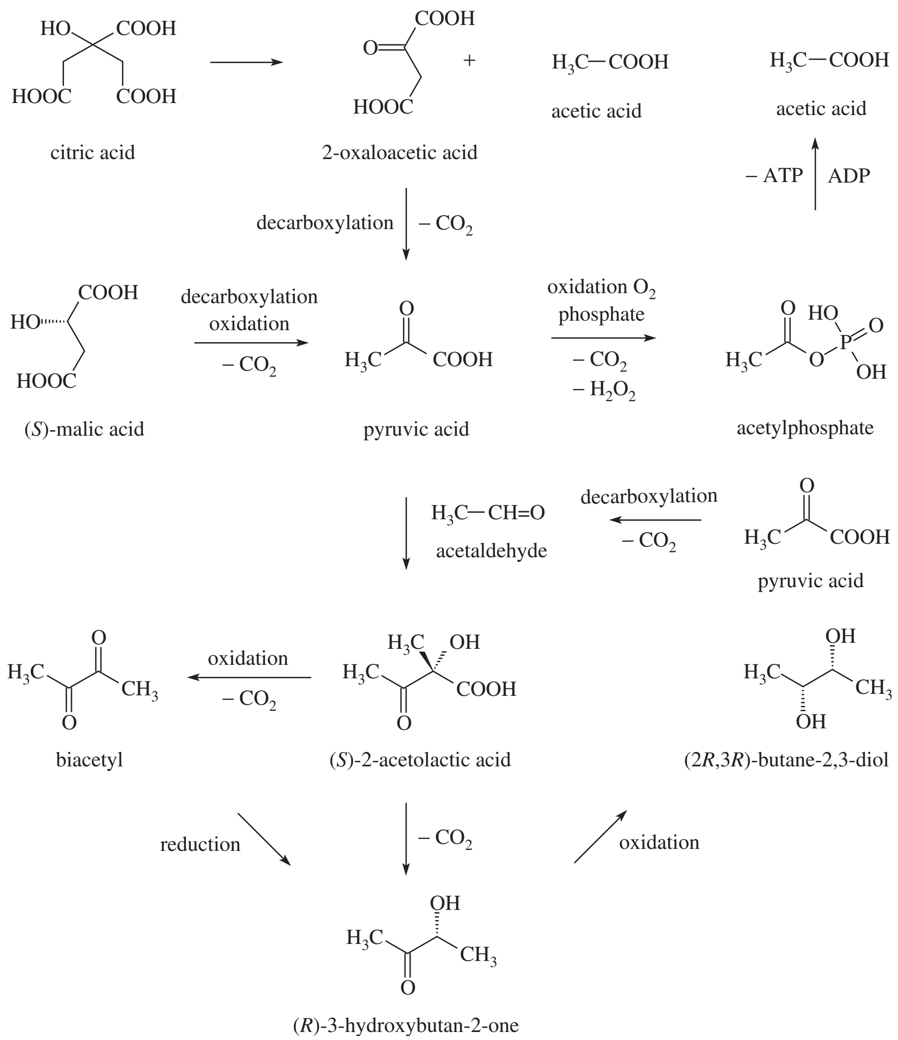


Figure 8.12 Formation of butane-2,3-diol, acetoin and biacetyl.

Five-carbon compounds are formed from (*S*)-aceto-2-hydroxybutyric acid, also known as (*S*)-2-ethyl-2-hydroxy-3-oxobutanoic acid, which is the intermediate of isoleucine biosynthesis from threonine. This acid is formed in the reaction of 2-oxobutanoic acid with acetaldehyde and its decarboxylation provides (*R*)-3-hydroxypentane-2-one, which is oxidised to pentane-2,3-dione and reduced to (2*R*,3*R*)-pentane-2,3-diol (Figure 8.13).

Glycerol (propane-1,2,3-triol) mainly occurs in foods in the form of triacylglycerols, and many other lipids (glycerolipids). Glycerol is also produced as a byproduct of alcoholic fermentation (also in alkaline media together with acetic acid salts) by reduction of the intermediate 1,3-dihydroxyacetone phosphate via glycerol 3-phosphate.

Glycerol is often found in beer, wine and other alcoholic beverages. The amount of glycerol depends mainly on the temperature during fermentation, yeast strain and, in wine, on the presence of sulfites. Glycerol concentrations in Pilsner-type beers are 1.5–2.9 g/l (in top-fermented beers). In wine, levels between 1 and 15 g/l are frequently encountered, with average values of approximately 7 g/l. Higher amounts of glycerol result from higher temperatures, so its content in red wines is usually higher (by about 20–30%) than the content in white wines. In the presence of higher amounts of sulfites, yeast *Saccharomyces cerevisiae* produces virtually no alcohol, because acetaldehyde is blocked in the form of the α-hydroxysulfonic acid, and cannot be reduced to ethanol. However, 1,3-dihydroxyacetone phosphate is still reduced to glycerol 3-phosphate, which is hydrolysed to glycerol. A higher glycerol content is also found in wines produced from grapes infected with the *Botrytis cinerea* fungus. Glycerol affects the organoleptic properties of beer and wine. Higher levels are thought to contribute to the viscosity, sweetness and smoothness of beverages.

8.2.2.2 Properties and reactions

Low molecular weight alcohols and glycols are toxic. Methanol and ethanol are both biotransformed by alcohol dehydrogenase; however, ethanol has the greater affinity for the enzyme. The toxicity resulting from higher doses of methanol is very well documented in both humans and animals and is attributed to its toxic metabolite formic acid, which is known to be toxic to the optic nerve. Formic acid requires folic acid as a cofactor for its elimination. Animal studies have shown that when folate levels are low, the elimination of formic acid is slower. Therefore, folate deficient chronic drinkers may be at higher risk of organ damage, blindness and even death. The lethal oral dose of methanol is 340 mg/kg body weight. Levels of methanol in fruit brandies are usually around 4 g/l, but can be much higher (e.g. 12 g/l in plum, apple, pear, raspberry, blackberry brandies and 2 g/l in wine brandies). The current EU general limit for naturally occurring methanol is 10 g of methanol per litre of ethanol (which equates to 0.4% v/v of methanol in a 40% alcohol beverage) – this provides a safety margin.

Ethanol acts on the central nervous system, causing euphoria at the beginning, but severe poisoning can lead to death. Ethanol is an addictive poison that causes alcoholism (ethylism). Ethylene glycol is a sweet toxic compound that can damage the kidneys, nervous system, heart and lungs.

As in water, hydrogen bonds also play the major role in the molecular attractive forces in alcohols (especially in lower alcohols

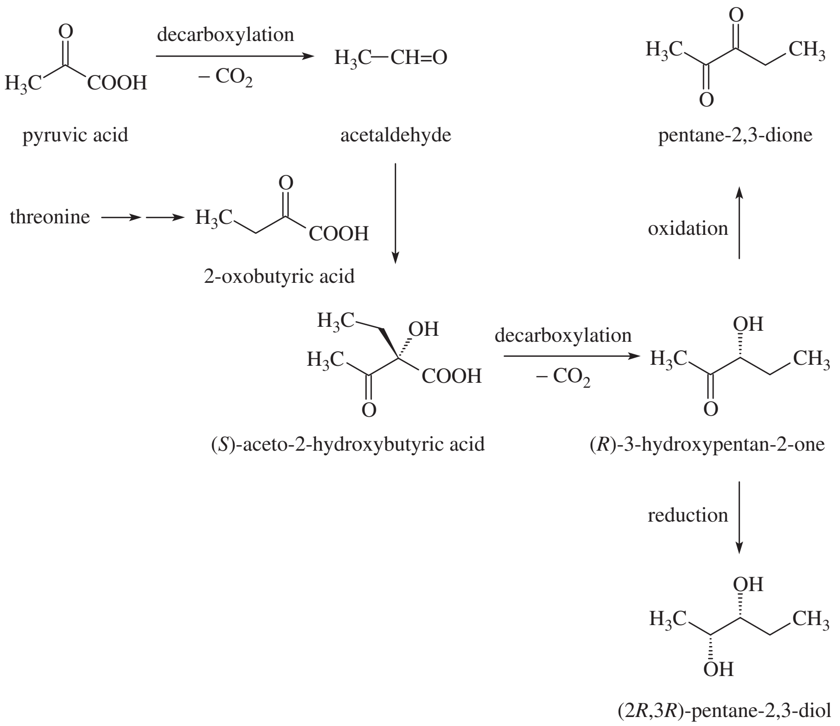

Figure 8.13 Formation of pentane-2,3-diol, 3-hydroxypentan-2-one and pentan-2,3-dione.

and polyols). This is related to the relatively good solubility of alcohols and glycols in water, and to their relatively high boiling points. The large number of hydroxyl groups allows polyols to create complex molecular associates through hydrogen bonding in solutions.

The most important reactions taking place on the hydroxy groups of alcohols are O–H bond cleavage and C–O bond cleavage. With the O–H bond cleavage, reactions with strong acids proceed, as do oxidations of primary alcohols to aldehydes, secondary alcohols to ketones and reactions with organic acids (formation of esters). In foods the last three reactions are particularly important, and are usually enzymatically catalysed. Other important reactions are dehydration and the opposite reaction, hydration, which yield unsaturated hydrocarbons from alcohols and isomeric alcohols from unsaturated hydrocarbons, respectively. These reactions are particularly important in terpenic alcohols. In oleochemistry, oxidation and esterification reactions are used for the production of various lipid derivatives.

8.2.3 Ethers

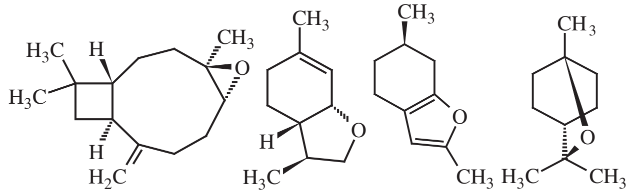
Symmetric and asymmetric aliphatic, alicyclic and aromatic ethers and ethers with the oxygen atom bound in the ring can be found in foods. Volatile dialkyl ethers are virtually absent from foods, but some are synthesised and used as flavourings, especially for cosmetic purposes. Odour- and taste-active ethers are mainly terpenoid ethers, derived from monoterpenes and sesquiterpenes, and aromatic ethers.

8.2.3.1 Classification structure, terminology and occurrence

8.2.3.1.1 Terpenoid ethers

Ethers, whose oxygen atom is bound to vicinal carbons or is part of a larger alicyclic ring, include 1,2-epoxides (oxiranes), 1,4-epoxides (furans) and 1,5-epoxides (pyrans). These and other terpenic epoxides are the primary components responsible for the odour of many foods. Terpenoid ethers also form as secondary products of the oxidation and dehydration of carotenoid pigments, steroids, fatty acids, polycyclic aromatic hydrocarbons and many other compounds.

An example of terpenic 1,2-epoxides is β-caryophyllene oxide, also known as (−)-epoxycaryophyllene (**8-31**), which occurs in many essential oils. An example of terpenic 1,4-epoxides is the so-called (+)-dill ether, (*3R*,4*S*,8*S*)-3,9-epoxy-*p*-menth-l-ene (**8-31**), which is a typical component of the essential oil of caraway (30%) and dill. An example of unsaturated 1,4-epoxides is (+)-menthofuran (**8-31**), the metabolite of ketone (+)-pulegone. Both compounds are components of peppermint oil (see Table 8.32, later) and are hepatotoxic. Monoterpenoid compound (+)-1,8-cineole (also known as limonene oxide, eucalyptol or 1,8-epoxy-*p*-menthane; **8-31**) is an example of more complex structures. It is present in essential oils of many types of spices, and higher quantities are found in the essential oil of trees of the genus *Eucalyptus* (Myrtaceae). Trivial and systematic names of selected ethers are given in Table 8.8.



epoxycaryophyllene dill ether menthofuran 1,8-cineole

8-31, terpenoid epoxides

Numerous other ethers containing pyran or furan rings are formed by the dehydration of aliphatic diols (e.g. linalool oxides, rose oxide or nerol oxide) and are components of many essential oils. For example, the furanoid (2*R*,5*R*)-(*E*)- and (2*R*,5*S*)-

Table 8.8 Trivial and systematic names of some terpenoid ethers.

Trivial name	Systematic name (IUPAC)
(−)-Epoxycaryophyllene	(1*R*,4*R*,6*R*,10*S*)-9-Methylene-4,12,12-trimethyl-5-oxatricyclo[8.2.0.0^{4,6}]dodecane
(+)-Dill ether	(3*S*,3a*S*,7a*R*)-3,6-Dimethyl-2,3,3a,4,5,7,7a-hexahydro-1-benzofuran
(+)-Menthofuran	(*R*)-3,6-Dimethyl-4,5,6,7-tetrahydro-1-benzofuran

(−)-Nerol oxide	(*S*)-3,6-Dihydro-4-methyl-2-(2-methylprop-1-enyl)-2*H*-pyrane
(−)-(*Z*)-Rose oxide	(2*S*,4*R*)-4-Methyl-2-(2-methylprop-1-enyl)oxane
(2*R*,5*S*)-(*Z*)-Linalool oxide (furanoid)	(2*R*,5*S*)-2-methyl-5-prop-1-en-2-yl-2-vinyltetrahydrofuran
(2*R*,5*R*)-(*E*)-Linalool oxide (furanoid)	(2*R*,5*R*)-2-methyl-5-prop-1-en-2-yl-2-vinyltetrahydrofuran
(3*R*,6*R*)-(*Z*)-Linalool oxide (pyranoid)	(3*R*,6*R*)-2,2,6-Trimethyl-6-vinyltetrahydro-2*H*-pyran-3-ol
(3*S*,6*S*)-(*Z*)-Linalool oxide (pyranoid)	(3*S*,6*S*)-2,2,6-Trimethyl-6-vinyltetrahydro-2*H*-pyran-3-ol

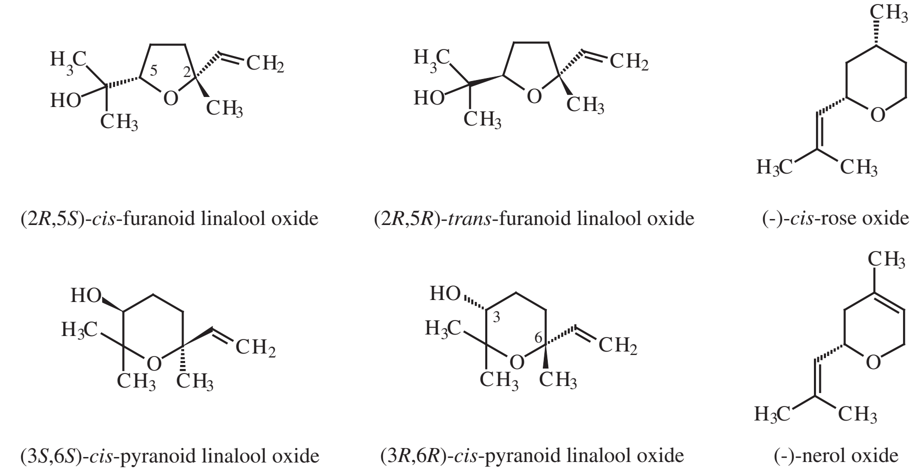
(*Z*)- and pyranoid (3*R*,6*R*)-(*Z*)- and (3*S*,6*S*)-(*Z*)-linalool oxides (**8-32**) are odorants of jasmine tea, aromatic wines, elderberry bush flowers and linden honey. In grapes, (−)-(*Z*)-rose oxide from (−)-citronellol is analogously produced. Rose oxide is also a component of rose and geranium essential oils (**8-32**). Nerol oxide in rose oil is a racemate.

8.2.3.1.2 Aromatic ethers

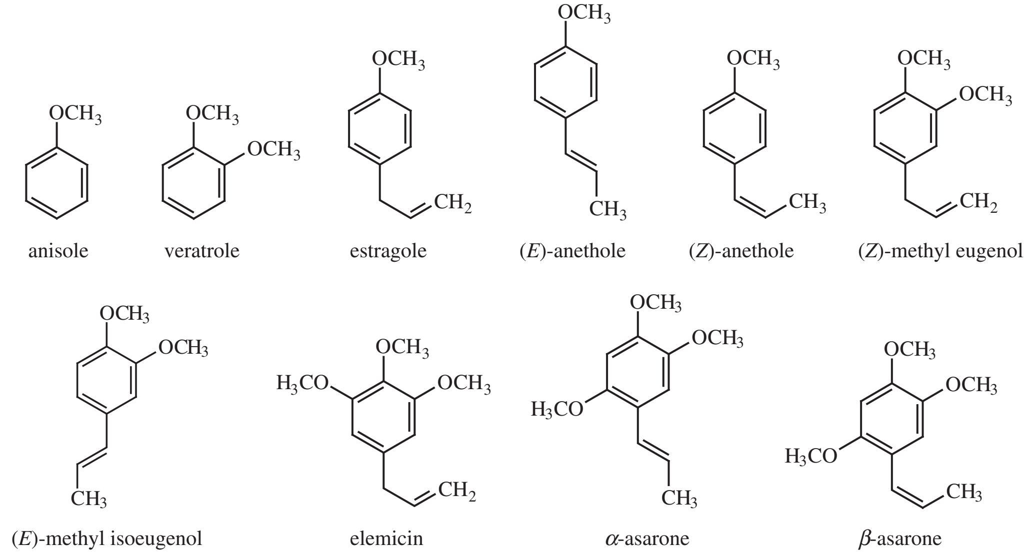
Foods may contain a number of alkyl aryl ethers that are components of essential oils of different spices as well as secondary substances. These ethers are most often derived from anisole (methoxybenzene, **8-33**) or veratrole (1,2-dimethoxybenzene, **8-33**), which are substituted by a prop-1-en-yl or 1-prop-2-en-1-yl (allyl) group at the C-4 position of the benzene ring. An important ether is estragole (also known as 4-allylanisole or methyl chavicol, **8-33**), which is the main component (over 80%) of basil essential oil (see Table 8.32, later) and tarragon (dragon's wort) essential oil (more than 60%). Estragole is a genotoxic carcinogen in experimental animals after chronic exposure, and therefore appears in the list of substances of Regulation (EC) No. 1334/2008, which shoud not be added to foods as flavourings. Its natural content in foods is restricted to 50 mg/kg in dairy products, processed fruits, vegetables including mushrooms (roots, tubers and legumes), nuts and seeds and fish products and to 10 mg/kg in non-alcoholic beverages.

Isomers of anethole (isoestragole, **8-33**) with a typical anise aroma are the main components of anise (more than 95%), fennel (more than 80%) and star anise (more than 95%) essential oils. In natural essential oils the (*E*)-isomer of anethole dominates, which is used as a flavour and fragrance agent as it has a liquorice-type odour and an anise-type taste. The (*Z*)-isomer of anethole has an anise-type odour. It was associated with liver cancer in rats, but is now regarded as safe.

Components of clove oil (see Table 8.32, later) and many other oils are β-caryophyllene (4–21%), eugenol (49–87%), eugenyl acetate (0.5–21%), methyleugenol and elemicin (**8-33**). Another



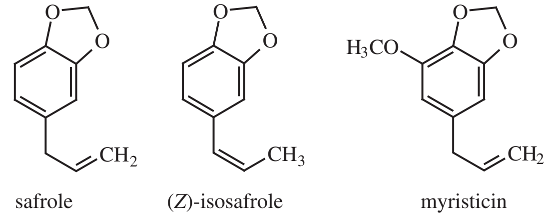
8-32, monoterpenoid oxides



8-33, aromatic ethers

compound derived from veratrole is methylisoeugenol, which can occur as both (*E*)- and (*Z*)-isomers (**8-33**). (*E*)-Methylisoeugenol occurs in high concentrations in the seed oil and oil obtained from aerial parts of carrot (*Daucus carota*), which is reported to be an antimicrobial against the human enteropathogen *Campylobacter jejuni*. Methylisoeugenol is found in lower amounts in many other essential oils (such as citronella, calamus, nutmeg and laurel leaf oils). Elemicin is also a component of carrot essential oil and banana aroma. A component of the essential oil obtained from the root of calamus, also known as sweet flag (*Acorus calamus*, Acoraceae), and occurring in some other plants (such as European wild ginger, *Asarum europaeum*, Aristolochiaceae), is asarone. It is present as a mixture of two isomers, of which α-asarone (**8-33**) is the (*E*)-isomer and β-asarone (**8-33**), also known as *cis*-isoasarone, is the (*Z*)-isomer. Calamus root is used as a medicinal plant for wound healing, as an antipyretic drug, against dyspepsia (indigestion, upset stomach), as well as a bittering agent for alcoholic beverages (including vermouth and beer) and in cosmetics (such as flavourings for toothpastes). β-Asarone has antifungal activity and completely inhibits mycelial growth of some plant pathogenic fungi, *Cladosporium cucumerinum*, *Colletotrichum orbiculare*, *Magnaporthe grisea* and *Pythium ultimum*, but also has toxic effects in mammals (it acts as a chemosterilant) and therefore appears in the list of substances of Regulation (EC) No. 1334/2008, which should not be added to foods as flavourings. Its natural content in alcoholic beverages is limited at a maximum level of 1 mg/kg and tetraploid forms of the plant should not be used for the production of flavourings and food ingredients with flavouring properties. A related North American species *A. americanus*, today described as a variety of calamus (*A. c.* var. *americanus*), does not contain β-asarone at all. β-Asarone and related 2,4,5-trimethoxybenzaldehyde have also been found in carrot seeds.

Methyleugenol (**8-33**), a component of several essential oils of, for example, fennel, citronella, basil, bay and tea tree (*Melaleuca* spp.), as well as eugenol and asarons are related to compounds with an attached 1,3-dioxol ring (methylenedioxy group). Most substances are simple allyl or prop-1-en-1-yl benzenes, substituted by methoxyl groups. Important compounds are safrole (1-allyl-3,4-methylenedioxybenzene, **8-34**), isosafrole, 1-(prop-1-en-1-yl)-methylene-3,4-dioxybenzene (**8-34**) and myristicin, also known as 5-methoxysafrole (1-allyl-5-methoxy-3,4-methylenedioxybenzene, **8-34**). Myristicin is a characteristic component of essential oils from the seeds of some root vegetables (carrots, parsley and celery) and herbs, in particular, of essential oils derived from nutmeg and mace (see Table 8.32, later). Safrole is the main component



8-34, aromatic ethers with a methylenedioxyphenyl moiety

(representing more than 80%) of sassafras oil (shikimol) derived from the root bark or the fruit of the sassafras tree (*Sassafras albidum*, Lauraceae) growing in North America, which was used in the United States to flavour beer and soft drinks until 1978. Locally, sassafras herbal tea is still in use in the treatment of rheumatism and skin diseases. Safrole is also a component of essential oils of nutmeg and mace (the content is about 0.1%) and of anise, cinnamon and some other essential oils. Isosafrole is also a common component of many essential oils (such as sassafras, laurel and clove essential oils).

Methyleugenol and safrole exhibit toxic effects of weak carcinogens in experimental animals. Myristicin is a psychomimetic compound tending to induce narcotic effects, hallucinations and other symptoms of a psychosis. Methyleugenol and safrole are in the list of substances of Regulation (EC) No. 1334/2008, which should not be added to foods as flavourings. The natural content of methyleugenol in foods (the maximum level of safrole is in parenthesis) is restricted to 60 (25) mg/kg in soups and sauces, to 20 mg/kg in dairy products and ready-to-eat savouries, to 15 (15) mg/kg in meat preparations and meat products, including poultry and game, to 10 (15) mg/kg in fish preparations and fish products and to 1 (1) mg/kg in non-alcoholic beverages. Sassafras leaves must be safrole-free to be used as food additives, and sassafras oil is not used at all.

8.2.3.1.3 Other ethers

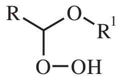
Simple oxiranes (e.g. oxirane, known as ethylene oxide, and methyloxirane, known as propylene-1,2-oxide) are used as food additives (such as preservatives). Some ethers can also be regarded as phenols, aromatic aldehydes (such as vanillin) or acetals. Certain acetals derived from aliphatic aldehydes are used as fragrances.

Particular non-volatile ethers are classified as lipids (e.g. plasmalogens, esters of 1-alkoxypropan-2,3-diols, such as chimyl alcohol). Some ethers also occur in small amounts as substances accompanying lipids. Examples of these compounds are dialicyclic ethers derived from sterols that occur in refined vegetable oils. Of great importance in oleochemistry are non-volatile ethers of glycerol and other polyols (dimers and higher oligomers) that are used, for example, as emulsifiers. The so-called vinyl ethers are formed as secondary oxidation products of essential fatty acids, representatives of which are pentylfuran and two isomeric 2-(pent-2-en-1-yl)furans that cause an off-flavour of some refined vegetable oils, known as reversion.

Dehydration of carbohydrates in acidic solution yields derivatives of furan-2-carbaldehyde. An example of a heterocyclic ether is the ether derived from 5-hydroxymethylfuran-2-carbaldehyde that accompanies the parent aldehyde in sugar hydrolysates. Furfuryl ethyl ether is an important flavour compound indicative of beer storage and aging conditions. It is most likely formed by protonation of furfuryl alcohol or furfuryl acetate followed by substitution of the leaving group by the nucleophilic ethanol. Another example of a heterocyclic ether is the ether formed by dehydration of 3-hydroxymethylindole in cruciferous vegetables, where 3-hydroxymethylindole arises by degradation of glucosinolate glucobrassicin.

8.2.3.2 Properties and reactions

Ethers are relatively stable in acidic and alkaline media, but they are easily oxidised to the corresponding hydroperoxides (**8-35**) that are often transformed into thermolabile polymeric peroxides.



8-35, ether hydroperoxide (α-hydroperoxyoxaalkane)

8.2.4 Carbonyl compounds

8.2.4.1 Classification, structure, terminology and occurrence

The carbonyl compounds molecules contain either an aldehyde group –CH=O or a keto group (oxo group) –C(=O)–, therefore carbonyl compounds can be divided into:

- aldehydes
- ketones.

Volatile aldehydes and ketones are the most important odour- and taste-active substances. They occur in foods as primary substances, as components of various essential oils and also result from enzymatic and chemical reactions from various precursors as secondary substances. They are often desirable flavour-active components of foods, but in some cases may also carry undesirable odour and taste. Then they serve as indicators of unwanted changes in sensory or nutritional value of foods (such as autoxidation of lipids).

Carbonyl compounds also include a range of non-volatile polar compounds, such as reducing sugars or some products of their transformation (degradation), which are often taste-active substances, usually with a sweet taste. A special group of carbonyl compounds are oxocarboxylic acids and, in a broader sense, all carboxylic acids, which often carry a sour taste. A special group of unsaturated diketones derived from aromatic systems are quinones, which are often significant natural dyes in foods.

8.2.4.1.1 Aldehydes

Aliphatic saturated and unsaturated aldehydes

Almost all saturated aliphatic aldehydes, starting with formaldehyde (methanal) and ending with dodecanal, are important odour-active compounds. Particularly important odour-active compounds are monoterpenic aldehydes.

Typical aminocarboxylic acids, unsaturated fatty acids bound in lipids, sugars and some other food components are precursors of many important sensory-active carbonyl compounds. Amino acids produce aldehydes mainly as secondary products of alcoholic or lactic acid fermentations and during thermal processes by Strecker degradation. Formaldehyde (methanal) is formed from glycine, acetaldehyde (ethanal) from alanine; propanal and butanal arise from threonine (Figure 8.3), 2-methylpropanal from valine, 3-methylbutanal from leucine, 2-methylbutanal from isoleucine (**8-36**), 2-mercaptoethanal from cysteine and methional from methionine. Of the straight chain unsaturated aldehydes formed from lipids, particularly important are the compounds propenal (acrolein), some alk-2-enals, alk-3-enals, alka-2,4-dienals and certain other aldehydes with two, three or four double bonds. Some volatile carbonyl compounds are formed by degradation of sugars, for example formaldehyde, acetaldehyde, biacetyl and derivatives of furan-2-carbaldehyde.

R—CH=O

8-36, saturated aliphatic aldehydes
methanal (formaldehyde), R = H
ethanal (acetaldehyde), R = CH_3
propanal (propionaldehyde), R = CH_2CH_3
butanal (butyraldehyde), R = $CH_2CH_2CH_3$
2-methylpropanal (isobutyraldehyde), R = $CH(CH_3)_2$
3-methylbutanal (isovaleraldehyde), R = $CH_2CH(CH_3)_2$
2-methylbutanal, R = $CH(CH_3)CH_2CH_3$

Formaldehyde is present in various foods (such as milk, cheeses and alcoholic beverages), but only in small amounts, as it is highly reactive and enters into reaction with many food components. It is mainly in spirits that acetaldehyde is formed in large quantities, as a degradation product of sugars in the presence of microorganisms (Figure 8.2). Small amounts of acetaldehyde can likewise be found in fermented dairy products, such as yoghurt. The presence of propenal (acrolein), which results from overheated fats (triacylglycerols) or directly by dehydration of free glycerol (Figure 8.14) is a negative outcome. Small amounts of acrolein are also present in alcoholic beverages, such as beer, wine and spirits. Acrolein is an irritating aldehyde with a disagreeable odour and toxic effects. According to the International Agency for Research on Cancer (IARC), acrolein is not classifiable with respect to its carcinogenicity towards humans.

The higher homologue of acrolein is (*E*)-but-2-enal (crotonic aldehyde), which is formed by aldolisation of acetaldehyde and dehydration of the product of aldolisation, facilitated by the presence of conjugated double bonds.

A component of tomato flavour, and possibly that of other vegetables too, is the sulfur-containing aldehyde 2-methylthioethanal (**8-37**), which arises by Strecker degradation of *S*-methylcysteine

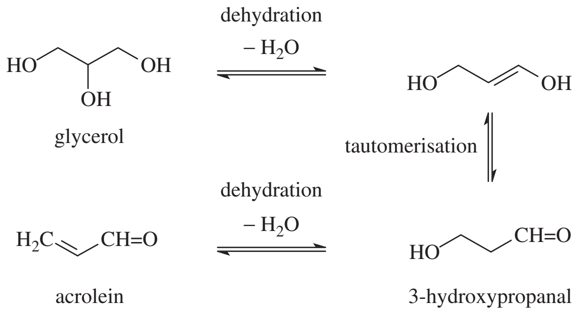


Figure 8.14 Formation of acrolein by thermal decomposition of glycerol.

8-37, methylthioalkanals
2-methylthioethanal, $n = 0$
3-methylthiopropanal (methional), $n = 1$

and its sulfoxide. The higher homologue of 2-methylthioethanal is methional (3-methylthiopropanal, **8-37**), which is formed by Strecker degradation of methionine. Methional is an important aroma component of cooked potatoes and of many other foods. However, the presence of methional in some foods has a negative effect. For example, methional (formed by riboflavin induced photooxidation) and its degradation product dimethyl disulfide give a burnt and oxidised odour to milk, as well as to wine and beer. Methional is also the key compound responsible for the defect of alcohol-free beers described as worty flavour. The other off-flavour in milk is a cardboard-like or metallic flavour, which develops in milk with a prolonged exposure to light. Compounds responsible for this off-flavour are secondary lipid oxidation products, such as hexanal, pentanal and some other substances formed by riboflavin-catalysed photooxidation of fatty acids.

Enzymatically active materials (fruits, vegetables and some fats) contain a large number of other aldehydes that are produced from essential fatty acids, mainly linoleic and linolenic acids (Table 8.9) by oxidation reactions catalysed by lipoxygenases. In some vegetables (e.g. in cucumbers), aldehydes also result from α-oxidation of fatty acids (Figure 8.15). The primary oxidation products of essential fatty acids are hydroperoxides, which break down to aldehydes and other products under the action of lyases and can be

Table 8.9 Organoleptic properties of aldehydes arising from amino acids and fatty acids.

Aldehyde	Odour	Precursor
Methanal (formaldehyde)	Pungent, sharp	Glycine
Ethanal (acetaldehyde)	Pungent, fruity, fresh	Alanine
Propanal	Pungent	Threonine, linolenic acid
2-Methylpropanal	Pungent, green	Valine
3-Methylbutanal	Green, bitter almond	Leucine
2-Methylbutanal	Green, bitter almond	Isoleucine
Methional	Boiled potatoes	Methionine
2-Phenylethanal (phenylacetaldehyde)	Floral, honey	Phenylalanine
Pentanal	Pungent	Linoleic acid
Hexanal	Tallowy, green	Linoleic acid
Heptanal	Oily, greasy	Oleic acid
Nonanal	Tallowy	Linolenic acid
(*E*)-Pent-2-enal	Oily, greasy, green	Linolenic acid
(*Z*)-Hex-3-enal	Green	Linolenic acid
(*E*)-Hex-2-enal	Oily, greasy, green	Linolenic acid

(2*E*,4*Z*,7*Z*)-Deca-2,4,7-trienal	Fish oil	Linolenic acid

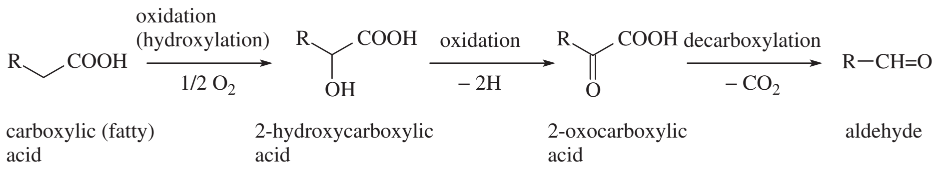

Figure 8.15 Formation of aldehydes by α-oxidation of fatty acids.

isomerised by isomerases (Figure 8.5). The same and some other hydroperoxides of linoleic and linolenic acids, their (*E*)-isomers and even oleic acid hydroperoxides (or peroxides of other unsaturated acids occurring as minor fatty acids in lipids or resulting from partial hydrogenation of unsaturated fats) are also formed by autoxidation and decompose to aldehydes and other products spontaneously (Figure 8.5 and Figure 8.6). Autoxidation of saturated fatty acids (such as palmitic and stearic acids) proceeds at higher temperatures. An overview of the main aldehydes produced from oleic, linoleic and linolenic acids is given in Table 8.10. An important indicator of the rancidity of fats is malondialdehyde. The amount of autoxidation products of unsaturated fatty acids commonly ranges in units to thousands of mg/kg. The main products of oleic acid autoxidation are octanal and nonanal, while hexanal is produced from linoleic acid (**8-38**, Figure 8.5) and (*Z*)-hex-3-enal and (2*E*,4*Z*)-hepta-2,4-dienal (**8-39**) from linolenic acid (Figure 8.6).

nonanal, $n = 7$

The organoleptic properties of some aldehydes produced by oxidation of fatty acids and organoleptic properties of the so-called Strecker aldehydes are listed in Table 8.9 together with their precursors. Aldehydes produced from fatty acids are often carriers of a rancid odour and taste. They are formed even from minor unsaturated fatty acids. In beef and mutton tallow and butter, for example, small amounts of (11*Z*,15*Z*)-octadeca-11,15-dienoic acid occur, autoxidation of which yields (*Z*)-hept-4-enal (**8-39**),

8-39, unsaturated aldehydes arising from polyenoic fatty acids

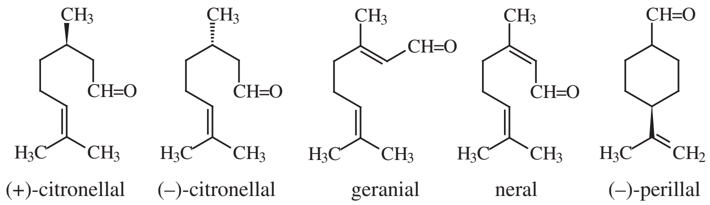
an important carrier of the rancid smell of these fats as the odour thresholds concentrations in fats are around 10 μg/kg. Important carriers of the so-called hydrogenation flavour of hydrogenated soybean oils are (*E*)-non-6-enal (**8-39**), which arises from (9*Z*,15*E*)-octadeca-9,15-dienoic acid that does not occur in natural fats, but is a product of the partial reduction of linolenic acid. An important contribution to the hydrogenation flavour of soybean oil is from (2*E*,6*E*)-octa-2,6-dienal, formed from (12*E*,16*E*)-11-hydroperoxy-12,16-octadecadienoic acid, higher alcohols and lactones.

Some aldehydes that appear from oxidised fats are desirable flavour-active compounds in low concentrations. For example, the mixture of arachidonic acid oxidation products, (*Z*)-non-3-enal, (*Z*)-dec-4-enal, (2*Z*,5*Z*)-undeca-2,5-dienal and (2*E*,4*Z*,7*Z*)-2,4,7-tridecatrienal (**8-39**) resembles the aroma of cooked chicken. Both isomers of deca-2,4-dienal (**8-39**) that arise from linoleic or arachidonic acids contribute to the smell of fried foods. The compounds, responsible for the pleasant herbal, green scent of fresh vegetables and fruits are hexanal (Figure 8.5), (*E*)-hex-2-enal (known as leaf aldehyde; Figure 8.6) and (*E*)-pent-2-enal (**8-39**), along with some alcohols The fresh cucumber scent is due to (2*E*,6*Z*)-nona-2,6-dienal and its isomer (3*Z*,6*Z*)-nona-3,6-dienal (**8-39**). The key odour-active component of oatmeal is (2*E*,4*E*,6*Z*)-nona-2,4,6-trienal (**8-39**) formed by oxidation of linolenic acid. It has a sweet, cereal-like smell with a very low odour detection threshold in air (0.000 02 ng/l). Higher aliphatic aldehydes, such as 12-methyltridecanal, have an odour resembling beef. They are formed during the thermal processing of meat by degradation of plasmalogens.

Terpenic aldehydes

Monoterpenic and some sesquiterpenic aldehydes are important flavour-active compounds with practical significance. Essential oils containing these aldehydes are used extensively in perfumery. The aliphatic aldehyde derived from (+)-citronellol is (+)-citronellal (**8-40**), which represents about 32–45% of citronella oil from the leaves and stems of grasses of the genus *Cymbopogon* (such as *C. winterianus*, Poaceae) originating from Southeast Asia (known as Javanese oil). (−)-Citronellal (**8-40**) occurs in amounts of up to 80% in the essential oil found in the subtropical Australian bush *Backhousia citriodora* (myrtle tree, Myrtaceae). Racemic citronellal (*rac*-citronellal) is a component, at levels of up to 85%, of the essential oil of plants of *Corymbia citriodora* (syn. *Eucalyptus citriodora*) from the same family of plants.

The aliphatic unsaturated aldehyde citral is one of the most frequently occurring compounds. Natural citral is always a mixture of geranial (**8-40**), also known as (*E*)-citral or citral a, and neral (**8-40**), which is known as (*Z*)-citral or citral b. The precursor of geranial and neral is geraniol. Citral occurs in the already mentioned citronella oil in concentrations of 11–13%. In the oil of the *Litsea cubeba* (Lauraceae) tree, native to Southeast Asia, citral is found in concentrations up to 75%. In much smaller amounts, citral is



8-40, monoterpenic aldehydes

a component of many other essential oils, especially oils of citrus fruits, as well as of ginger and pepper oils, and also occurs in wine and other products.

The essential oil from the leaves of the African plant *Plectranthus scutellarioides* (syn. *Perilla nankinensis* or *P. frutescens*, Lamiaceae) contains as a main component (50–60%) monocyclic (−)-perrillyl aldehyde (perillal, **8-40**), whose biosynthesis starts with (−)-limonene and proceeds via (−)-perillyl alcohol as the intermediate. Animal studies suggest that perillyl alcohol may help slow the growth of pancreatic, mammary and liver tumours.

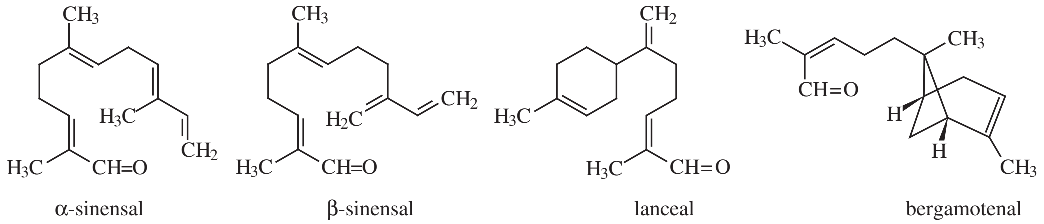
A significant acyclic sesquiterpenic aldehyde occurring in orange essential oil is α-sinensal (**8-41**), which is formed by oxidation of (3*E*,6*E*)-α-farnesene. The mandarin essential oil contains β-sinensal (**8-41**), which is produced by oxidation of (*E*)-β-farnesene (**8-7**). Some other sesquiterpenic aldehydes are minor, but still significant components of citrus oils, such as monocyclic aldehyde lanceal (**8-41**) and bicyclic aldehyde bergamotenal (**8-41**).

The alicyclic monoterpenic aldehyde safranal has a different biochemical origin, and is the main characteristic odorous component of saffron (*Crocus sativus*, Iridaceae). Safranal is classified as a degraded carotenoid (apocarotenoid) as it is produced from zeaxanthin via hydrolysis of the bitter intermediate picrocrocin. Degradation of carotenoids produces a number of other aromatic compounds (see Section 9.9.5.2). A list of the names of major terpenoid aldehydes is shown in Table 8.11.

Aromatic aldehydes

Aromatic aldehydes very often occur in essential oils and as odour-active components of different foods. Their biosynthesis is based, in principle, on transformations of phenylalanine, the key decomposition product of which is cinnamic acid (Figure 8.10).

A widespread aromatic aldehyde is benzaldehyde (**8-42**), which is biosynthesised by the reduction of benzoic acid, the precursor



8-41, sesquiterpenic aldehydes

Table 8.11 Trivial and systematic names of selected terpenoid aldehydes.

Trivial name	Systematic name (IUPAC)
(+)-Citronellal	(*R*)-3,7-Dimethyloct-6-enal
(−)-Citronellal	(*S*)-3,7-Dimethyloct-6-enal
Geranial	(*E*)-3,7-Dimethylocta-2,6-dienal
Neral	(*Z*)-3,7-Dimethylocta-2,6-dienal

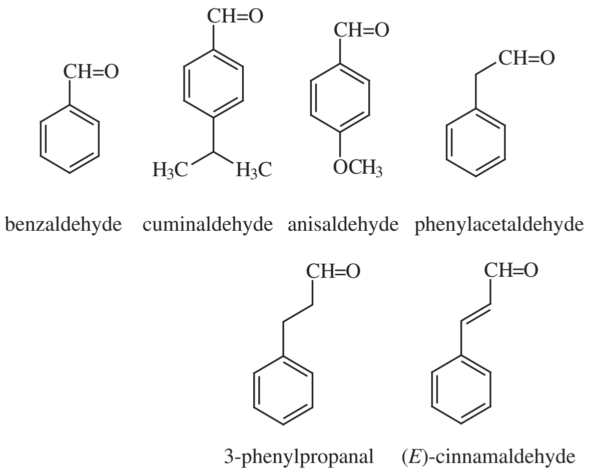
α-Sinensal	(2*E*,6*E*,9*E*)-2,6,10-Trimethyldodeca-2,6,9,11-tetraenal
β-Sinensal	(2*E*,6*E*)-2,6-Dimethyl-10-methylidenedodeca-2,6,11-trienal
Lanceal	(*Z*)-6-Methyl-2-(4-methylcyclohex-3-en-1-yl)hepta-1,5-dienal
Bergamotenal	(1*S*,3*E*,5*S*)-4-Formyl-7-methyl-7-(4-methylpent-3-enyl)bicyclo[3.1.1]hept-3-ene



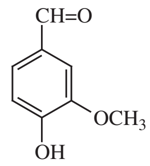
8-42, aromatic aldehydes

of which is cinnamic acid. Benzaldehyde can also be formed thermally from phenylalanine, phenylacetaldehyde and some other compounds. Benzaldehyde is present in bound form in some cyanogenic glycosides and is released by their hydrolysis (see Section 10.3.2.3.1). It is therefore a prominent component of bitter almond oil and is also present in the essential oil of cinnamon, and occurs as an important odorous component of all alcoholic beverages obtained by the fermentation of stone fruits (such as plum brandy).

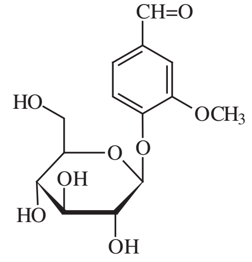
Alkyl derivatives of benzaldehyde include cuminaldehyde (4-isopropylbenzaldehyde, **8-42**), which is a component of cumin, cinnamon and basil essential oils (see Table 8.32, later). A methoxyl derivative of benzaldehyde, anisaldehyde (4-methoxybenzaldehyde, **8-42**) is a fragrance ingredient of anise, star anise, vanilla and some other essential oils. A higher homologue of benzaldehyde phenylacetaldehyde (**8-42**) is a common component of many essential oils. It has a floral aroma resembling hyacinth flowers and has therefore been used in perfumery. The cinnamon essential oil also contains its higher homologue dihydrocinnamaldehyde (3-phenylpropanal, **8-42**), which accompanies (together with cuminaldehyde) the key odorant of cinnamon, known as cinnamaldehyde (**8-42**). Cinnamon essential oil (representing about 0.5–1% by weight of cinnamon bark) contains around 90% cinnamaldehyde. The dominant isomer is the (*E*)-isomer. However, in fresh cinnamon bark, cinnamyl acetate is predominant. Cinnamaldehyde arises from this ester during fermentation by enzymatic hydrolysis and reduction of the resulting cinnamic acid by aldehyde–alcohol oxidoreductase. Without the participation of enzymes, cinnamaldehyde is produced by Strecker degradation of phenylalanine.

Other cinnamic acids also produce aldehydes, but they have no significance as odour-active substances. By analogy, coumaraldehyde is produced from 4-coumaric acid, caffeoyl aldehyde from caffeic acid, conifer aldehyde (also known as ferulyl aldehyde) from ferulic acid, 5-hydroxyconifer aldehyde from 5-hydroxyferulic acid and sinapyl aldehyde from sinapic acid. These aldehydes can be reduced to the corresponding alcohols, with which they play a role as the building units of lignin biosynthesis.

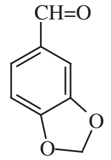
Some hydroxyaldehydes derived from benzaldehyde are also important: these can be simultaneously classified as phenols. The main characteristic component of vanilla beans (*Vanilla planifolia*, syn. V. fragrans, Orchidaceae) is vanillin (see Table 8.32, **8-43**). Vanillin is present in the green pods of orchids exclusively in the conjugated form as β-D-glucopyranoside, called glucovanillin (also known as avenin, **8-44**). The characteristic aroma of vanilla appears after fermentation (hydrolysis by β-D-glucosidase). Vanillin content in fermented pods is usually 2–2.5%. Low-quality species of vanilla contain, in addition to vanillin, the aromatic aldehyde piperonal (heliotropin, **8-45**). Vanillin can also produce many microorganisms. In biotechnological production of vanillin, different substrates are used, such as curcumin, stilbenes, eugenol and ferulic acid. Ethylvanillin (bourbonal) has an odour resembling vanillin, but slightly rougher. It does not occur in nature, but synthetic ethylvanillin is used as food flavouring, especially in the production of vanilla sugar (see Section 8.2.14.4).



8-43, vanillin



8-44, glucovanillin



8-45, piperonal

Heterocyclic aldehydes

In carbohydrate-containing foods, furan-2-carbaldehyde is often present, arising from pentoses and ascorbic acid as a dehydration product. Other common furan-derived aldehydes are 5-hydroxymethylfuran-2-carbaldehyde (from hexoses) and 5-methylfuran-2-carbaldehyde (resulting from 6-deoxyhexoses). Other heterocyclic aldehydes derived from pyrrole, thiophene, pyridine, pyrazine and other heterocyclic compounds are formed as products of the Maillard reaction.

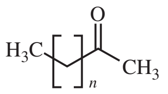
8.2.4.1.2 Ketones

As with aldehydes, various ketones can also occur as primary constituents of food raw materials and foods, or they may arise as secondary compounds in various processes. Many ketones are categorised by a characteristic odour and therefore may be either desirable or undesirable substances. An important group of ketones originating from the degradation of sugars (e.g. abhexon and sotolon) are described in the section dealing with lactones

(Section 8.2.7.1.2). A number of significant ketones arise by the degradation of carotenoids (see Section 9.9.5.2).

Aliphatic and alicyclic ketones

Foods frequently contain saturated and unsaturated aliphatic ketones with between 3 and 17 carbon atoms in the molecule. These ketones are formed by several different mechanisms. Frequently occurring aliphatic ketones are methylketones. The most common methylketone is acetone (propanone, **8-46**, $n = 0$). Acetone is present, usually in small quantities, in all biological substrates, where it arises by decarboxylation of acetoacetic (3-oxobutanoic) acid. Acetoacetic acid is formed as an intermediate during degradation of fatty acids by β-oxidation. Acetone in the skins of apples, for example, is produced from pyruvic acid via citramalic acid (Figure 8.16). The relatively large amount of acetone is generated by acetone–butanol fermentation (see Section 8.2.2.1.1). Many other saturated and unsaturated methylketones occur as odour-active components of essential oils. For example, a component of cinnamon and star anise essential oils is heptane-2-one, also known as methyl pentyl ketone (**8-46**, $n = 4$).



8-46, methylketones

Many methylketones occur in foods as secondary substances of lipid degradation during the so-called ketonic (perfume) rancidity. These methylketones have higher odour detection threshold concentrations than the corresponding aldehydes, but nevertheless play important roles as flavour-active components of some foods. They appear as desirable flavour components in cheeses with molds on the rind or throughout, such as blue cheeses (Roquefort and Gorgonzola cheeses), in the manufacture of which the mold *Penicillium roqueforti* is used. Significant methylketones (**8-46**) in blue cheeses are mainly acetone ($n = 0$), pentan-2-one ($n = 2$), heptan-2-one ($n = 4$) nonan-2-one ($n = 6$) and undecan-2-one ($n = 8$). The amount of individual compounds is between 5 and 180 mg/kg of dry matter. The last three methylketones are also used for aromatisation of cheeses.

The presence of methylketones is undesirable in some fats, such as butter, coconut and palm oil. Also undesirable are unsaturated ketones produced by oxidation of fatty acids, which are called alkyl vinyl ketones. For example, pent-1-en-3-one (**8-47**) smells of fish oil, oct-1-en-3-one (**8-47**) has a metallic taste, and (*Z*)-octa-1,5-dien-3-one (**8-47**) has an oily, greasy and metallic taste. A related ketone similarly formed by oxidation of fatty acids is (*E*)-5-methylhept-2-en-4-one (**8-47**), known as filbertone (Table 8.1), a key component of the odour of hazelnut and some chocolate products, such as nougat. Its content in raw nuts is low (about 1.4 μg/kg), but increases to 660 μg/kg in nuts roasted at 180 °C for 9 minutes, and to 1150 μg/kg in nuts roasted for 15 minutes. Hazelnuts contain a mixture of (+)-(2*E*,5*S*)- and (−)-(2*E*,5*R*)-isomers (**8-47**). The enantiomeric composition of raw hazelnuts

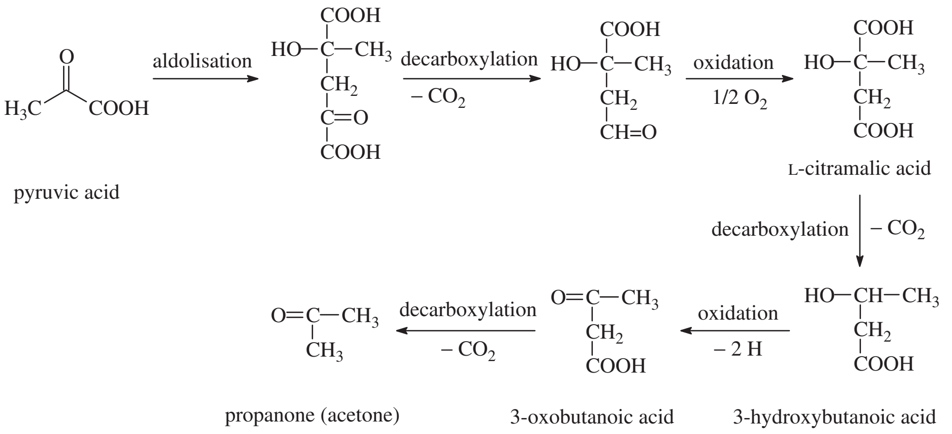


Figure 8.16 Formation of acetone from pyruvic acid.

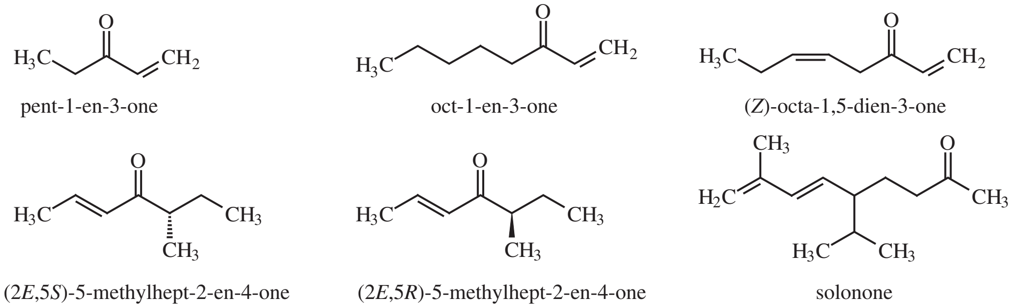
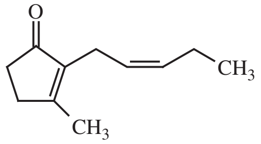


8-47, aliphatic unsaturated ketones

falls in the ratio of 80–85% (+)-(*E*,*S*) and 15–20% (−)-(*E*,*R*), whereas for roasted hazelnuts the ratio is about 71.5–72.5% (+)-(*E*,*S*) and 27.5–28.5% (−)-(*E*,*R*). The odour detection threshold for racemate (in 3% solution of sucrose) is 0.005 μg/l, and the odour recognition threshold value is 0.030 μg/l. Filbertone is also present in hazelnut oils. Oils from raw nuts contain filbertone at a level of <10 μg/kg, but its content in oils from roasted nuts is much higher (around 315 μg/kg). Identification of filbertone as a characteristic marker has been used to detect the presence of cheaper hazelnut oil in olive oil, hazelnuts in nut and cocoa spreads, and hazelnut traces in products during monitoring for hazelnut allergies (known to be one of the most common types of food allergy).

A number of unsaturated aliphatic and alicyclic ketones are formed by degradation of carotenoid pigments. For example, components of tomato flavour are unsaturated methylketones (*E*)-6-methylhept-5-en-2-one, (3*E*,5*E*)-6-methylhepta-3,5-dien-2-one (see Section 9.9.5.2.4) and other methylketones, and the flavour-active component of tobacco is (*E*)-5-isopropyl-8-methylnona-6,8-dien-2-one, known as solonone (**8-47**). Alicyclic ketones, which are the result of degradation of carotenoid pigments, include flavour-active ionones, damascones and many others (see Section 9.9.5.2.1).

An important ketone obtained from the essential oil of jasmine flowers (*Jasminum grandiflorum*, Oleaceae) is (*Z*)-3-methyl-2-(pent-2-en-1-yl)-2-cyclopenten-1-one, also called *cis*-jasmone (**8-48**), which belongs to the group of structurally related compounds called jasmonoids (see Section 3.8.1.8.5) that are used in perfumery and cosmetics. Jasmine flowers are used to scent tea in China.



8-48, (*Z*)-jasmone

Cyclotene (2-hydroxy-3-methylcyclopent-2-en-1-one) is a secondary transformation product of sugars (see Figure 4.62) the odour of which resembles caramel. It is a characteristic aroma component of maple syrup obtained from the sugar maple tree (*Acer saccharum*, Aceraceae).

Unusual genotoxic ketones are 2-alk(en)ylcyclobutanones (**8-49**) that develop in irradiated meat and fish. The list of foods and food ingredients that may be treated with ionising radiation in the EU (Directives 1999/2/EC and 1999/3/EC) does not include meat and meat products, except for chicken meat (The Netherlands), mechanically recovered chicken meat (France) and poultry (France and the United Kingdom). 2-Alkylcyclobutanones are formed by the loss of an electron from the oxygen on the carbonyl of a free fatty acid or fatty acid bound in triacylglycerol, followed by a rearrangement to produce products having the same number of carbon atoms as the parent fatty acid. For example, 2-dodecylcyclobutanone, 2-tetradecylcyclobutanone, and (*Z*)-2-(tetradec-5′-en-1-yl)cyclobutanone have been identified in irradiated cured pork products. The amount of 2-dodecylcyclobutanone in salami irradiated at a dose of 5 kGy was 0.026 mg/kg immediately after the irradiation and 0.068 mg/kg after 60 days of storage.

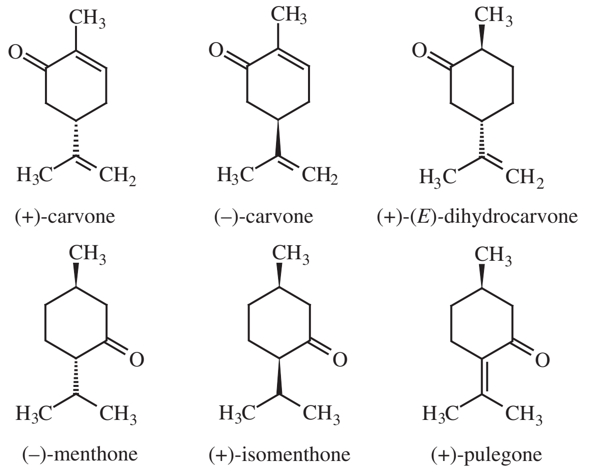
Terpenic ketones

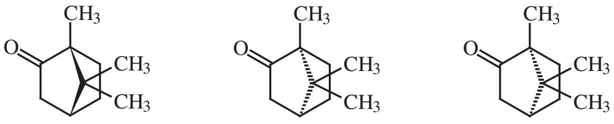
Monoterpenic ketones are frequently very important aromatic substances of many food raw materials, spices and medicinal herbs. Monocyclic ketone (+)-carvone (**8-50**) is a key component of caraway and dill oils, where it is accompanied by (+)-(*E*)-dihydrocarvone, that is (1*S*,4*S*)-dihydrocarvone (**8-50**) that also possesses caraway odour. (−)-Carvone (**8-50**) is a typical component of spearmint essential oil, where it is accompanied by (−)-(*E*)-dihydrocarvone, (1*R*,4*R*)-dihydrocarvone, which has the same odour (see Table 8.32). Isomeric (−)-menthone (**8-50**) and its precursor (+)-pulegone (**8-50**) occur in the essential oils of the European pennyroyal (*Mentha pulegium*, Lamiaceae), a traditional culinary herb and folk remedy, and other *Mentha* species (such as *M. longifolia*), as well as in marjoram essential oil. In the essential oil of mint, (−)-menthone is accompanied by (+)-isomenthone (**8-50**) and other terpenoids.



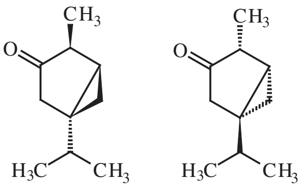
8-50, cyclic monoterpenic ketones

An example of bicyclic monoterpenic ketones is thujone, which occurs as stereoisomeric (+)-3-thujone (α-thujone, **8-51**) and (−)-3-thujone (β-thujone, **8-51**) in the sage essential oil (see Table 8.32), usually in a 1 : 2 ratio, and in other species of the genus *Artemisia* (Asteraceae). Thujone is produced from hydrocarbon sabinene by gradual oxidation and reduction. Both thujones show neurotoxic effects and therefore appear in the list of substances of Regulation (EC) No. 1334/2008, which should not be added to foods as flavourings. Their natural content is restricted to 35 mg/kg in alcoholic beverages produced from *Artemisia* species, to mg/kg in other alcoholic beverages and to 0.5 mg/ kg in non-alcoholic beverages produced from *Artemisia* species.

Bicyclic ketone camphor, formed by oxidation of borneol, is a component of cinnamon, sage and rosemary essential oils. In nature, camphor is formed by the oxidation of borneol, and usually occurs as a mixture of two isomers, (+)-camphor (**8-51**), which is more common, and (−)-camphor (**8-51**). Camphor is obtained from the camphor laurel tree wood (*Camphor officinalis*, syn. *Cinnamomum camphora*, Lauraceae) originating in Indochina, where it grows in large numbers. A further sesquiterpenic ketone is (−)-fenchone (**8-51**), which is found in many essential oils, for example in fennel essential oil.



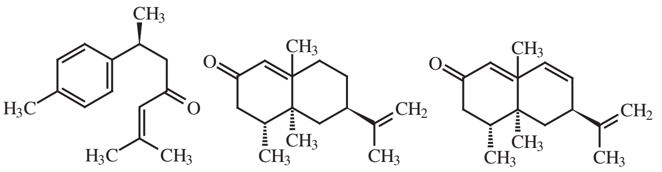
(+)-camphor (–)-camphor (–)-fenchone



α-thujone β-thujone

8-51, bicyclic monoterpenic ketones

Monocyclic sesquiterpenic ketone (+)-*ar*-turmerone (**8-52**) is the main component (25–50%) of turmeric essential oil (see Table 8.32). It is formed by oxidation of hydrocarbon (+)-*ar*-curcumene, which is present in turmeric rhizomes at a level of about 6%. Bicyclic sesquiterpenic ketone is (+)-nootkatone (**8-52**), which is an important odorous compound of grapefruits formed by oxidation of hydrocarbon (+)-valencene via alcohol (+)-β-nootkatol. Another oxidation product of valencene is (+)-8,9-didehydronootkatone (**8-52**). The trivial and systematic names of important terpenic ketones are listed in Table 8.12.



(+)-*ar*-turmerone (+)-nootkatone (+)-8,9-didehydronootkatone

8-52, sesquiterpenic ketones

Aromatic ketones

The basic substance is acetophenone, also known as phenyl methyl ketone (**8-53**), which occurs in a small amount in some essential oils. A component of fennel (see Table 8.32) and star anise essential oils is anise ketone, also known as 4-methoxyphenylacetone (**8-53**). 1-(4-Hydroxyphenyl)butan-3-one, called raspberry ketone (**8-53**), is a natural component of raspberry aroma.

Hydroxycarbonyl and dicarbonyl compounds

Common α-hydroxycarbonyl compounds in foods include various acyloins (**8-54**), also referred to as ketols or α-hydroxyketones, which together with α-dicarbonyl compounds (**8-55**) can be

Table 8.12 Trivial and systematic names of selected terpenic ketones.

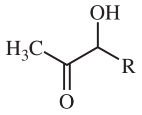
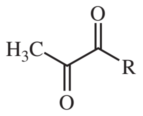
considered as oxidation products of ethylene glycol (ethane-1,2-diol) and other polyols, but they are produced from other precursors. Some important hydroxycarbonyl and dicarbonyl compounds are formed as physiological secondary fermentation metabolites that can be either desirable or undesirable substances of foods.



8-54, α-hydroxyketones (acyloins)



8-55, α-dicarbonyl compounds

Important three-carbon compounds are methylglyoxal and products of its reduction, acetol and D-lactic acid aldehyde (D-lactaldehyde) (Figure 8.11). The four-carbon compounds comprise acetoin (2-hydroxybutanone) and its oxidation product biacetyl (Figure 8.12). Of the higher homologues, 3-hydroxypentan-2-one and pentane-2,3-dione are important. Acetoin, biacetyl and pentane-2,3-dione are organoleptically important compounds. The acetoin and biacetyl are flavour-active compounds that have a pleasant butter-like odour and creamy taste in diluted solutions, and are actually components of butter volatiles. For example, the biacetyl content in butter made from sour cream is around 4 mg/kg. In alcoholic beverages, such as beer and wine, biacetyl (as well as pentane-2,3-dione) is an undesirable substance as it imparts a characteristic buttery aroma to beer when present above its odour detection threshold (0.04 mg/l in air). It is an indicator of unwanted bacterial contamination. The contents of the main hydroxycarbonyl and dicarbonyl compounds in wine are given in Table 8.13. Red wines tend to have slightly higher levels of acetoin and biacetyl than white wines.

In addition to the already mentioned acyloins, food products contain numerous other odorous α-hydroxyketones. For example, 3-hydroxypentan-2-one has ben identified in cheeses, durian, wines, sherry, asparagus, honey, tea, butter and soy sauce, 2-hydroxypentan-3-one in cheeses, durian, coffee, wine, sherry honey, butter and soy sauce, 2-hydroxyhexan-3-one in wine, 4-hydroxyhexan-3-one in durian and tea, 3-hydroxy-5-methylhexan-2-one in cheeses, 3-hydroxyoctan-2-one in beef and heated mutton fat, 5-hydroxyoctan-4-one in cocoa and 3-hydroxy-4-phenylbutan-2-one in wine, sherry and honey.

Table 8.13 Content of main hydroxycarbonyl and dicarbonyl compounds in wines.

Compound	Content (mg/l)
Propane-1,2-dione (methylglyoxal)	0.06–0.42
3-Hydroxybutan-2-one (acetoin)	0.7–53
Butane-2,3-dione (biacetyl)	0.1–7.5
3-Hydroxypentan-2-one	0.5–2.8
Pentane-2,3-dione	7.0–18

Some α-hydroxycarbonyl and α-dicarbonyl compounds, such as glycolaldehyde, 1-hydroxypropanone (hydroxyacetone or acetol), glyoxal (oxalic acid dialdehyde), methylglyoxal (pyruvic acid aldehyde), 3-hydroxybutan-2-one (acetoin) and many others are important products of carbohydrate degradation. These compounds are generally not characterised by distinct organoleptic properties, but are precursors to many important compounds, especially heterocyclic volatiles formed in the Maillard reaction. The 1,2-dicarbonyl compound glyoxal, 1,3-dicarbonyl compound malondialdehyde and various ketols are similarly formed as products of fatty acid oxidation.

8.2.4.2 Properties and reactions

Aliphatic aldehydes with between 1 and 7 carbon atoms in the molecule generally have a sharp, pungent and sometimes rancid aroma, while aldehydes with 8–14 carbon atoms (including monoterpenic aldehydes) are generally characterised by a pleasant aroma. Higher aldehydes are usually odourless.

Symmetric and asymmetric aliphatic ketones of low molecular weight have a pleasant smell. Higher ketones, especially, methyl ketones, have a characteristic smell, which is sometimes desirable and sometimes not. Flavour-active substances in the essential oils of different spices are various monoterpenic ketones. Aliphatic ketones of medium chain length and terpenic ketones are used as flavouring substances in foods and cosmetic products. In the food flavouring industry, some α-hydroxycarbonyl compounds, such as acetoin and some α-dicarbonyl compounds (e.g. biacetyl) are usually mixed with other ingredients to produce a butter flavour or other flavours in a variety of food products, including butter made from sweet cream, margarine and popcorn. Pentane-2,3-dione does not have a significant impact on the flavour of foods.

The most important reactions of carbonyl compounds are addition, oxidation and reduction taking place on the carbonyl group. Owing to the presence of free electron pairs on the carbonyl group oxygen, carbonyl compounds are weak bases, and in acidic media may exist in protonated forms (as conjugated acids; Figure 8.17). Bases split the acidic hydrogen on the carbons adjacent to the carbonyl group to form reactive carbanions (Figure 8.18). Cleavage of hydrogen from the carbon in position α to the carbonyl group and its addition to the carbanion oxygen leads to an equilibrium between the oxo form and the enol form. This isomerisation reaction is called enolisation (Figure 8.19). Enolisation is catalysed by both acids and bases, thus it is an acid–base catalysed reaction. Under normal conditions, the equilibrium in simple aldehydes

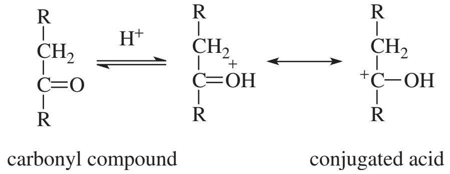


Figure 8.17 Formation of conjugated acids from carbonyl compounds in acidic media.

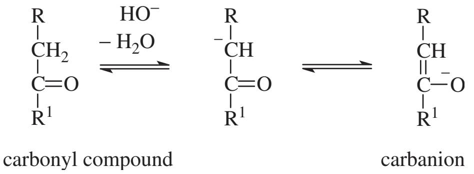

Figure 8.18 Formation of carbanions from carbonyl compounds in basic media.

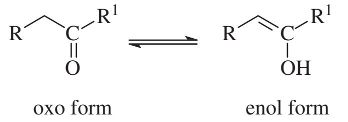

Figure 8.19 Enolisation of carbonyl compounds.

and ketones is almost completely shifted in favour of carbonyl compounds. However, if the methylene group hydrogens are activated, as is the case with malondialdehyde, the proton splits easily and the dominating form of such a carbonyl compound is then the thermodynamically stable enol form.

8.2.4.2.1 Addition reactions

Carbon of the carbonyl group reacts readily with nucleophilic reagents. The first step is an addition of a nucleophile on the carbon atom of the polarised carbonyl group double bond, which is followed by reaction with an electrophile, usually with a proton (Figure 8.20). The most important addition reactions of carbonyl compounds are reactions with water, alcohols, sulfan, thiols, ammonia, amines and aminocarboxylic acids. Reactions are generally acid–base catalysed, so are influenced to a great extent by pH. Addition of acid leads to the formation of a more reactive conjugated acid, but also reduces the concentration of the nucleophile. An addition of hydroxides has the opposite effect. The ease of addition primarily affects the inductive effect of substituents. Alkyl and aryl substituents have a positive inductive effect (+I), and the reactivity of the carbonyl compounds, therefore, decreases in the following order: formaldehyde > aromatic aldehydes > higher aliphatic aldehydes, unsaturated aldehydes > methyl ketones > alkyl aryl ketones > dialkyl ketones. The presence of electronegative functional groups with negative inductive effect (–I) in the aliphatic substituent in the position adjacent to the carbonyl group (such as another carbonyl group or hydroxy group) results in correspondingly higher reactivity of the carbonyl group. Reactivity then declines in the order: α-dicarbonyl compounds (such as glycosuloses) and α-hydroxycarbonyl compounds (such as current aldoses and ketoses). If the carbonyl group is conjugated with a double bond (e.g. in alk-2-enals), the 1,4-addition of nucleophilic reagents may occur (Figure 8.21).

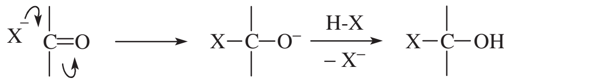

Figure 8.20 Nucleophilic addition to carbonyl compounds (X = OH, SH, NH_2, NH–R).

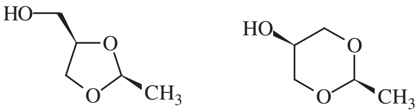
Reactions with water and alcohols

The addition of water to the carbonyl group in aqueous solutions can lead to the formation of hydrates. The reactions and stability of hydrates depend primarily on the inductive effect of substituents. Hydration of formaldehyde readily yields methylene glycol (methanediol), which polymerises to linear oligomers and also to polymers known as paraformaldehyde. Hydrates of α-dicarbonyl and α-hydroxycarbonyl compounds spontaneously dimerise into various cyclic 1,4-dioxanes (see Figure 4.62). These hydrates are intermediates of other α-dicarbonyl and α-hydroxycarbonyl compounds in the oxidation–reduction reactions and precursors of carboxylic acids. Dialkyl ketones do not form hydrates.

Adducts resulting from reactions of carbonyl compounds with alcohols (also with sugars) are called hemiacetals. This reaction (1,2-addition) is catalysed by acids, and primary alcohols are more reactive than secondary alcohols. Splitting a water molecule in acidic media yields a conjugate acid that reacts with another molecule of alcohol with the formation of **acetals**, products of ketones with alcohols that were formerly known as ketals (Figure 8.22). The formation of acetals has considerable importance in the development of flavour-active compounds in alcoholic beverages. In the case of alk-2-enals (such as acrolein), the reaction proceeds in a manner identical with alkene electrophilic addition and, in addition to the 1,2-addition, 1,4-addition is also possible (Figure 8.23). Reactions of glycols with carbonyl compounds yield cyclic acetals, known as that 1,3-dioxolanes (Figure 8.24). The condensation reaction between glycerol and acetaldehyde under acid conditions (at the pH of wine) leads analogously to the formation of four isomers: (*Z*)- and (*E*)-5-hydroxy-2-methyl-1,3-dioxane and (*Z*)- and (*E*)-4-hydroxymethyl-2-methyl-1,3-dioxolane (**8-56**). It is expected that these acetals contribute to the aroma of old sherry and Port wines.



(*Z*)-4-hydroxymethyl-2-methyl-1,3-dioxolane (*Z*)-5-hydroxy-2-methyl-1,3-dioxane

8-56, reaction products of glycerol with acetaldehyde

Acetals are stable in neutral and alkaline solutions. Those derived from aldehydes are more stable than acetals derived from ketones

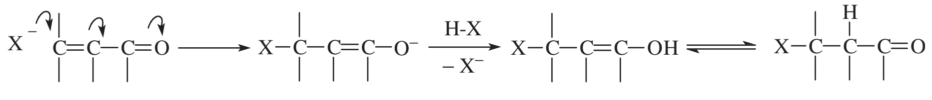


Figure 8.21 1,4-Addition to carbonyl compound double bond.

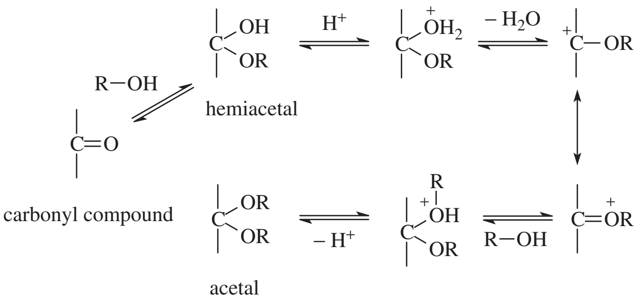

Figure 8.22 Addition of alcohols and formation of acetals.

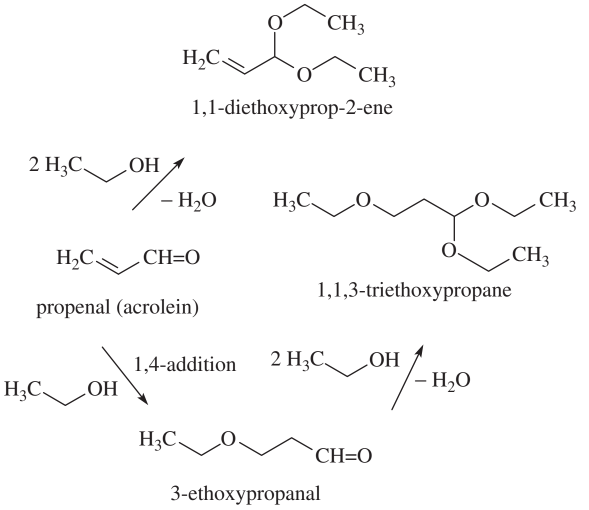

Figure 8.23 Reactions of acrolein with ethanol.

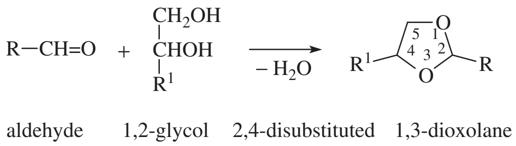

Figure 8.24 Formation of cyclic acetals from aldehydes and 1,2-glycols.

and cyclic acetals are more stable than aliphatic acetals. In acidic solutions, they are hydrolysed to the parent compounds.

Reactions with sulfan and thiols

Similarly to water and alcohols, carbonyl compounds react with sulfan (hydrogen sulfide) and thiols. Addition of sulfan gives unstable α-hydroxythiols as intermediates (Figure 8.25). Mercapto alcohols easily dehydrate to thioaldehydes or thioketones, form cyclic compounds (mostly trimers, which are termed trithioaldehydes and trithioketones) or linear polymers. The reaction is of great importance, for example, in the formation of many aromatic compounds arising during the thermal processing of meat. An example is the reaction of acetaldehyde with sulfan (Figure 8.26).

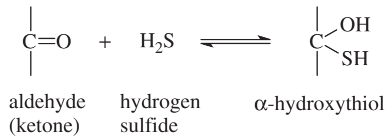

Figure 8.25 Reaction of carbonyl compounds with hydrogen sulfide.

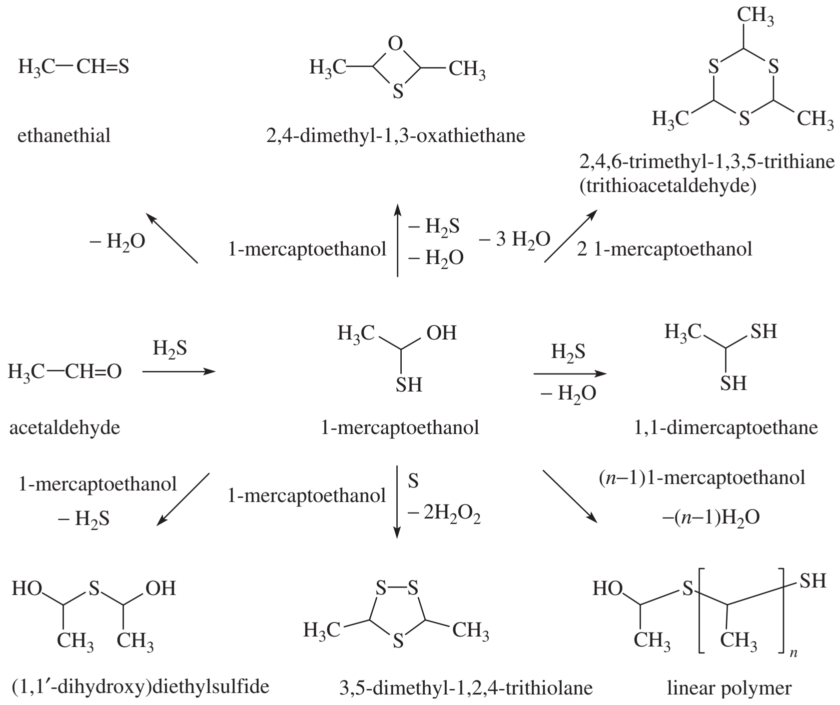

Figure 8.26 Reactions of acetaldehyde with hydrogen sulfide.

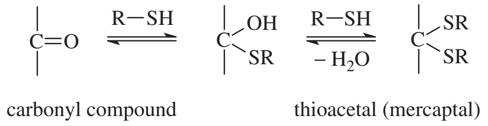

Figure 8.27 Reactions of carbonyl compounds with thiols.

Thiols react with aldehydes and ketones to form thioacetals (mercaptals). The reaction equilibrium is, in comparison with the reaction of alcohols, shifted more in favour of products that are mainly involved as flavour-active components of meat, vegetables and mushrooms (Figure 8.27). The reaction intermediates (semithioacetals) give rise to a number of other compounds.

Reactions with ammonia and amines

Addition products of aldehydes and ketones with ammonia and amines (hemiaminals) are unstable compounds that are then stabilised by a number of subsequent reactions (Figure 8.28). Dehydration of addition products yields imines. Other possible products are enamines, amines containing a double bond linkage –CH=CH–NH– (Figure 8.29), cyclic trimers (symmetrical 1,3,5-triazines) and various coloured polymers, generally of unknown structures. Reaction of the addition products with another amine molecule gives rise to aminals, reaction with another molecule of the carbonyl compounds yields α,α′-dihydroxyamines. For example, in addition to 1,3,5-triazines, it is mostly polymers that are formed from aliphatic aldehydes and ammonia or amines. The reaction of formaldehyde with ammonia yields hexamethylenetetramine,

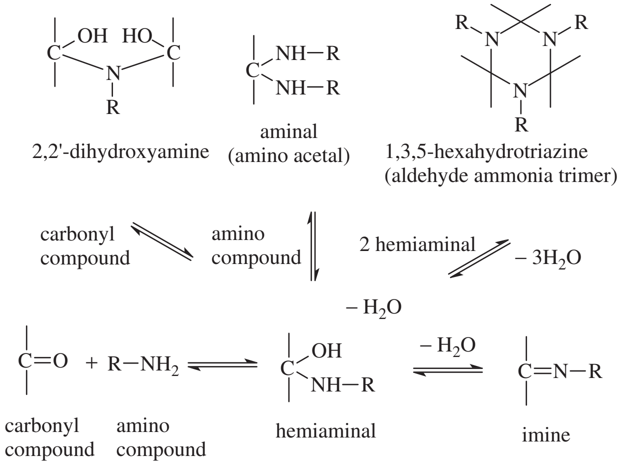

Figure 8.28 Reactions of carbonyl compounds with ammonia (R = H) and amines.

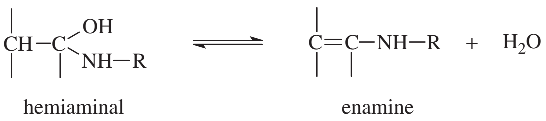

Figure 8.29 Formation of enamines.

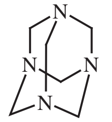
known as urotropine (**8-57**). If cyclisation of the intermediate is possible, stable heterocyclic compounds may be formed, such as those produced in reactions of aldehydes with some aminocarboxylic acids. However, the main reaction products are polymeric brown pigments called melanoidins (see Section 4.7.5.7).



8-57, hexamethylenetetramine

Aldol condensation

Aldol condensation or aldolisation is a reaction of aldehydes and ketones, which have at least one hydrogen on the α-carbon (in position C-2 to the carbonyl group). The nucleophile in aldolisation is an anion of the carbonyl compound. It reacts with the carbonyl group of the second aldehyde or ketone molecule to form α-hydroxycarbonyl compounds, called aldols. Up to this point the reaction is an aldol reaction. The following reaction step is an elimination reaction of water. The aldol produced dehydrates at elevated temperatures, in the presence of a strong base or in acidic media, yielding an α,β-unsaturated aldehyde with conjugated double bonds. Saturated aldehydes produce unsaturated aldehydes, alk-2-enals (Figure 8.30). For example, aldolisation of acetaldehyde and dehydration of the product provides both enantiomers of but-2-enal, which is also known as crotonic acid aldehyde or crotonaldehyde (Figure 8.31). Formaldehyde can react with other aldehydes or ketones having at least one hydrogen atom on the α-carbon to the carbonyl group. High reactivity of formaldehyde causes aldolisation of other molecules of formaldehyde, the number of which corresponds to the number of α-hydrogen atoms available in the reaction partner. For example, acetaldehyde reacts with formaldehyde with formation of mono-, di- and trimethylolacetaldehyde, which yields pentaerythritol by a Cannizzaro reaction (Figure 8.32).

The aldolisation of acetone in alkaline media yields diacetone alcohol, which, on heating in the presence of traces of acids,

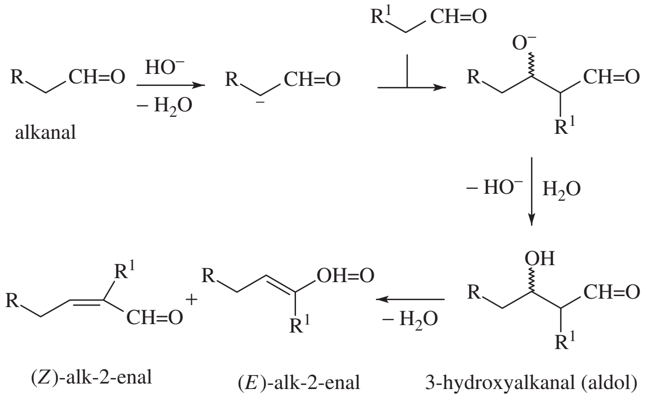


Figure 8.30 Aldolisation of carbonyl compounds.

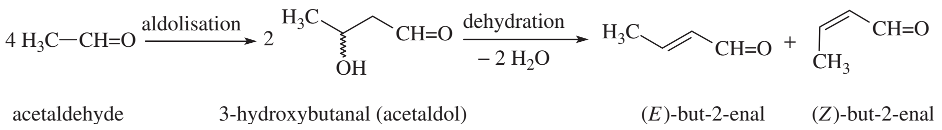

Figure 8.31 Aldolisation of acetaldehyde.

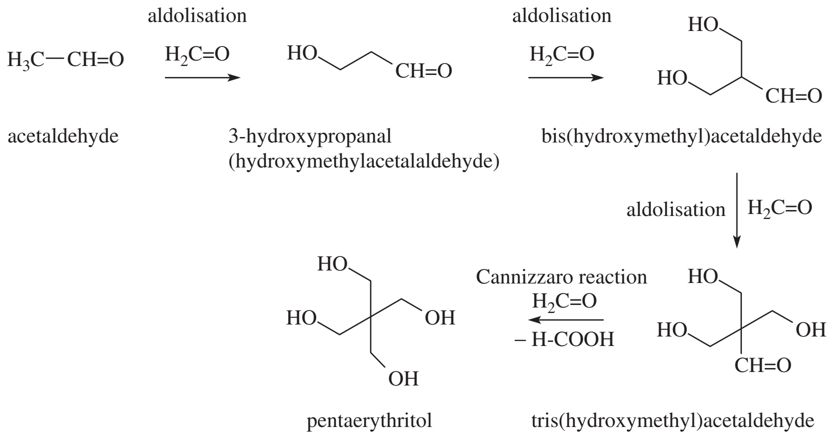

Figure 8.32 Reactions of formaldehyde with acetaldehyde.

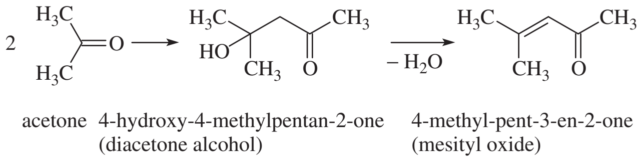

Figure 8.33 Aldolisation of acetone.

produces mesityl oxide (4-methylpent-3-en-2-one) with the aroma resembling peppermint (Figure 8.33). Mesityl oxide is a precursor of other aromatic compounds.

8.2.4.2.2 Oxidations and reductions

The carbonyl group of aldehydes, in contrast to the carbonyl group of ketones, is readily oxidised by oxygen to a carboxyl group. The primary product of autoxidation is a peroxyacid that oxidises another molecule of aldehyde to form two molecules of carboxylic acids (Figure 8.34). The autoxidation of formaldehyde gives rise to formic acid, acetaldehyde yields acetic acid, benzaldehyde gives benzoic acid and furan-2-carbaldehyde gives 2-furancarboxylic acid, also known as furoic or pyromucic acid. The oxidation of a ketone carbonyl group in food does not occur. The hydrocarbon chains of aldehydes and ketones are also subject to autoxidation, as are the hydrocarbon chains of fatty acids.

Reduction of aldehydes generates primary alcohols; ketones are formed by reducing secondary alcohols. This is usually an enzymatic reaction. For example, benzyl alcohol arises from benzaldehyde (see Section 8.2.2.1.2).

Cannizzaro reaction

A specific case of an oxidation–reduction reaction is the Cannizzaro reaction, in which one molecule of aldehyde is oxidised with

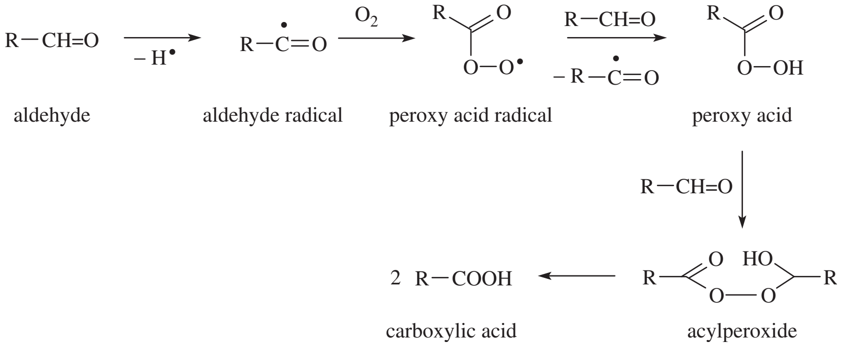

Figure 8.34 Oxidation of aldehydes to carboxylic acids.

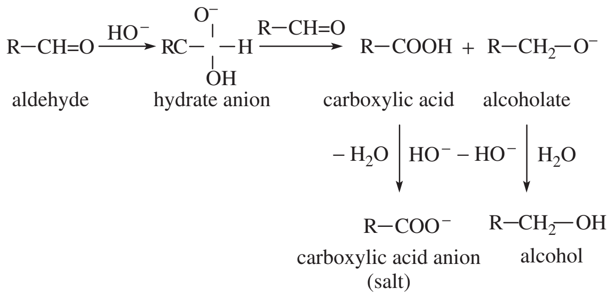

Figure 8.35 Cannizzaro reaction of aldehydes.

reduction of the second molecule. A Cannizzaro reaction occurs in aldehydes that do not have a hydrogen atom in position α to the carbonyl group. The reaction products are mixtures of primary alcohols and carboxylic acids. A Cannizzaro reaction is catalysed by hydroxyl ions; the key step is the transfer of the hydride from the hydride anion to the second aldehyde molecule (Figure 8.35).

For example, Cannizzaro reaction of formaldehyde gives methanol and formic acid. Methanol reacts with another molecule of formaldehyde (its hydrate) to form acetal 1,1-dimethoxymethane, also known as 2,4-dioxapentane. The reaction of methanol with formaldehyde hydrate oligomers yields, by analogy, higher dioxaalkanes. The Cannizzaro reaction of benzaldehyde also proceeds easily (especially in the presence of heavy metal traces), yielding benzyl alcohol and benzoic acid. Benzoic acid is otherwise also formed by autoxidation of benzaldehyde. The Cannizzaro reaction of furan-2-carbaldehyde yields furfuryl alcohol and 2-furancarboxylic acid.

In the presence of formaldehyde, a Cannizzaro reaction even occurs with aldehydes, which do not have hydrogen atoms on the carbon in position α to the carbonyl group. Formaldehyde is then oxidised to formic acid, and the aldehyde is reduced to the corresponding alcohol (Figure 8.36). Reaction of formaldehyde with aldoses produces small amounts of formic acid and the corresponding alditol.

In the case of 2-oxoaldehydes, such as glyoxal and methylglyoxal, the Cannizzaro reaction proceeds in the same way as the intramolecular reaction, and the product is 2-hydroxycarboxylic acid. The aldehyde group of oxo aldehyde is oxidised to a carboxylic group with the simultaneous reduction of the oxo group to a hydroxyl group (Figure 8.37). For example, glyoxal yields glycolic acid and methylglyoxal yields lactic acid (racemate).

8.2.5 Acetals

8.2.5.1 Classification, structure, terminology and occurrence

Acetals occur wherever aldehydes and ketones are present with an excess of alcohol. Relatively large amounts of acetals are therefore found in alcoholic beverages, particularly spirits with higher ethanol content. However, even there the proportion of aldehydes bound as acetals does not usually exceed 15–30% of the total aldehyde content.

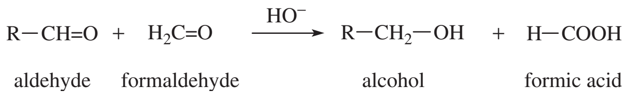

Figure 8.36 Cannizzaro reaction of aldehydes and formaldehyde.

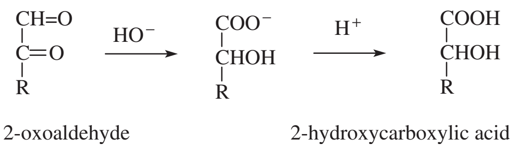

Figure 8.37 Cannizzaro reaction of α-dicarbonyl compounds.

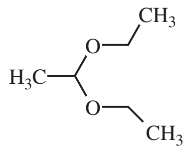
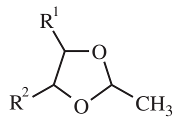
Acetaldehyde is more reactive than higher alkanals, alkenals and aromatic aldehydes, and is present in alcoholic beverages in a relatively high concentration. Therefore, the most common substance found in alcoholic beverages is so-called diethylacetal (1,1-diethoxyethane) resulting from the reaction of acetaldehyde with ethanol (**8-58**). It is characterised by a sharp fruity aroma and a flavour reminiscent of nuts. The content, depending on the time of ripening of the whiskies and brandies, varies from about 4 to 60 mg/l. Acetals derived from formaldehyde and ethanol and acetals derived from higher aldehydes are present in lower amounts, as well as acetals arising from fusel oil alcohols.



8-58, 1,1-diethoxyethane

Reaction of the unsaturated aldehyde acrolein with ethanol leads either to 1,1-diethoxyprop-2-ene or to 3-ethoxypropanal. Both compounds can react with another ethanol molecule to give the final product, 1,1,3-triethoxypropane (Figure 8.23). All three compounds are found in alcoholic beverages.

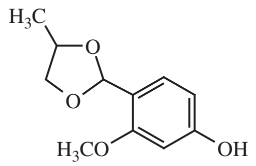
1,3-Dioxolanes (**8-59**) are cyclic acetals resulting from the condensation of carbonyl compounds with glycols in acidic media. They are common in alcoholic beverages. Brandies and other spirits contain 4-hydroxymethyl-2-methyl-1,3-dioxolane ($R^1 = CH_2OH$, $R^2 = H$), which forms from acetaldehyde and glycerol, 2,4-dimethyl-1,3-dioxolane ($R^1 = CH_3$, $R^2 = H$) is a product of acetaldehyde and propane-1,2-diol (propylene glycol) condensation (propane-1,2-diol is a product of methylglyoxal



8-59, 1,3-dioxolanes

reduction), 2,4,5-trimethyl-1,3-dioxolane ($R^1 = R^2 = CH_3$) results from acetaldehyde and butane-2,3-diol.

The most commonly occurring cyclic acetals of commercial aromas are 1,3-dioxolane derivatives that are derived from propane-1,2-diol used as a solvent. In vanilla flavours, for example, a considerable amount of 2-(4-hydroxy-2-methoxyphenyl)-4-methyl-1,3-dioxolane (**8-60**) occurs, which is formed in the reaction of propane-1,2-diol with vanillin.



8-60, 2-(4-hydroxy-2-methoxyphenyl)-4-methyl-1,3-dioxolane

8.2.5.2 Properties and reactions

Acetals, especially those compounds derived from lower alcohols, generally have a pleasant smell similar to the original carbonyl compounds, but weaker and softer. Those derived from higher alcohols usually have pleasant smells, associated with aging of alcoholic beverages. Acetals are more stable than the corresponding aldehydes and ketones, especially in alkaline media and during oxidation. Therefore, they are often used as flavourings for soaps. Under acidic conditions, acetals are easily hydrolysed to the parent compounds.

8.2.6 Carboxylic acids

Carboxylic acids are particularly important components of foods of plant origin. They influence the course of enzymatic and chemical reactions, the microbiological stability of foods during storage and processing and the organoleptic and technological properties. In foods the predominant compounds that can be found are aliphatic, alicyclic, aromatic and heterocyclic carboxylic acids that contain one carboxyl group (monocarboxylic acids) or more carboxyl groups (polycarboxylic acids) in the molecule. Many carboxylic acids also contain other functional groups such as hydroxyl groups (hydroxycarboxylic acids) and carbonyl groups (oxocarboxylic acids), amino groups (aminocarboxylic acids), mercapto groups (mercaptocarboxylic acids); certain halogen-containing carboxylic acids, the molecule of which contains, for example, one or more chlorine atoms, are food contaminants .

It is mainly the lower carboxylic acids and some aromatic carboxylic acids that are active as odour- or taste-active compounds. Taste-active substances are predominantly polyhydric carboxylic acids and some aliphatic carboxylic acids such as acetic and lactic acids, which are major carriers of the sour taste in food raw materials and foods. Short chain fatty acids also have some importance as flavour-active substances (C_4 and C_6) and medium chain fatty acids (C_8–C_{12}). A number of carboxylic acids can become precursors of important flavour-active derivatives, such as, for example, esters and lactones.

8.2.6.1 Classification structure, terminology and occurrence

8.2.6.1.1 Aliphatic monocarboxylic acids

Important odour-active acids are mainly saturated monocarboxylic acids containing 1–10 carbon atoms in the molecule (**8-61**), which in apart from the carboxyl group do not contain other functional groups. Acids with four or more carbon atoms in the molecule are classified as fatty acids (see Section 3.3.1.1).

R—COOH

8-61, lower carboxylic acids

formic(methanoic), R = H
acetic(ethanoic), R = CH_3
propionic(propanoic), R = CH_2CH_3
butyric(butanoic), R = $[CH_2]_2CH_3$
isobutyric(2-methylpropanoic), R = $CH_2CH(CH_3)2$
valeric(pentanoic), R = $[CH_2]_3CH_3$
isovaleric(3-methylbutanoic), R=$CH_2CH_2CH(CH_3)2$
caproic(hexanoic), R = $[CH_2]_4CH_3$
caprylic (octanoic), R = $[CH_2]_6CH_3$
capric(decanoic), R = $[CH_2]_8CH_3$

The basic member of the homologous series of these acids is formic acid. It occurs as a free compound and is esterified mainly in vegetables, fruits and also in alcoholic beverages, where it arises (in addition to ethanol and acetic acid) as a byproduct of the anaerobic fermentation of sugars by some microorganisms. The precursor of formic acid is pyruvic acid that reacts with HS-CoA with the formation of acetyl-CoA and formic acid, which is decomposed into carbon dioxide and hydrogen. This reaction is catalysed by pyruvate formate-lyase. Formic acid is also produced in the seeds and leaves of plants by α-oxidation of fatty acids. The product of oxidation is α-hydroxycarboxylic acid which is transformed into formic acid and carbon dioxide. The final product is a fatty acid containing one less carbon atom.

Sugars (hexoses) yield formic acid as a product of the Cannizzaro reaction of formaldehyde and as one of the final products of the dehydration of sugars in acidic media and their degradation in neutral and alkaline media. At high concentrations (in quantities of up to 2%), formic acid therefore occurs in acid protein hydrolysates, where it is formed by 5-hydroxymethyl-2-furancarbaldehyde degradation. In rancid fats, formic acid arises by oxidative decomposition of aldehydes. Formic acid is sometimes used as a preservative.

Acetic acid (**8-61**) is the most common monocarboxylic acid occurring in foods. It is a typical component of fruits (as the free acid and its esters) and foods produced by fermentation processes. Acetic acid is produced as a degradation product of sugars in the Maillard reaction and in thermal processes. For food purposes, acetic acid is produced from ethanol or fruit wines as vinegar by microbial oxidation of ethanol via acetaldehyde using aerobic bacteria of the genus *Acetobacter* (Figure 8.38). In the manufacture of vinegar, the bacterium *Acetobacter aceti* is traditionally used. The fermented ethanol (including wines) has a resulting acetic acid concentration of about 5%, with a pH of about 2.4. Any type of vinegar can be distilled to produce a colourless solution that contains about 8% acetic acid.

The higher homologues of acetic acid, propionic, butyric, isobutyric, valeric, isovaleric, caproic acid and some other acids, are formed by different mechanisms. Butyric acid, caproic, caprylic

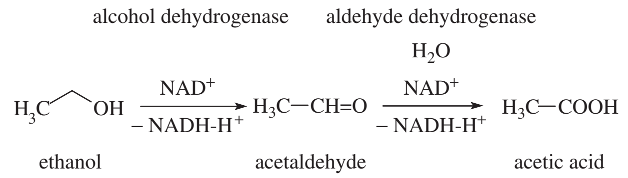


Figure 8.38 Oxidation of ethanol and formation of acetic acid.

and capric acids occur, along with other acids (such as isoacids, anteisoacids and acids with an odd number of carbon atoms), in relatively high quantities in milk fat, in the form of triacylglycerols. Their biosynthesis is primarily based on acetyl-CoA (see Section 3.2). Propionic acid is biosynthesised if the parent compound is propionyl-CoA instead of acetyl-CoA. Numerous other acyl-CoAs are intermediates in the biosynthesis of amino acids formed by elongation of 2-oxoacids under the catalytic activity of acyl-CoA synthetases. Examples of these acyl-CoAs are butanoyl, 2-methylpropanoyl-, pentanoyl-, 3-methylbutanoyl-, 4-methylpentanoyl- and hexanoyl-CoA. The corresponding 2-oxoacids are formed as amino acid catabolic products by transamination catalysed by transaminases, or by oxidative deamination catalysed by oxidases (see Section 2.5.1.3.2). Their decarboxylation catalysed by decarboxylases yields aldehydes that are finally oxidised to carboxylic acids by aldehyde dehydrogenases. For example, valine is the precursor of isobutyric acid, isovaleric acid arises from leucine, 2-methylbutyric acid from isoleucine and propionic acid from threonine. These acids are the byproducts of fermentation processes (Table 8.14).

Carbohydrates are also precursors of carboxylic acids. Bacteria of the genera *Clostridium*, *Butyribacterium* and *Butyrivibrio* ferment sugars primarily to acetic and butyric acids. Bacteria of the genus *Propionibacterium* (*P. freudenreichii* subsp. *shermanii*) ferment lactose to lactic acid, which is reduced to propionic acid, an important acid of the most famous Swiss cheese, Emmental (Figure 8.39). The first step of this biosynthesis is the reaction of pyruvic acid with (*S*)-malonyl-CoA catalysed by methylmalonyl-CoA carboxyl transferase, which yields propionyl-CoA and 2-oxaloacetic (2-oxosuccinic) acid. 2-Oxaloacetic acid is reduced to (*S*)-2-hydroxybutanedioic (L-malic) acid by malate dehydrogenase, dehydrated to (*E*)-but-2-enedioic (fumaric) acid by fumarase, which is reduced to succinic acid by succinate dehydrogenase. In the reaction catalysed by propionyl-CoA:succinate-CoA transferase, propionyl-CoA is used in the next step as a donor of coenzyme A, which creates succinyl-CoA and propionic acid as the final reaction product. Succinyl-CoA is then transformed into (*R*)-methylmalononyl-CoA by methylmalonyl-CoA with mutase, isomerisation of which by methylmalonyl-CoA epimerase yields the starting compound (*S*)-methylmalonyl-CoA.

Table 8.14 Lower carboxylic acids contents in beer.

Acid	Content (mg/l)	Acid	Content (mg/l)
Acetic	12–155	Isovaleric	0.4–3.4
Butyric	0.6–2.6	Caproic	0.9–22.8
Isobutyric	0.3–3.3	Caprylic	1.8–15.4
Valeric	0.1–0.2	Capric	0.1–5.2

An important lower unsaturated carboxylic acid is (*E*)-but-2-enoic (crotonic) acid (**8-62**). This acid occurs in small quantities, together with other unsaturated acids with 5–10 carbon atoms in the molecule, in beer and fermented drinks and foods. Examples of acids with five carbon atoms in the molecule are (*Z*)-2-methylbut-2-enoic (angelic) (**8-62**) and (*E*)-2-methylbut-2-enoic acid (tiglic) acids, the precursor of which is threonine (**8-62**). Valine is converted into (*Z*)-3-methylbut-2-enoic (senecioic) acid with five carbon atoms (**8-62**). These acids, along with a number of other related acids, are a frequent component of pyrrolizidine alkaloids known as senecio alkaloids (see Section 10.3.2.1.3).

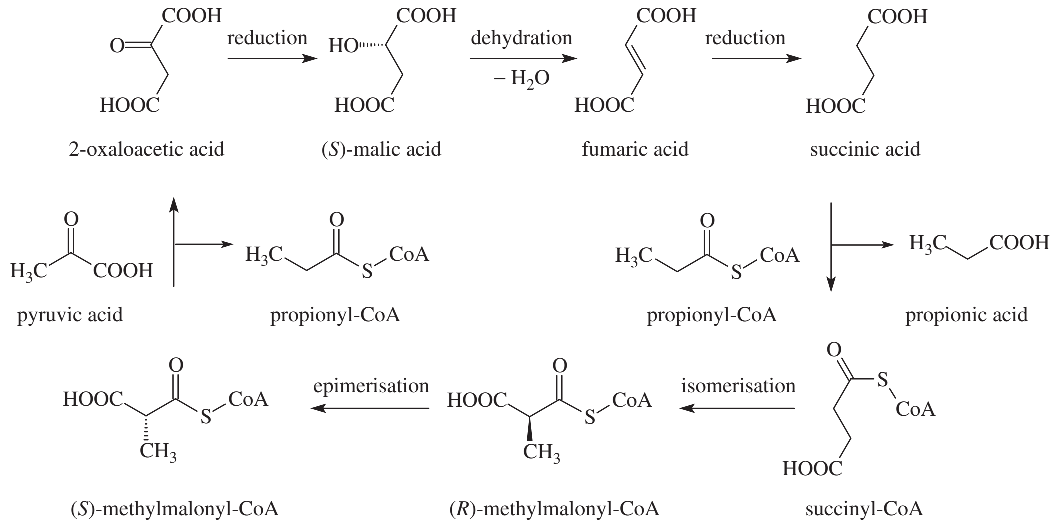

Figure 8.39 Mechanism of propionic acid fermentation.

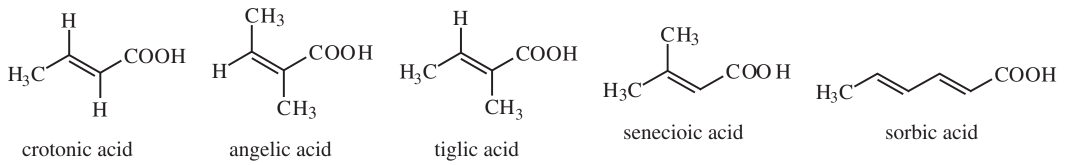

8-62, unsaturated carboxylic acids

An important unsaturated acid is (2*E*,4*E*)-hexa-2,4-dienoic acid known as sorbic acid (**8-62**). It was first isolated from fruits of the rowan tree (*Sorbus aucuparia*, Rosaceae), where it results from dehydration and ring opening of (*S*)-2-methyl-2,3-dihydropyran-6-one, which is called parasorbic acid. Sorbic acid has antimicrobial effects and is therefore used as a preservative (see Section 11.2.1.1.2).

8.2.6.1.2 Aliphatic dicarboxylic and tricarboxylic acids

Aliphatic dicarboxylic and tricarboxylic acids are non-volatile compounds and may therefore just have a role as taste-active (acidic) food components.

The basic member of the homologous series of aliphatic dicarboxylic acids (**8-63**) is oxalic acid. The main precursor of oxalic acid is L-ascorbic acid; therefore oxalic acid is a normal constituent of fruits and vegetables (Figure 8.40). It occurs as a soluble potassium salt (e.g. in bananas) or a calcium salt (especially in fruits and vegetables) that is soluble in acidic and insoluble in neutral and alkaline media. Oxalic acid is categorised among the antinutritional compounds, as it interferes with the metabolism of calcium. Regulation

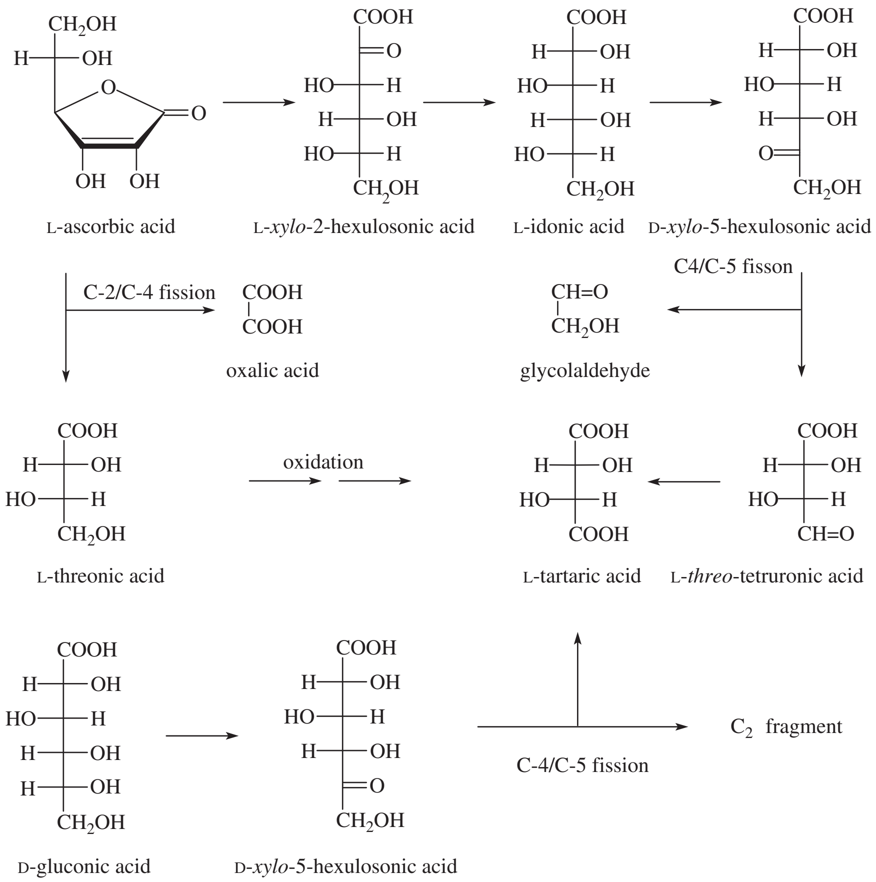

Figure 8.40 Biosynthesis of oxalic and L-tartaric acids.

of the calcium content in plants is based on the same principle. At higher concentrations, oxalic acid occurs in rhubarb and spinach, where its content can be somewhat decreased by blanching. A similar amount of oxalic acid is found in ripe carambola fruits (*Averrhoa carambola*, Oxalidaceae), tea and cocoa (Table 8.15). Tea is considered the major source of oxalic acid in countries where it is consumed in large quantities (such as the United Kingdom).

Higher saturated aliphatic dicarboxylic acids, such as malonic, succinic and glutaric acids and other higher homologues of oxalic acid, are found in many food raw materials and foods, but usually in smaller quantities. They are mainly intermediates of fatty acids biosynthesis, the citric acid cycle and other metabolic processes, but only succinic acid occurs in a somewhat larger amount in some fruits (e.g. in currants and strawberries). All the above mentioned dicarboxylic acids, including oxalic, adipic, pimelic, suberic acids and their higher homologues, are present in small amounts in wine and beer.

Among the unsaturated dicarboxylic acids, (*E*)-but-2-enedioic acid, known as fumaric acid (**8-64**) has a certain importance. It is formed in the ornithine cycle, and occurs in small quantities in virtually all products of animal and vegetable origin, and in greater quantities in some fungi. Fumaric acid arises as a non-enzymatic deamination product of aspartic acid. Along with isomeric (*Z*)-but-2-enedioic acid, known as maleinic (maleic) acid (**8-64**), fumaric acid forms by pyrolysis of malic acid during thermal processes, such as coffee roasting.

A higher homologue of fumaric acid is (*E*)-2-methylbut-2-enedioic acid, (*E*)-prop-1-ene-1,2-dicarboxylic acid, which is known trivially as mesaconic or methylfumaric acid (**8-64**). It occurs in significant quantities in sugar beets. It is used as a

8-64, unsaturated dicarboxylic and tricarboxylic acids

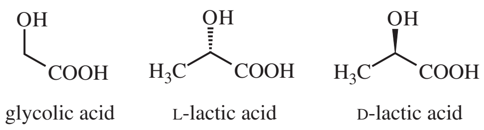
fire retardant. The *cis*-isomer of mesaconic acid is (*Z*)-2-methylbut-2-enedioic acid, also called (*Z*)-prop-1-ene-1,2-dicarboxylic acid, methylmaleic acid or citraconic acid (**8-64**). Blueberries contain higher amounts. 2-Methylidenebutanedioic acid, also known as prop-1-ene-2,3-dicarboxylic acid or itaconic acid (**8-64**), is produced, together with mesaconic and citraconic acids, by thermal degradation of citric acid. Citric acid degradation occurs, for example, during the roasting of coffee and the refining (deodorisation) of vegetable oils, where citric acid is used as an additive agent (about 100 mg of 20% citric acid per kg oil) to chelate traces of metals, resulting in increased oil stability during storage. The common, older name of these three acids is thus pyrocitric acid.

Tricarboxylic acid, known as aconitic acid (prop-1-ene-1,2,3-tricarboxylic acid, also known as achilleic or citridinic acid), occurs in two geometric isomers, the (*Z*)- and the (*E*)-isomers (**8-64**). (*Z*)-Aconitate is widespread as an intermediate produced in the isomerisation of citrate to D-isocitrate (catalysed by aconitase) in the citric acid cycle. About 5% aconitic acid is found in molasses from cane sugar production, where the (*E*)-isomer prevails, as it is formed by isomerisation of (*Z*)-aconitic acid at elevated temperatures and low pH. The amount of (*Z*)-aconitic acid in the growing cane is low, because it is used in the citric acid cycle and not stored in the plant. Decarboxylation of aconitic acid at elevated temperatures yields itaconic acid.

8.2.6.1.3 Aliphatic hydroxycarboxylic acids

Hydroxycarboxylic acids are mostly non-volatile and polar compounds that are not important as odour-active food components. Certain hydroxy acids are, however, the major substances influencing the sour taste of fruits, vegetables and other foods. Some of their reaction products are odour-active substances, especially lactones.

The simplest hydroxycarboxylic acid is glycolic (hydroxyethanoic) acid (**8-65**), which occurs in small amounts in most plant materials as a natural component. It also arises by the Cannizzaro reaction of glyoxal.



8-65, hydroxycarboxylic acids

The most important representative of this group of carboxylic acids is lactic (2-hydroxypropanoic) acid. (+)-L-Lactic acid is present in meat, that is (*S*)-2-hydroxypropanoic acid (**8-65**), which is formed in anaerobic glycolysis from glycogen. For example, fresh beef usually contains lactic acid at a level of 0.2–0.8%.

Homofermentative lactic acid bacteria (such as *Lactococcus lactis* and *Streptococcus lactis*) produce (+)-L-lactic acid (e.g. in sour cream). Both isomers, (+)-L-lactic acid and (−)-D-lactic acid (**8-65**), are formed during milk fermentation by heterofermentative bacteria (lactic acid bacteria are mostly heterofermentative bacteria) and lactic acid thus also occurs as a racemate in sauerkraut, pickled cucumbers, olives and silage. For example, bacteria of the genus *Leuconostoc* produce D-lactic acid, while bacteria *Pediococcus acidilactici* and other bacteria produce racemic lactic acid. The content of lactic acid in dairy products is 0.5–1.0%. L-Lactic acid in yoghurt represents about 54% and in sour cream 96% of the total lactic acid content. The total lactic acid content in sauerkraut is 1.5–2.5%, in fermented cucumbers it ranges from 0.5 to 1.5% and fermented green olives contain 0.8 to 1.2% lactic acid.

Fermentation with homofermentative lactic acid bacteria involves phosphorylation of α-lactose to α-lactose 6′-phosphate and hydrolysis to α-D-galactose 6-phosphate and β-D-glucose. α-D-Galactose 6-phosphate is then degraded via D-tagatofuranose 6-phosphate and D-tagatofuranose 1,6-bisphosphate to D-glyceraldehyde 3-phosphate. β-D-Glucose is phosphorylated to β-D-glucose 6-phosphate. All sugars are then activated by different mechanisms and converted into D-fructose 1,6-bisphosphate, which is degraded, via D-glyceraldehyde 3-phosphate and other metabolites, to pyruvic acid, which is reduced to L-lactic acid, virtually the only product of homofermentative lactic acid fermentation[3] (Figure 8.41).

Heterofermentative lactic acid bacteria produce L- and D-lactic acids, ethanol, carbon dioxide and a small amount of acetic acid from glucose and fructose. Sugars are phosphorylated in the bacterial cells: glucose to β-D-glucose 6-phosphate by glucokinase and fructose usually to D-fructose 1-phosphate by fructokinase.

[3] The reaction sequences involve phosphoglycerate kinase, phosphoglyceromutase, enolase, pyruvate kinase, L-lactate dehydrogenase, galactokinase, UDP-galactose pyrophosphorylase, UDP-galactose 4-epimerase, UDP-glucose pyrophosphorylase, phosphoglucomutase, glucokinase, fructokinase, phosphoglucose isomerase, fructose bisphosphate aldolase, 1-phosphofructokinase, phospho-β-galactosidase, D-galactose-6-phosphate isomerase, D-tagatose-6-phosphate kinase and tagatose-1,6-bisphosphate aldolase.

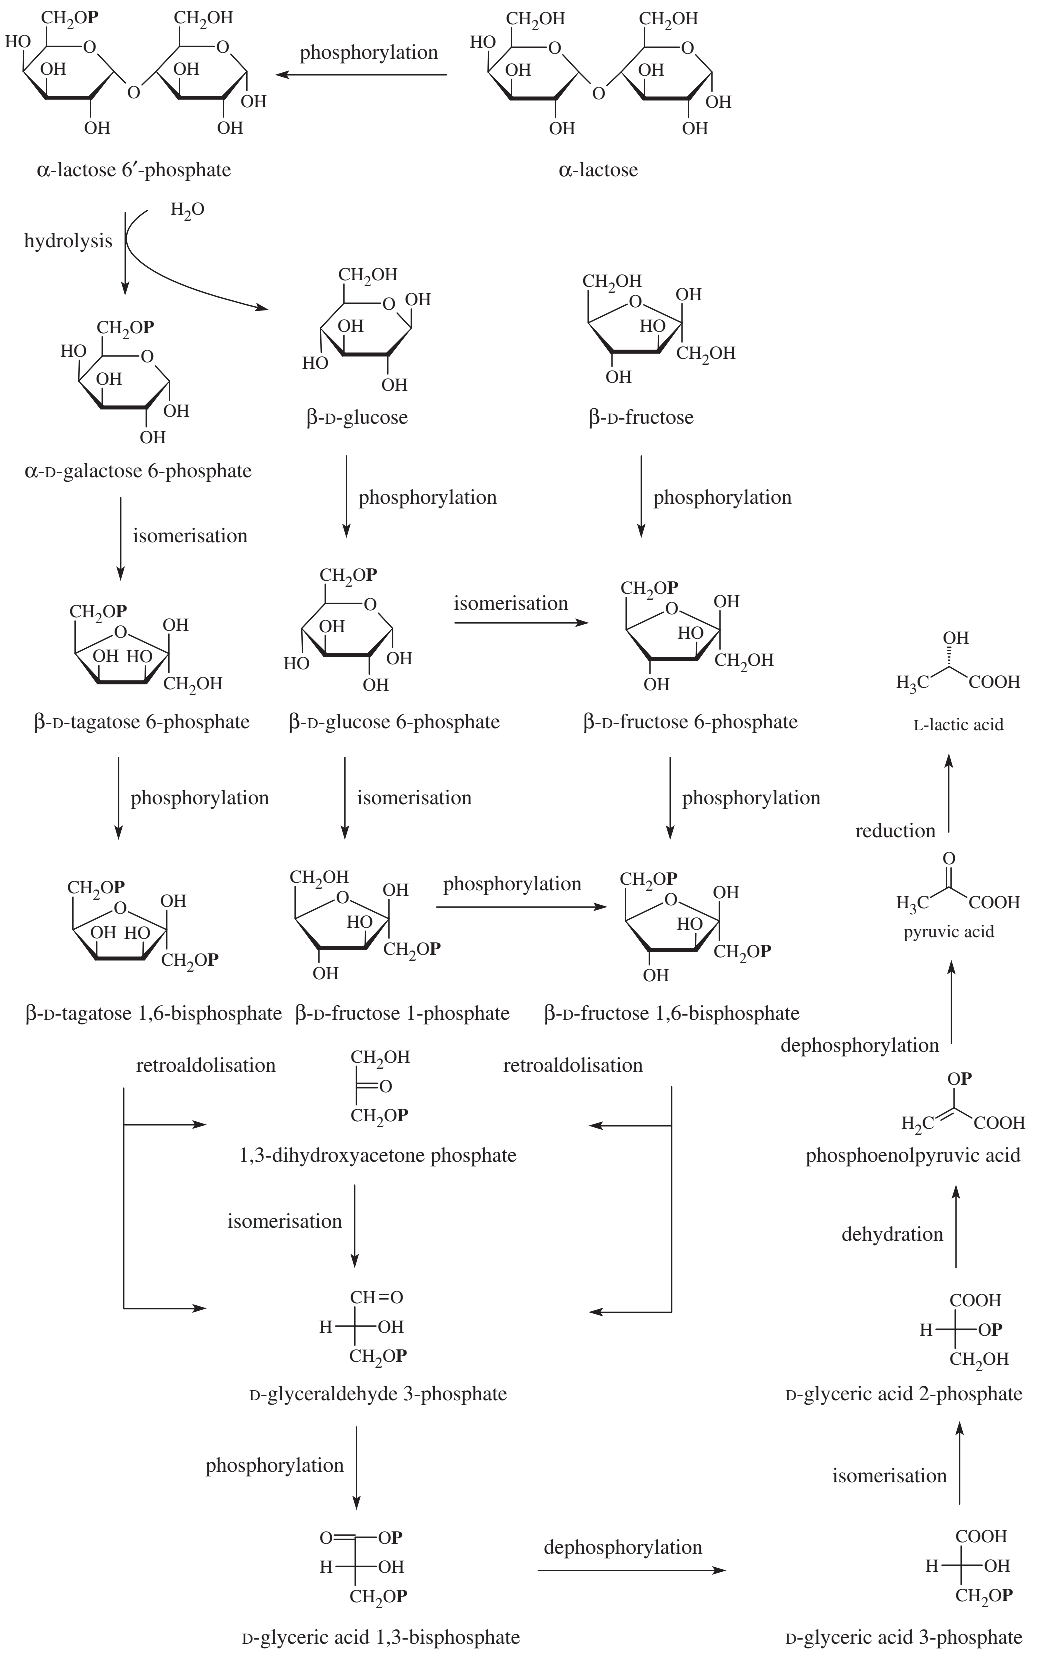


Figure 8.41 Mechanism of homofermentative lactic acid bacteria fermentation (**P** = phosphate residue).

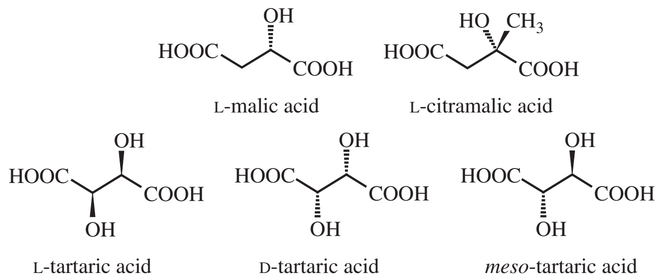
D-Fructose 1-phosphate, with the catalysis of glucose-6-phosphate isomerase, isomerises to β-D-glucose 6-phosphate (which is sometimes produced directly), which is further metabolised (Figure 8.42; structures of compounds are shown in Figure 8.41). Saccharose is first hydrolysed to glucose and fructose by invertase, and maltose is hydrolysed to glucose by maltase.

Polycarboxylic hydroxy acids are important carriers of the acidic taste of foods. Dicarboxylic hydroxy acids primarily include malic (hydroxysuccinic) acid (**8-66**) occurring only as (−)-L-isomer that is the (*S*)-isomer, which results as an intermediate in the citric acid



8-66, hydroxydicarboxylic acids

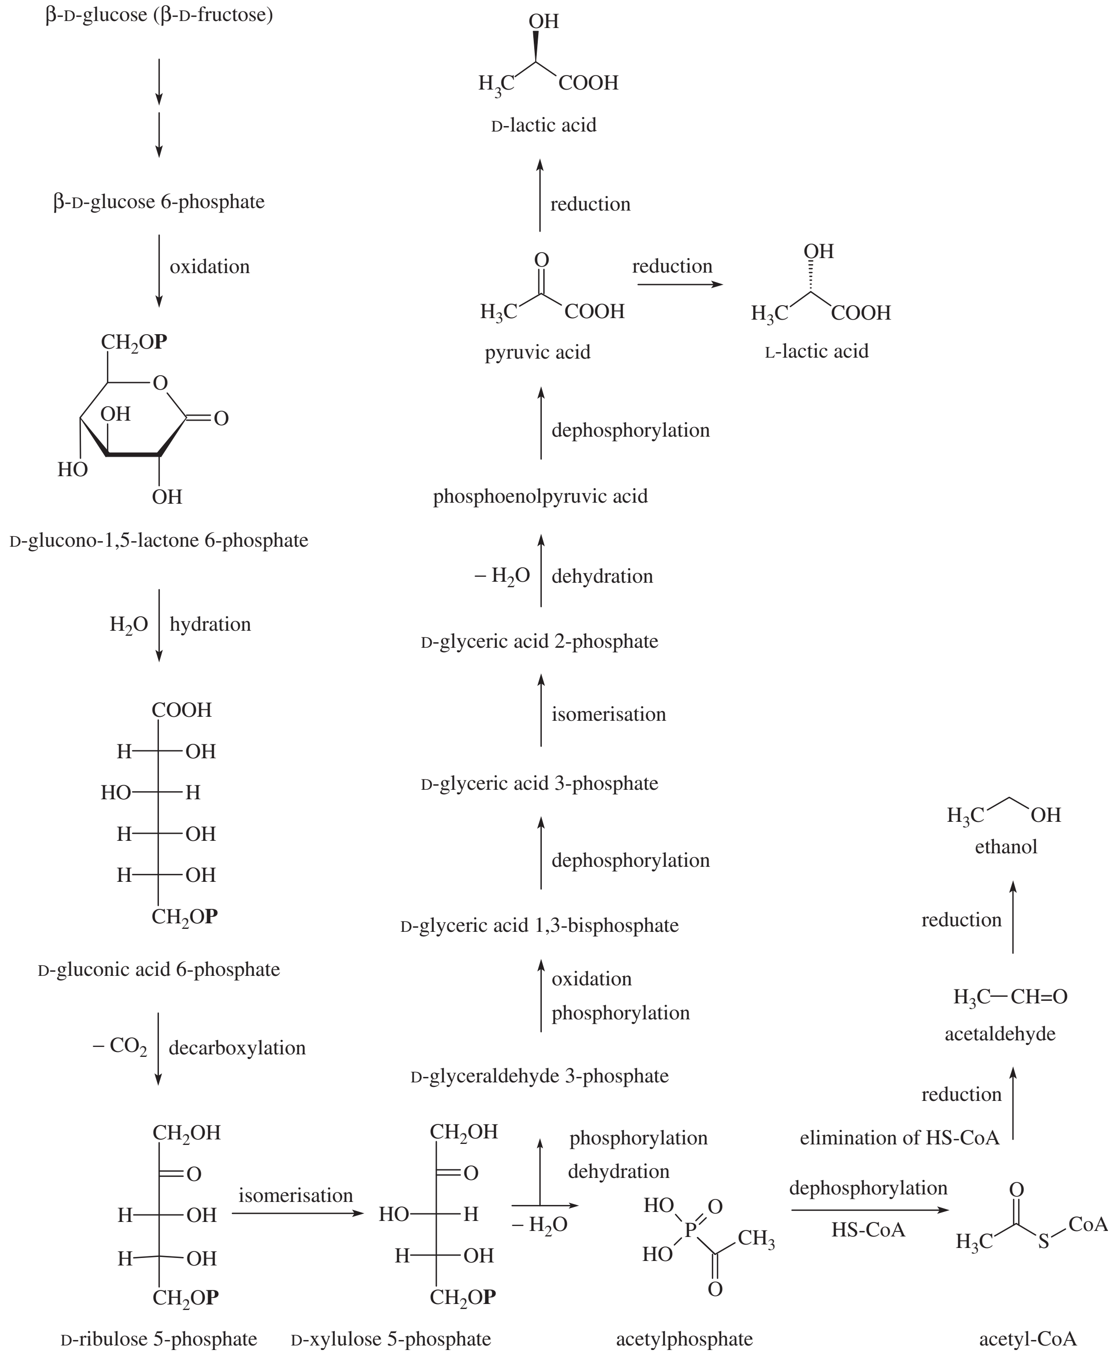


Figure 8.42 Mechanism of heterofermentative lactic acid bacteria fermentation (**P** = phosphate residue).

cycle. It is found in abundance primarily in fruits and vegetables. Malic acid is used as a food additive (acidulant), and is synthesised from fumaric acid using the bacteria *Lactobacillus brevis* or yeasts of the genus *Candida*.

In the skins of apples, pyruvic acid is the precursor of (+)-L-citramalic acid, which is also known as (*S*)-2-hydroxy-2-methylsuccinic acid or (*S*)-2-methylmalic acid (**8-66**). During fruit ripening, citramalic acid is oxidised to 2-oxobutyric acid and its decarboxylation yields acetone, which is a component of apple odour. The same isomer of citramalic acid is produced by some enterobacteria as a degradation product of glutamic acid to pyruvic acid. The (*R*)-isomer of citramalic acid is an intermediate in the biosynthesis of isoleucine in spirochetes.

Tartaric (2,3-dihydroxysuccinic) acid is an important representative of dihydroxydicarboxylic (aldaric) acids and the most prominent acid in wine. In nature it occurs almost exclusively as (+)-L-tartaric acid (**8-66**), also known as dextrotartaric acid or L-threaric acid, which is (2*R*,3*R*)-isomer. Occasionally tartaric acid occurs as (−)-tartaric, laevotartaric acid, which is the (2*S*,3*S*)-isomer, also known as D-threaric acid (**8-66**). An optically inactive racemic mixture of both isomers, called racemic (uvic) acid, has been demonstrated in grape juice, the optically active symmetric (2*R*,3*S*)-tartaric acid (**8-66**) called *meso*-tartaric or erythraric acid does not occur in nature. Synthetic racemic and *meso*-tartaric acids are used as acidulants.

L-Tartaric acid is found in wines as the poorly soluble potassium hydrogen tartrate salt (potassium bitartrate) that often crystallises in young wines and when the wine is cooled as cream of tartar, known in winemakers' jargon as tartrates. The crystals are harmless, but their presence is generally undesirable to consumers. The cream of tartar formation can be prevented by cold stabilisation of wines.

L-Tartaric acid biosynthesis starts from L-ascorbic acid or from D-gluconic acid (Figure 8.40). In grapes and other plants of the Vitaceae family, tartaric acid arises from the ascorbic acid intermediate D-*xylo*-5-hexulosonic acid via the cleavage between carbons C-4 and C-5. The second option, which is apparently used by most plants (the reaction is catalysed by ascorbate 2,3-dioxygenase), is the ascorbic acid cleavage between carbons C-2 and C-3, which simultaneously yields oxalic acid. The third possibility for the biosynthesis of L-tartaric acid from D-gluconic acid is used mainly by plants of the Fabaceae family.

The optically inactive citric acid (**8-67**) is the most important representative of tricarboxylic hydroxy acids. Citric acid, as well as malic acid, occurs in many fruits (especially in lemons). Industrially, it is obtained from lemon juice or produced by fermentation of molasses using fungi *Aspergillus niger*. Along with malic acid, citric acid is used as an additive in widely different canning products and soft drinks as an acidulant, but also serves in refination (degumming) of vegetable oils and for other purposes.

The malic and citric acids contents in fruits and vegetables are summarised in Table 8.16. In addition to these major acids, other carboxylic acids are also present in smaller amounts, such as tartaric acid, which occurs in higher amounts in grapes. Generally, fruits and vegetables contain, as well as malic, citric and tartaric acids, a number of other acids of which succinic, fumaric, quinic, pyruvic and oxalic acids (together with ascorbic acid) predominate. For example, depending on variety, growing stage and many other factors, the total amount of organic acids in carrots is about 2000–3000 mg/kg. After harvest, isocitric and malic acids represent about 90–95% of the total acids. The content of isocitric and malic acids is approximately 1000 mg/kg and 800 mg/kg, respectively. Tartaric (18–55 mg/kg), succinic (22–130 mg/kg), fumaric (5–8 mg/kg), quinic (42–60 mg/kg) and oxalic acids (100 mg/kg) are found in smaller amounts, as are some other acids in lower amounts.

An isomer of citric acid is (1*R*,2*S*)-1-hydroxypropan-1,2,3-tricarboxylic acid (**8-67**), also known as D-isocitric acid (D-*threo* isomer), which is another intermediate of the citric acid cycle. This acid is the dominant acid in blackberries (Table 8.17) and occurs in other fruits in small or insignificant amounts (e.g. in apples). The isocitric acid content is one of the most important markers in the estimation of the proportion of fruit in coloured fruit mixtures, for example in mixtures of blackcurrants, strawberries and raspberries with apples. The concentration ratio of citric acid to isocitric acid is also employed for the detection of adulteration, and can reveal the addition of synthetic citric acid to optimise the taste of fruit drinks, especially in the case of added sugar.

The hydroxy derivative of citric acid, (1*S*,2*S*)-1,2-dihydroxypropane-1,2,3-tricarboxylic acid, also known as garcinic or (−)-hydroxycitric acid (**8-67**), together with the corresponding γ-lactone, occurs in amounts of 16–18% of dry matter in the skin of the Southeast Asian fruit of *Garcinia gummi-gutta* (syn. *G. cambogia*, Clusiaceae) tree, known as the Malabar tamarind. This fruit is related to the more common mangosteen (*G. mangostana*). Extracts from the fruit rind, called citrin, are used as dietary supplements for weight loss because garcinic acid inhibits the activity of ATP citrate lyase, an enzyme involved in conversion of glucose into fat, thereby reducing the extent of lipogenesis by increasing the formation of glycogen in the liver and suppression of appetite.

The garcinic acid isomer, (1*S*,2*R*)-1,2-dihydroxypropane-1,2,3-tricarboxylic acid, also known as hibiscus acid (**8-67**), is located in the spicy leaves of hibiscus called roselle (*Hibiscus sabdariffa*, Malvaceae), which is prepared like spinach in the tropics. Its fleshy flower calyces, containing intense staining anthocyanine pigments,

Strawberries	30–90	100–230

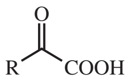
are increasingly used as food colourings and are often added to fruit and herbal teas.

An unusual citric acid derivative is toxic agaricinic (agaric) acid, which occurs in some fungi (see **10-241**). Foods also contain numerous hydroxy acids derived from sugars.

8.2.6.1.4 Aliphatic oxocarboxylic acids

2-Oxocarboxylic acids are major products of the metabolism of proteins, lipids and carbohydrates, and also arise as intermediates in fermentation processes, as products of other enzymatic reactions, which are not linked with the metabolism of major nutrients, and also as products of non-enzymatic reactions. They usually occur in low concentrations in all foods of animal and vegetable origin. Oxoacids are polar and non-volatile compounds, but some of their reaction products are important odour-active substances in foods. An example is 5-ethyl-3-hydroxy-4-methyl-5*H*-furan-2-one (abhexon), which appears in acid protein hydrolysates from threonine via 2-oxobutyric acid.

The simplest 2-oxocarboxylic acid is glyoxylic acid (**8-68**), which occurs in the immature fruits of many plants. Glyoxylic acid is produced as the main intermediate of the glyoxylic acid cycle (ongoing in plants and microorganisms) and is also formed by other biochemical reactions, such as degradation of purine bases,

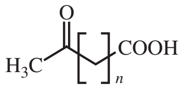


8-68, 2-oxoacids

glyoxylic, R = H
2-oxopropionic (pyruvic), R = CH_3
2-oxobutyric, R = CH_2CH_3
2-oxosuccinic (oxaloacetic), R = CH_2COOH

4-hydroxyproline and other compounds. The key compound of metabolism of carbohydrates, lipids and proteins in animals and plants is pyruvic (2-oxopropionic) acid (**8-68**) that also occurs in fruits and vegetables. It is similarly formed by enzymatic cleavage of alliin and other *S*-alk(en)yl-L-cysteine derivatives in garlic, onion and other plants. Some higher homologues of glyoxylic acid, such as 2-oxobutyric (**8-68**), 2-oxovaleric, 2-oxoisovaleric, 2-oxoisokapronic and 2-oxo-3-methylvaleric acids, are precursors of fusel oil alcohols in alcoholic beverages.

Foods also contain various oxodicarboxylic and oxotricarboxylic acids that arise predominantly in the citric acid or glyoxylic acid cycles. A common acid is oxaloacetic (2-oxosuccinic) acid (**8-68**). 3-Oxoacids are usually represented by acetoacetic (3-oxobutanoic) acid (**8-69**). The main non-volatile dicarboxylic acids, hydroxy acids and oxoacids contents in beer are given in Table 8.18 as an example.

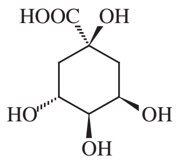


8-69, acetoacetic acid, *n*= 1
laevulinic acid, *n*= 2

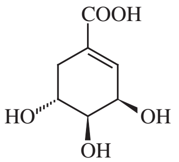
It is common to find laevulinic (4-oxopentanoic) acid (**8-69**) in foods containing carbohydrates, as it is one of the final dehydration products of hexoses via 5-hydroxymethylfuran-2-carbaldehyde in acidic media. It is present in very high concentrations (about 1–2% w/w) in acid hydrolysates of proteins.

8.2.6.1.5 Alicyclic carboxylic acids

One of the most important substances derived from tetrahydroxycyclohexane is (1*S*,3*R*,4*S*,5*R*)-1,3,4,5-tetrahydroxycyclohexane-1-carboxylic acid, known as (−)-L-quinic acid (**8-70**). The trihydroxycyclohexene derivative is related (3*R*,4*S*,5*R*)-3,4,5-trihydroxycyclohex-1-ene-1-carboxylic acid known as (−)-L-shikimic acid (**8-71**), which is a key intermediate in the biosynthesis of phenolic compounds. As free acids, but mainly as esters (depsides) with (*E*)-cinnamic acids (caffeic, ferulic and 4-coumaric acids), both compounds are the major components of coffee beans. In smaller amounts they are found in tea leaves, cocoa beans, fruits, vegetables, potatoes and other plant materials. In the juices of berries (e.g. gooseberries, currants and blueberries) and mango, these acids occur in hundreds of thousands of mg/l, but in other fruits their content is about ten times lower. For example, the quinic acid content can be used to differentiate the North American blueberry products (juices or jams) made from northern high bush blueberries (*Vaccinium corymbosum*, Ericaceae), which contain from 0.37 to 2.53 g/kg quinic acid, from European blueberry (bilberry) products prepared from *V. myrtillus* berries that contain 3.74–7.84 g/kg quinic acid.



8-70, L-quinic acid



8-71, L-shikimic acid

Acid	Content (mg/kg)	Acid	Content (mg/kg)
Succinic	5–166	L-Malic	0–213
L-Lactic	2–362	Citric	5–262
D-Lactic	0–372	Pyruvic	5–230

8.2.6.1.6 Aromatic carboxylic acids

The simplest aromatic carboxylic acid is benzoic acid (**8-72**), which is relatively widespread in plant materials, mainly as 1-*O*-benzoyl-β-D-glucopyranose (see Section 4.3.3.3), but both compounds are non-volatile polar substances that do not have any impact on food flavour. In essential oils, benzoic acid is found in the form of flavour-active esters. Benzoic acid arises from cinnamic acid or cinnamoyl-CoA through side-chain shortening by a C_2 unit. Its content in fruits and vegetables is generally very low, at around 0.05%. In cranberries it is present predominantly as 6-*O*-benzoyl-β-D-glucopyranose, known as vaccinin (see **4-92**), in an amount of around 0.2%. Free benzoic acid is also present in a very small amount (about 0.0015%) in yoghurts where it results from hippuric acid hydrolysis. It is often also added to foods as a preservative. A typical example of a preserved product is table mustard, where concentrations of benzoic acid typically reach 1000 mg/kg.

Benzoic acids substituted by hydroxyl and methoxyl groups (**8-72**) are produced through different biochemical mechanisms. In the shikimate pathway via shikimic acid (its precursors or metabolites), 2-hydroxybenzoic (salicylic), 4-hydroxybenzoic, 2,3-dihydroxybenzoic, 3,4-dihydroxybenzoic (protocatechuic) and 3,4,5-trihydroxycarboxylic (gallic) acids are formed. Salicylic acid occurs in small quantities (0.3–3 mg/kg) in different types of fruit. It is also present in the form of glycosides and esters. Salicylic acid participates in thermogenesis, the metabolism of minerals, induces plant flowering, affects ethylene biosynthesis, resistance to pathogens and other processes. A mixture of 6-alkatrienyl, 6-alkadienyl, 6-alkenyl and 5-alkyl substituted salicylic acids, collectively known as anacardic acid, occur in the cashew nutshell liquid at a level of 60–65%, together with decarboxylated products known as cardol (see Section 10.2.3.4) and the corresponding phenols that are called cardanol (see Section 8.2.8.1). The main components are (8*Z*,11*Z*)-2-hydroxy-6-(pentadeca-8,11,14-trien-1-yl)benzoic acid, (8*Z*,11*Z*)-2-hydroxy-6-(pentadeca-8,11-dien-1-yl)benzoic acid, (8*Z*)-2-hydroxy-6-(pentadeca-8-en-1-yl)benzoic acid and 2-hydroxy-6-pentadecylbenzoic acid. Anacardic acid possesses antimicrobial, antiacne and other medicinal properties. Owing to its antimicrobial effects, 4-hydroxybenzoic acid has found use as a preservative mainly in the form of esters (so-called parabens). 2,3-Dihydroxybenzoic acid is a part of various bacterial

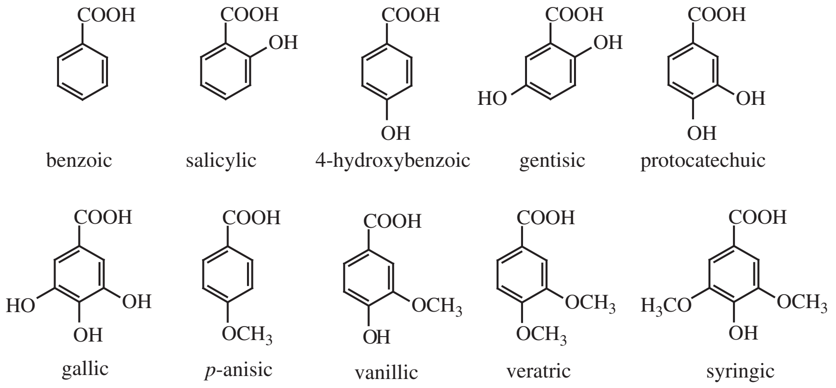
siderophores (see Section 6.3.6.1.2), 2,4-dihydroxybenzoic (β-resorcylic or *p*-hydroxysalicylic) acid is a common phenolic acid in wheat and rye, 2,5-dihydroxybenzoic (gentisic) acid occurs in wine and 3,4-dihydroxybenzoic (protocatechuic) acid is an effective antioxidant in fruits, vegetables and also *in vivo*. Gallic acid is present in foods of plant origin in small amounts as the free acid. The frequently occurring gallic acid dimer is known as ellagic acid. Gallic acid is usually present in a number of other related compounds, which, like gallic acid, are components of hydrolysable tannins (see Section 8.3.5.1).

Analogously, various hydroxy- and methoxy substituted benzoic acids are formed in plants by shortening of the side chain of hydroxy- and methoxy substituted cinnamic acids by C_2 units (**8-72**). The hydroxy- and methoxy substituted precursors are biosynthesised from cinnamic acid and also arise as lignin degradation products with some bacteria and fungi. Relatively common substances are 4-hydroxybenzoic and 2,5-dihydroxybenzoic (gentisic) acids. The latter acid occurs in significant quantities, for example in cocoa, and is used as an antioxidant in some pharmaceutical products. 4-Methoxybenzoic (*p*-anisic) acid is found in anise, 4-hydroxy-3-methoxybenzoic (vanillic) acid accompanies vanillin in vanilla pods, other acids, such as 3-hydroxy-4-methoxybenzoic (isovanillic), 3,4-dimethoxybenzoová (veratric) acid, 3,4-dihydroxy-5-methoxybenzoic (3-*O*-methoxygallic) acid and 4-hydroxy-3,5-dimethoxybenzoic (syringic) acid occur in small amounts in all foods of plant origin.

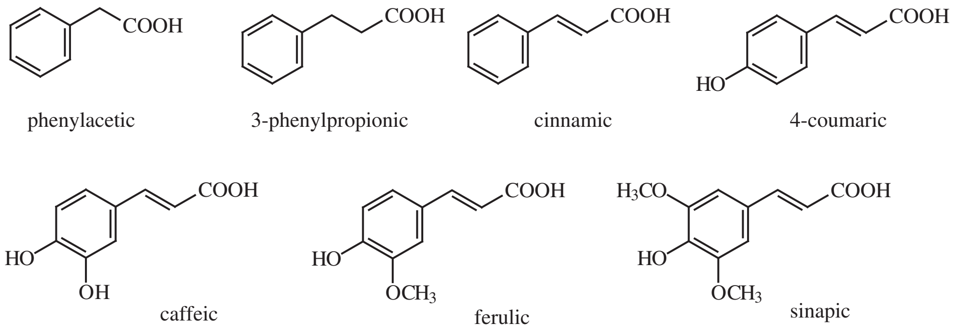
Higher homologues of benzoic acid are phenylacetic and 3-phenylpropionic acids (**8-73**), which result from the microbial degradation of organic matter (such as lignin) and by oxidation of the corresponding aldehydes. Phenylacetic acid has a low odour threshold concentration and is reminiscent of honey. In the form of esters it is often present in some essential oils, and is also used in perfumery. 3-Phenylpropionic acid is found at low concentrations in cheeses produced in the presence of molds.

The most common unsaturated aromatic carboxylic acid is cinnamic acid (**8-73**). In cinnamon and other spices the (*E*)-isomer predominates. Cinnamic acid oxidation products are 4-hydroxycinnamic acid (also known as 4-coumaric or *p*-coumaric acid) and 3,4-dihydroxycinnamic acids, which is called caffeic acid. A 3-methoxy derivative of caffeic acid is ferulic acid and the 3,5-dimethoxy derivative is known as sinapic acid.

The content of the major phenolic acids in different fruits differs qualitatively and quantitatively, and changes significantly during fruit growth and ripening. For example, apples at harvest time contain in their fresh weight about 12 mg/kg *p*-coumaric, 85 mg/kg caffeic and 4 mg/kg ferulic acid. At maturity, the content of these acids is 1.9, 10.4 and 0.4 mg/kg, respectively. Ripe strawberries contain as the main acid *p*-coumaric acid (175 mg/kg) and present in larger quantities are gallic (121 mg/kg), 4-hydroxybenzoic acid (108 mg/kg), caffeic (39 mg/kg) and vanillic (34 mg/kg) acids. In cereal grains, phenolic acids are concentrated in the aleurone cells and other outer layers of the grain that form the bran on



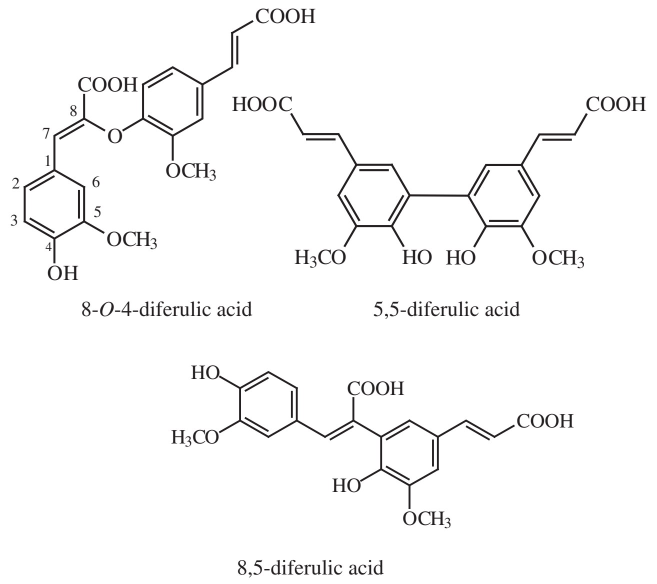
8-72, benzoic acid and substituted benzoic acids



8-73, higher homologues of benzoic acid and common (*E*)-cinnamic acids

milling. They are present mainly in the bound forms, linked to cell wall structural components, such as cellulose, lignin and proteins. The majority of the feruloyl groups are attached to the cell wall arabinoxylan via the carboxyl groups acylating the primary hydroxyl groups at the C-5 positions of the α-L-arabinofuranosyl residues. It has been shown that ferulates can form dimers through oxidative cross-linking between esterified feruloyl groups, which may serve to cross-link cell-wall polysacharides. The main ferulic acid dehydrodimer is 8-*O*-4-diferulic acid. Examples of other dehydrodimers are 5,5- and 8,5-diferulic acids (**8-74**). Sinapic acid dehydrodimers and sinapate-ferulate heterodimers have also been identified in cereal grain dietary fibers. The phenolic acids contents in different wheat species and rye cultivars are given as an example in Table 8.19. Their content in beer is illustrated in Table 8.20.

Cinnamic acids are present in plant tissues as free substances, but in larger quantities are found as esters, amides or glycosides. An example is a glycoside with antioxidant effects, (*E*)-1-*O*-sinapoyl-β-D-glucopyranose (**8-75**), occurring in germinating seeds of cruciferous plants (Brassicaceae), where it is produced from sinapine. An effective antioxidant in olives (*Olea europea*, Oleaceae) and also of some mullein species (*Verbascum sinuatum*, Scrophulariaceae) and perhaps of other plants, is verbascoside (**8-76**), a glycoside derived from 3,4-dihydroxyphenylethanol (hydroxytyrosol). The sugar component is the disaccharide 6-deoxy-β-D-glucopyranosyl-(1→3)-β-D-glucopyranose (chinovose) esterified by (*E*)-caffeic acid.



8-74, ferulic acid dimers

8.2.6.1.7 Heterocyclic carboxylic acids

In addition to benzoic and cinnamic acids, plant materials and foods contain a number of heterocyclic carboxylic acids, the most

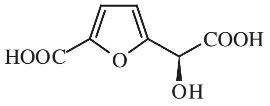
common of which are carboxylic acids with substituted furan and 4*H*-pyran (γ-pyran) skeletons. Examples of these acids are furan-2-carboxylic acid, which arises, for example, by oxidation of furan-2-carbaldehyde and by degradation of ascorbic (dehydroascorbic) acid. Analogously, oxidation of 5-hydroxymethylfuran-2-carbaldehyde yields 5-hydroxymethylfuran-2-carboxylic acid. A number of biologically active C_7 dicarboxylic acid are synthesised by plants across a range of plant families, such as carrots, wheat, sunflower, sugar beet and tobacco, as secondary metabolites . Examples of these carboxylic acids are vasorelaxation active (+)-osbeckic acid found, for example, in buckwheat, (−)-daucic acid from carrot with antioxidative activity, chelidonic acid that is active in allergic reactions, first identified in celandine (*Chelidonium majus*, Papaveraceae) sap and antiinflammatory and antibacterial meconic acid, which is found in plants of the Papaveraceae family, such as *Papaver somniferum* (opium poppy) (**8-77**). These acids occur either free or esterified with various phenolic acids. An example of such esters is 4,5-di-*O*-caffeoyldaucic acid found in tubers of sweet potato (*Ipomoea batatas*, Convolvulaceae).



(+)-osbeckic acid

meconic acid

8-77, *O*-heterocyclic carboxylic acids

Several carboxylic acids are also derived from various *S*- and *N*-heterocyclic compounds. Many of them are natural biologically active compounds and other acids are formed during food processing. Examples are some vitamins, such as biotin, lipoic acid, nicotinic acid, 4-pyridoxic acid or orotic acid. Yeast autolysates, for example, contain a number of carboxylic acids derived from thiophene.

8.2.6.2 Properties and reactions

8.2.6.2.1 Properties

In solutions and also in the gaseous state, carboxylic acids are molecules associated by hydrogen bonds. The acidity of carboxylic acids is conditioned, according to electron theory, by the presence of carbonyl groups, which facilitate the dissociation of the hydroxyl to carboxylate anion:

$$R-COOH + H_2O \rightleftharpoons R-COO^- + H_3O^+$$

The strength of acids (their acidity) is expressed by their dissociation constants K_a, which depend on temperature and type

Table 8.21 Dissociation constants of acids.

Acid	pK_a value at 25 °C			Acid	pK_a value at 25 °C		
	pK_{a1}	pK_{a2}	pK_{a3}		pK_{a1}	pK_{a2}	pK_{a3}
Formic	3.75	-	-	Glyoxylic	2.98	-	-

of solvent (its relative permittivity).[4] The acidity of carboxylic acids lies between the strong mineral acids and carbonic acid. An overview of pK_a values of some acids is given in Table 8.21.

The dissociation of acids is influenced considerably by other functional groups in the vicinity of the carboxyl group. If in the neighbourhood there is a group repelling electrons (+I effect), such as alkyl, the acid is a weak acid (the K_a value is lower). Electronegative substituents in the vicinity of the carboxyl group, such as hydroxyl or carbonyl group, facilitate dissociation (–I effect). The inductive effects are less observable (or not at all) with increasing distance from the carboxyl group. The strongest aliphatic monocarboxylic acid is therefore formic acid, and hydroxycarboxylic acids and oxocarboxylic acids are stronger acids than the corresponding unsubstituted carboxylic acids.

8.2.6.2.2 Reactions

The most common chemical transformations of carboxylic acids in food are reactions caused by the cleavage of the O–H bond of the carboxylic group (salt formation), esterification, decarboxylation and reactions ongoing on the hydrocarbon residue.

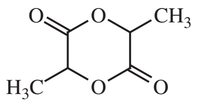
Reactions of aliphatic unsubstituted carboxylic acids

The most important reaction is the formation of salts and esters. Acids usually eliminate carbon dioxide with difficulty. The prominent reaction of higher fatty acids is oxidation of the hydrocarbon chain.

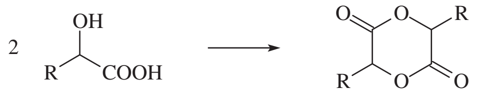
[4]Dissociation constants of acids $K_a = \frac{[RCOO^-][H_3O^+]}{[RCOOH]}$; values in parentheses are the molar concentrations. The K_a value includes the almost constant molar concentration of water. Negative decimal logarithms of dissociation constants K_a, which are referred to as pK_a values, are used for practical purposes.

Reactions of hydroxycarboxylic acids

Heating aliphatic α-hydroxycarboxylic acids leads to their dehydration and the formation of six-membered cyclic esters, derivatives of 1,4-dioxane, that are called lactides (Figure 8.43). Lactic acid is an α-hydroxy acid, which forms a cyclic diester 3,6-dimethyl-2,5-dioxo-1,4-dioxane (**8-78**) by heating. Heating of 3-hydroxy acids (β-hydroxy acids) leads to elimination of water to form α,β-unsaturated (alk-2-enoic) acids (Figure 8.44). Heating of γ- and δ-hydroxy acids leads to intramolecular esterification to form **lactones** (γ- and δ-lactones, Figure 8.45 and Figure 8.46). Higher lactones than δ-lactones do not result from hydroxy acids.

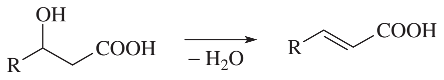


8-78, 3,6-dimethyl-2,5-dioxo-1,4-dioxane



2-hydroxycarboxylic acid — lactide (2,5-dioxo-1,4-dioxane)

Figure 8.43 Dehydration of α-hydroxycarboxylic acids.



3-hydroxycarboxylic acid — alk-2-enoic acid

Figure 8.44 Dehydration of β-hydroxycarboxylic acids.

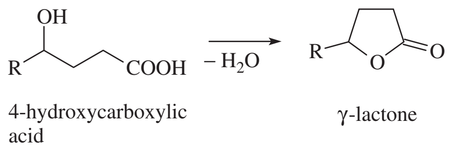


Figure 8.45 Dehydration of γ-hydroxycarboxylic acids.

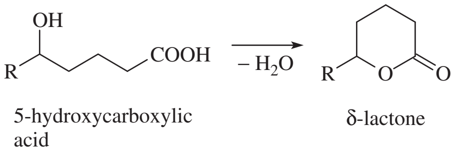

Figure 8.46 Dehydration of δ-hydroxycarboxylic acids.

Hydroxycarboxylic acid with the hydroxyl groups at distant carbons in the molecule, such as ricinoleic acid and related hydroxy fatty acids, yield internal esters called **estolides** upon heating. Estolides have also been found in oxidised lipids (see Section 3.8.1.14).

Malic acid dehydrates to form maleic acid when heated. During wine aging, tartaric acid yields 2,3-dihydroxymaleinic, (*S*)-2-hydroxy-3-oxobutanedioic, 2,3-dioxobutanedioic, formylglyoxylic (the precursor of glyoxal) and 2-hydroxymalonic (tartronic) acids (Figure 8.47). Heating of tartaric acid to temperatures of about 150 °C yields metatartaric acid lactide (see **11-39**). At higher temperatures, dehydration and isomerisation (as with β-hydroxy acids) leads to the formation of an intermediate oxosuccinic acid (Figure 8.48), decarboxylation of which (it behaves as α-hydroxy acid) yields pyruvic acid. Citric acid at temperatures around 150 °C (e.g. during roasting coffee or when it is used as a synergist in oil deodorisation) decomposes to form anhydrides, which react with water to form aconitic, itaconic and citraconic acids (Figure 8.49). Isomerisation of itaconic acid gives rise to citraconic acid.

Reactions of oxocarboxylic acids

Thermal degradation of 2-oxocarboxylic acids (α-ketocarboxylic acids) proceeds with elimination of carbon monoxide (decarbonylation, Figure 8.50) and the formation of the corresponding carboxylic acids. Heating of 3-oxoacids (β-keto acids) leads to decarboxylation and the formation of alkyl methyl ketones (Figure 8.51). Higher keto acids, such as γ-keto acids, partly isomerise by heating to the corresponding unsaturated hydroxy acids that form lactones by dehydration. For example, laevulinic acid yields two isomeric lactones, α-angelica lactone (see **8-101**, later) and β-angelica lactone (see **8-102**, later).

Reactions of aromatic carboxylic acids

Phenolic acids are precursors of a number of simple phenols, which result from the activities of microorganisms or during thermal processes. The main products of thermal degradation of cinnamic acids are 4-vinyl phenols that arise as decarboxylation products. The subsequent reactions yield the corresponding 4-formyl phenols, 4-ethyl phenols, 4-(prop-2-en-1-yl) phenols, 4-acetyl phenols

and many other compounds. Oxidation of phenolic acids and formation of condensation products are described in Section 9.12.4.

8.2.7 Functional derivatives of carboxylic acids

Numerous functional derivatives of carboxylic and substituted carboxylic acids have been found to be natural food components. In particular, important compounds are esters, lactones, anhydrides, amides and nitriles. The most important functional derivatives of carboxylic acids that act as odour-active substances are esters and lactones.

8.2.7.1 Classification, structure, nomenclature and occurrence

8.2.7.1.1 Esters

Volatile esters of aromatic carboxylic acids are often important components of plant floral scents, spices, fruits and vegetables. More than 1000 different compounds have been identified. In the flowers of plants, esters serve as signalling molecules, attractants, repellents and act in various defence mechanisms.

Numerous non-volatile esters derived from cinnamic acids are present in fruits, cereals, flowers, medicinal herbs, spices, fruits and vegetables. For example, common esters in grapes are diethyl malate and diethyl tartrate and depsides of tartaric acid with phenolic acids. An important group of non-volatile esters occurring in many plant materials are phenolic acid depsides with quinic, shikimic, malic and tartaric acids. For example, in coffee, esters of (*E*)-cinnamic acids with L-quinic acid, known as chlorogenic acid, occur. Most of these esters have virtually no effect on the odour of foods. However, they can influence the taste and colour of the foods, either by themselves or through some of their reaction products. For example, chlorogenic acid contributes to the bitter taste of coffee and has antioxidant, hypoglycaemic, antiviral, hepatoprotective and immunoprotective effects.

Esters of higher fatty acids are classified either as lipids or lipid accompanying substances. Some of these (esters of higher fatty acids with lower aliphatic alcohols, such as ethanol) are odour-active constituents found mainly in alcoholic beverages, but they usually only affect the taste or are flavour-indifferent substances.

Certain esters of higher fatty acids (e.g. esters of xanthophylls) are important colouring substances in foods of plant origin.

Volatile esters

Esters, reaction products of carboxylic acids with alcohols of general formula R^1-COOR^2, belong to the most widely occurring compounds in foods. They are often accompanied by the corresponding carboxylic acids and alcohols. The odour-active esters are mostly common esters of monocarboxylic acids, while esters of polycarboxylic acids are found less frequently. Alcohols bound in esters are either monohydric alcohols (containing only one hydroxyl group in each molecule) or polyhydric alcohols. Esters of lower aliphatic acids with lower aliphatic and aromatic alcohols are common odour-active compounds. They are especially important components of the primary flavour of fruits, vegetables, beverages and various spices. These esters arise by alcoholysis of acyl coenzymes A:

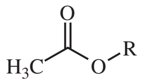
$$R^1\text{–CO–SCoA} + R^2\text{–OH} \rightarrow R^1\text{–CO–O–}R^2 + \text{HS–CoA}$$

For example, acetyl-CoA produces ethyl acetate by ethanolysis. In disrupted plant tissues, for example during production of juices, esters are rapidly broken down by various hydrolases, which results in a change of the flavour character. Also, many esters of aromatic acids are components of the aroma of fruits and spices.

During heating and long storage of foods, esters may also be formed in small quantities as secondary odour-active compounds. For example, esters are formed during aging of wines and spirits by esterification of carboxylic acids with alcohols (ethanol or fusel oil alcohols, but the non-enzymatic esterification is a very slow reaction), acidolysis (reaction of acids with esters), alcoholysis (reaction of alcohols with esters) or ester exchange (reaction of esters with other esters).

The lower fatty acid most frequently bound in esters is acetic acid, while formic, propionic, butyric and isobutyric acids occur less often. The common alcohol bound in esters is ethanol. However, esters of methanol, allyl alcohol, butan-1-ol; higher alcohols and very often esters of monoterpenic and aromatic alcohols also occur in foods, and esters of sulfur-containing alcohols are also common. Esters of low molecular weight acids and alcohols usually have a fruity odour; esters of terpenic alcohols with low molecular weight acids tend to have fragrant odours resembling flowers. Esters of aromatic acids and aromatic alcohols generally have heavy balsamic odours.

The most common ester of alcoholic beverages is ethyl acetate (**8-79**). In beer, for example, ethyl acetate concentrations range from 25 to 33 mg/l and in wines from 11 to 261 mg/l. Its threshold concentration is 150–170 mg/l; therefore ethyl acetate in wines very often acts as an odour-active component. Ethyl acetate in spirits (such as whisky) is present at levels of 45–460 mg/l.



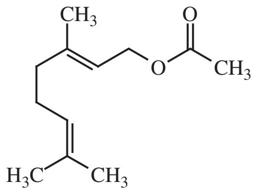
8-79, acetic acid esters (acetates)

ethyl acetate, R = CH_2CH_3
isobutyl acetate, R = $CH_2CH(CH_3)_2$
isopentyl acetate, R = $CH_2CH_2CH(CH_3)_2$

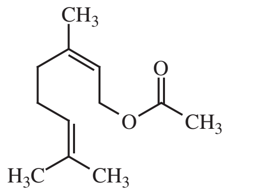
Other esters present in high concentrations in alcoholic beverages include isoamyl acetate and isobutyl acetate (**8-79**) that arise, as well as ethyl acetate, by alcoholysis of acetyl-CoA through the respective alcohols. Isobutyric and isovaleric acids yield virtually no esters in beer and wine, as the non-enzymatic esterification is too slow and the equilibrium is shifted to the detriment of esters. In spirits, these esters occur at levels up to units of mg/l.

Fatty acids bound in esters tend to have an even number of carbon atoms. These esters belong to the most aromatic substances influencing the bouquet of wines. For example, they are an important carrier of the fine flavour of Riesling wines and occur in larger quantities in heavy aromatic varieties such as Traminer, Muscat Ottonel and Sauvignon. The content of the main esters in wines is presented in Table 8.22. The ester content of musts is about ten times lower. Some sulfur-containing esters are also characteristic aromatic constituents of wines. For example, 3-mercaptohexyl acetate, produced by the fermentation of 3-mercaptohexan-1-ol (**8-15**), may occur in some wines (such as Traminer and Riesling) at a level of 0.5 μg/l, which is perceived as a fruity flavour.

Terpenoid esters occur in various fruits and many spices. Examples are the fairly widespread geranyl (**8-80**) and neryl acetates (**8-81**), which are components of citrus oils and odours of some spices (such as coriander).



8-80, geranyl acetate



8-81, neryl acetate

Table 8.22 Content of main esters in wines.

Ester[a]	Content (mg/kg)	Ester[a]	Content (mg/kg)
Ethyl acetate	11–261	Ethyl butyrate	0.2–4
Isobutyl acetate	0.1–11	Ethyl capronate	0.2–9
Isoamyl acetate	0.9–12	Ethyl caprylate	0.3–9
Hexyl acetate	0–9	Ethyl caprinate	0.1–9
Fenylethyl acetate	0–9	Ethyl lactate	12–378

[a] Composition refers to wines from the common grape vine *Vitis vinifera* (Vitiaceae). The natural component of grapes and wines from fox grape (*V. labrusca*) and some of its hybrids, originating in North America, is methyl anthranilate and ethyl anthranilate. In wines, these esters occur at levels up to 3.1 mg/l. Along with 2-aminoacetophenone formed by degradation of tryptophan, these esters may cause the characteristic unpleasant odour.

Non-volatile esters

The main aromatic carboxylic acids of coffee are **chlorogenic acids**, esters (depsides) of L-quinic acid with predominantly (*E*)-cinnamic acid, caffeic, ferulic and 4-coumaric acids. In smaller amounts, chlorogenic acids are found in tea, cocoa, apples and pears, in other fruits and in vegetables and potatoes.

Green and roasted coffees, for example, contain more than 50 esters of cinnamic acids. Their level in green coffee beans ranges from 4 to 14%. The main groups are caffeoylquinic, dicaffeoylquinic, feruloylquinic, *p*-coumaroylquinic and caffeoyl-feruloylquinic acids. Moreover, all esters and diesters of quinic acid are found in three types of positional isomers that include 3-*O*-esters, 4-*O*-esters and 5-*O*-esters. The main component is chlorogenic acid, that is 3-*O*-caffeoyl-L-quinic acid, but this name also refers to all the natural quinic acid esters. The structures of the basic esters and diesters of caffeoylquinic acids are given in formulae **8-82**.

Numerous minor chlorogenic acids have recently been identified in coffee, which include diferuloylquinic, di-*p*-coumaroylquinic, dimethoxycinnamoylquinic and other chlorogenic acids, such as 3,4-di-*p*-coumaroylquinic, 3,5-di-*p*-coumaroylquinic and 4,5-di-*p*-coumaroylquinic acids; 3-*p*-coumaroyl-4-caffeoylquinic, 3-*p*-coumaroyl-5-caffeoylquinic, 4-*p*-coumaroyl-5-caffeoylquinic, 3-caffeoyl-4-*p*-coumaroylquinic, 3-caffeoyl-5-*p*-coumaroylquinic and 4-caffeoyl-5-*p*-coumaroylquinic acids; 3-*p*-coumaroyl-4-feruloylquinic, 3-*p*-coumaroyl-5-feruloylquinic and 4-*p*-coumaroyl-5-feruloylquinic acid; and 4-dimethoxycinnamoyl-5-*p*-coumaroylquinic acid. The minor chlorogenic acids amount to less than 1% of all chlorogenic acids.

The chlorogenic acids content in roasted coffee and coffee beverages depend on the type and method of roasting the coffee seeds. Of about 80 varieties of three coffee trees, namely Arabic coffee (*Coffea arabica*, Rubiaceae), robusta coffee (*C. canephora*) and Liberian coffee (*C. liberica*), only the first two species are of commercial importance. *C. arabica* (the most common varieties are *typica*, *bourbon*, *mocha* and *maragogips*) represents about 75%, *C. canephora* (varieties *robusta*, *typical* and others) represents about 25% and *C. liberica* about 1% of world production. All varieties of *C. canephora* are commercially known by the name robusta. Their seeds have a higher content of chlorogenic acids than the seeds of *C. arabica*. Acid	Content (mg/kg)	Acid	Content (mg/kg)
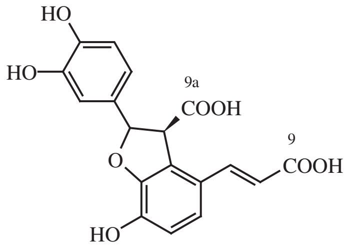
3-Caffeoylquinic (chlorogenic)	20	3,4-Dicaffeoylquinic (isochlorogenic a)	0.1
4-Caffeoylquinic (cryptochlorogenic)	2	3,5-Dicaffeoylquinic (isochlorogenic b)	0.9
5-Caffeoylquinic (neochlorogenic)	1	4,5-Dicaffeoylquinic (isochlorogenic c)	0.1

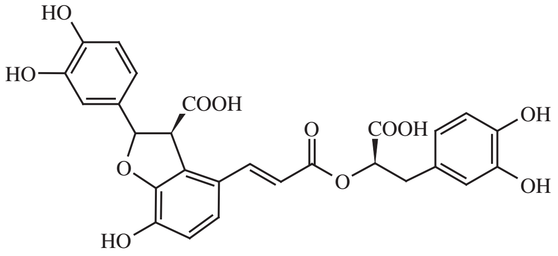
(caffeoyl-feruloyl quinic acids) and derivatives of some amino acids (such as *N*-caffeoyl-L-tryptophan and *N*-caffeoyl-L-tyrosine) are found only in the robusta coffee.

During roasting of coffee seeds, about 30–70% chlorogenic acids are transformed into γ-lactones of 3-*O*- and 4-*O*-cinnamoylquinic acids (cinnamoyl-1,5-quinolactones) and other products. These lactones are the most important bitter substances of roasted coffee. The main component is 3-*O*-caffeoyl-L-quino-1,5-lactone, also known as 3-*O*-caffeoyl-γ-quinide (see Section 8.3.5.1.4). The levels of chlorogenic acids in roasted coffee are given in Table 8.23. The chlorogenic acids contents in coffee surrogates, for example in roasted chicory root, are lower than in roasted coffee seeds. Raw potatoes contain 100–200 mg/kg of chlorogenic acids, their content in boiled potatoes is about 35% of this amount, and the content in baked potatoes is almost negligible.

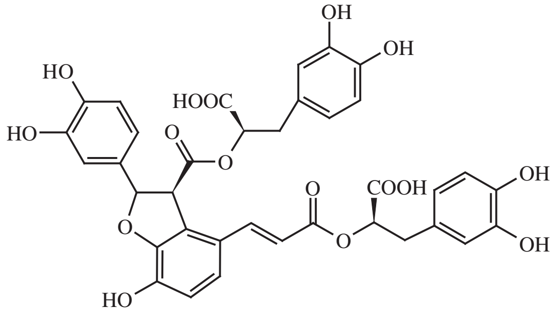
Some other caffeic acid esters found in aromatic and medicinal plants have significant antioxidant and other biological effects. An example is caffeic acid ester with (+)-(*R*)-3,4-dihydroxyphenyllactic acid known as rosmarinic acid (**8-83**), which is an important antioxidant distributed mainly in plants of the mint family (*Lamiaceae*). These plants include rosemary (*Rosmarinus officinalis*), oregano (*Origanum vulgare*), sage (*Salvia officinalis*) and thyme (*Thymus vulgaris*). For example, rosmarinic acid and more than 20 caffeic acid derivatives, including various oligomers, have been isolated from red sage, also known as Chinese sage (*Salvia miltiorrhiza*), the root of which is used in traditional Chinese medicine against coronary and cerebrovascular diseases, various types of hepatitis and chronic renal disease. Examples of oligomers of the dihydrobenzofuran type is a dimer called prolithospermic acid (**8-84**), lithospermic acid (**8-85**) (a trimer), and lithospermic acid B, also known as salvianolic acid B (**8-86**), which is a tetramer. In lithospermic acid and lithospermic acid B, the C-9 (and respectively C-9a) carboxyl of prolithospermic acid is esterified with 3,4-dihydroxyphenyllactic acid. The plant also contains a number of diterpenoids with antioxidant effects.



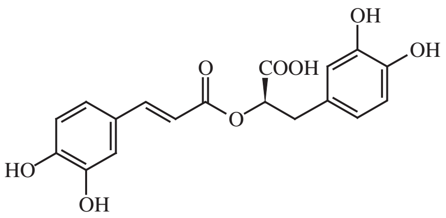
8-84, prolithospermic acid



8-85, lithospermic acid



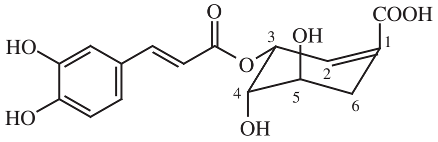
8-86, lithospermic acid B



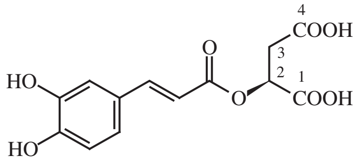
8-83, rosmarinic acid

A representative of shikimic acid depsides is 3-*O*-caffeoyl-L-shikimic acid, known as dactyliferic acid (**8-87**), which occurs in dates. This acid and other related depsides are substrates of oxidoreductases in enzymatic browning reactions in dates. The seeds and shoots of plants of the genus *Brassica* of the cabbage family (Brassicaceae) contain various esters of cinnamic acids with malic

acid, such as 2-*O*-(4-coumaroyl)-L-malic, 2-*O*-caffeoyl-L-malic (**8-88**), 2-*O*-feruloyl-L-malic and 2-*O*-sinapoyl-L-malic acids.



8-87, 3-*O*-caffeoyl-D-shikimic acid



8-88, 2-*O*-caffeoyl-L-malic acid

Grape musts and wines contain depsides of some phenolic acids with L-tartaric acid. Common esters are depsides of caffeic (**8-89**), 4-coumaric and vanillic acids. For example, the vanilloyltartaric acid content in musts and wines ranges from 1.4 to 11.7 mg/l, and of 4-coumaroyltartaric (cutaric) acid and caffeoyltartaric (caftaric) acid is 0.6–5.5 and 10.2–26.9 mg/l, respectively. In all these depsides, (*E*)-isomers dominate. 2,3-Di-*O*-caffeoyl-L-tartaric acid, known as cichoric acid (**8-90**), is an example of diesters of L-tartaric acid, which occur in plants of the Asteraceae family. Cichoric acid is situated in the root and leaves of chicory (*Cichorium intybus*), endive (*C. endivia*) and lettuce (*Lactuca sativa*).

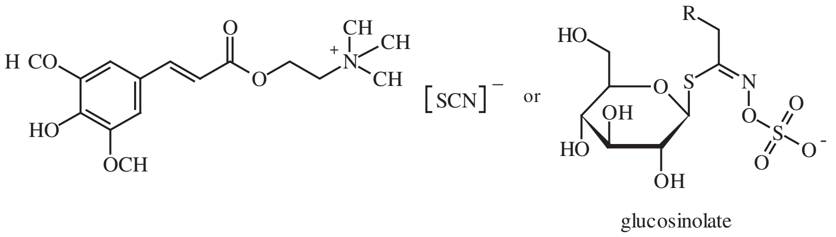
8-92, esters of 5-hydroxymethylfuran-2-carbaldehyde with malic acid

Esters of sinapic acid, such as *O*-sinapoyl choline (**8-93**) and sinapoyl malate (2-*O*-sinapoyl-L-malic acid; **8-94**), are found primarily in cruciferous plants (Brassicaceae), where they belong to the main phenylpropanoids accumulated. Their counter ions are normally thiocyanate ions ($S{=}C{=}N^- \leftrightarrow {}^-S{-}C{\equiv}N$) and in the intact seeds, glucosinolates. Sinapine-glucoraphanin salt (see Table 10.13) has recently been isolated from broccoli seeds. Sinapoyl choline is found exclusively in plant seeds, which means that it occurs also in the seeds of oilseed rape (rape seed, *Brassica napus*) and turnip rape (*B. rapa*, syn. *B. campestris*), used as a source of rapeseed oil. The seeds contain up to 1% sinapoyl choline, known as sinapine. In sinapine both sinapic acid isomers occur, but the (*E*)-isomer always prevails (**8-93**). The term sinapines is used generally for all choline esters with phenolic acids. The composition of phenolic acids in rapeseed flour is shown in Table 8.24. About 85% of phenolic acids are bound in sinapines, while the rest are free acids or their glycosides. 4-Hydroxybenzoic acid, rather than sinapic acid, prevails in the white mustard seeds (*Leucosinapis alba*, syn. *Brassica alba*) that are used raw or roasted in dishes, and mixed with other ingredients are used to produce a mustard paste or sauce that is used as a condiment.

In germinating seeds, the choline esters are transformed into the corresponding malates. In young plants 2-*O*-sinapoyl-L-malic acid predominates (**8-94**), while the main depsides in older plants are 2-*O*-(4-coumaroyl)-L-malic acid and 2-*O*-caffeoyl-L-

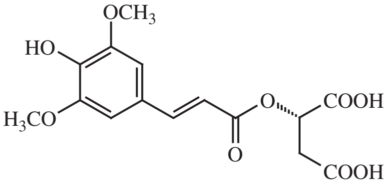
Table 8.24 Phenolic acids in rapeseed flour.

	Content (mg/kg)			Content (mg/kg)	
Acid	Free acids	Esters	Acid	Free acids	Esters
Salicylic	1-31	7-10	*o*-Coumaric	3-11	-
Gentisic	Traces-8	Traces-9	*p*-Coumaric	Traces-30	Traces-8
4-Hydroxybenzoic	0-22	Traces-27	(*E*)-Caffeic	Traces-18	0-Traces
Protocatechuic	4-14	Traces-18	(*Z*)-Caffeic	-	Traces-21
Vanillic	Traces-9	Traces-12	(*E*)-Ferulic	9-47	8-79
Syringic	1-24	Traces-23	(*E*)-Sinapic	35-516	1713-5971
Cinnamic	Traces-10	-	(*Z*)-Sinapic	32-101	445-989



8-93, (*E*)-*O*-sinapoyl choline thiocyanate and its counter ions

malic acid. Sinapoyl malate protects plants against UV-B radiation (280–320 nm); the function of sinapoyl choline is still mainly unknown.

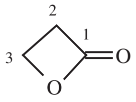


8-94, 2-*O*-sinapoyl-L-malic acid

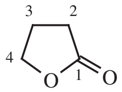
Sinapoyl esters are considered antinutritional compounds because they have a bitter and astringent taste, thus contributing to the bitter taste of rapeseed meal. The intensity of the bitter taste is comparable to the intensity of the bitter taste of caffeine. In the refining of rapeseed oil, sinapines form complexes with proteins. They show lower antioxidant activity than the corresponding phenolic acids and do not have antimicrobial effects. Sinapines present in the feed of some breeds of laying hens cause an off-flavour and fish-like odour of yolks.

8.2.7.1.2 Lactones

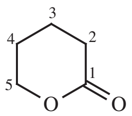
Lactones are internal esters of hydroxycarboxylic acids. They are characterised by the number of carbon atoms (methylene groups) present between the carboxyl group and carbon to which is bound the hydroxyl group. β-Lactones ($n = 1$) (**8-95**), γ-lactones ($n = 2$) (**8-96**) and δ-lactones ($n = 3$) (**8-97**) have been identified. γ-Lactones and δ-lactones are formed by dehydration of the hydroxy acids. Dehydration of β-hydroxy acids, however, does not produce β-lactones, but gives rise to α,β-unsaturated carboxylic acids.



8-95, β-propiolactone



8-96, γ-butyrolactone

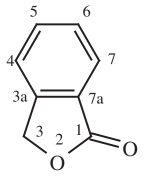


8-97, δ-valerolactone

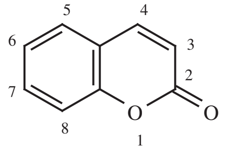
Nomenclature of lactones is based on the nomenclature of hydroxycarboxylic acids. The simplest β-lactone hypothetically derived from β-hydroxycarboxylic acids is propano-3-lactone (formerly also known as 3-propanolide and β-propiolactone, **8-95**), which can be considered an internal ester of 3-hydroxypropanoic acid. The simplest γ-lactone is butano-4-lactone, also known as 4-butanolide or γ-butyrolactone (**8-96**), which is derived from 4-hydroxybutanoic acid. The basic member of the homologous series of δ-lactones is pentano-5-lactone, also known as 5-pentanolide or δ-valerolactone (**8-97**), which is derived from

5-hydroxypentanoic acid. Lactones can also be considered as oxygen heterocyclic compounds. β-Lactones are actually oxetanes, γ-lactones are oxolanes or tetrahydrofuranes and δ-lactones are oxanes or tetrahydropyranes.

Lactones occur as natural odorants in all major food commodities, including meat and meat products, milk, dairy products, cereals, fruits, vegetables and various beverages, such as tea, wine and spirits. Odour-active compounds in foods are γ- and δ-lactones derived from aliphatic saturated and unsaturated γ-hydroxycarboxylic and δ-hydroxycarboxylic acids derived from fatty acids or sugars, but some lactones also arise from other precursors (e.g. mint lactone is a terpenoid compound and pantolactone is produced by hydrolysis of pantothenic acid via pantoic acid). Some lactones derived from aromatic hydroxycarboxylic acids are also common compounds. The most important representatives of these compounds are phthalides that are 3*H*-isobenzofuran-1-ones (**8-98**) and coumarins (**8-99**) that are 2*H*-1-benzopyran-2-ones (δ-lactones of 2-hydroxycinnamic acids).



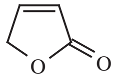
8-98, phthalide



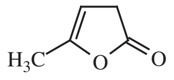
8-99, coumarin

Lactones of aliphatic hydroxycarboxylic acids

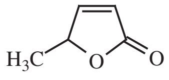
The simplest lactones are γ-butyrolactone (butane-4-lactone, **8-96**) and γ-crotonolactone (but-2-eno-4-lactone, **8-100**). These compounds are found as common constituents of many foods in small amounts. γ-Butyrolactone has a faintly sweet odour reminiscent of rancid butter, and the smell of γ-crotonolactone is like rancid fat. The methyl derivatives pent-3-eno-4-lactone (α-angelica lactone, **8-101**) and pent-2-eno-4-lactone (β-angelica lactone, **8-102**) are produced as degradation products of hexoses in acid solutions via laevulinic acid and have a sweet, herbal odour.



8-100, γ-crotonolactone

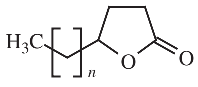


8-101, α-angelica lactone



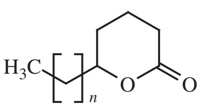
8-102, β-angelica lactone

γ-Lactones (**8-103**) and δ-lactones (**8-104**) of some aliphatic straight chain hydroxycarboxylic acids are flavour-significant components of fruits and dairy products. For example, the odour of γ-nonalactone (nonano-4-lactone) is reminiscent of coconut. γ-Decalactone (decano-4-lactone) has a fruity odour reminiscent of peaches, and is a component of apricots and strawberries. δ-Decalactone (decano-5-lactone), the odour of which resembles peaches, is a component of raspberries and coconuts. γ-Undecalactone (undecano-4-lactone) has an intense peach-like odour, and the odour of γ-dodecalactone (dodecano-4-lactone) is reminiscent of peaches with butter notes. δ-Dodecalactone (dodecano-5-lactone) and γ-decalactone are the major carriers of flavour of condensed milk and heated milk fat (butter). Dishes prepared with butter then have a typical odour reminiscent of clarified butter. Some lactones, such as γ-undecalactone and δ-dodecalactone are used for flavouring dairy products and margarines. All these lactones exist as a pair of enantiomers, the abundance of which varies greatly, but the dominating forms are (+)-(*R*)-stereoisomers. For example, coconut oil contains 75% of the (*R*)-isomer of δ-decalactone and 25% of the desired (*S*)-isomer (**8-105**), the content of (*R*)-γ-dodecalactone in raspberries is about 50% of the total γ-dodecalactone concentration, while strawberries contain this enantiomer exclusively.



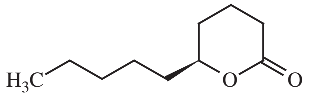
8-103,γ-lactones of saturated hydroxycarboxylic acid

nonano-4-lactone, *n* = 4
decano-4-lactone, *n* = 5
undecano-4-lactone, *n* = 6
dodecano-4-lactone, *n* = 7



8-104, δ-lactones of saturated hydroxycarboxylic acids

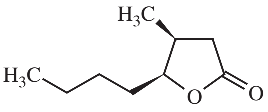
nonano-5-lactone, *n* = 3
decano-5-lactone, *n* = 4
undecano-5-lactone, *n* = 5
dodecano-5-lactone, *n* = 6



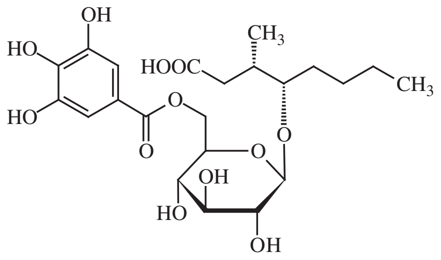
8-105, (*S*)-δ-decalactone

Other important odorous components of foods are fragrant lactones derived from branched aliphatic hydroxycarboxylic acids. The trivial names are normally preferred. An important component of the aroma of wines and spirits aged in oak barrels (such as whisky) is the so-called whisky lactone, 5-butyl-4-methyl-4,5-dihydro-3*H*-furan-2-one (3-methyloctano-4-lactone, 3-methyl-4-octanolide or 4-butyl-3-methylbutyrolactone), also known as cognac or oak lactone, which can exist in four stereoisomers, of which the (3*S*,4*S*)-isomer (**8-106**) predominates. In brandy, for example, the content of the (*Z*)-isomers, (3*R*,4*R*)- and (3*S*,4*S*)-isomers, that have a desirable flavour, ranges between 30 and 247 μg/l. The (*E*)-isomers, (3*S*,4*R*)- and (3*R*,4*S*)-isomers, are found at a concentration of 115–736 μg/l. The precursor of the (3*S*,4*S*)-isomer in oak wood

(*Quercus petraea*, Fagaceae) is 6′-*O*-gallate derivative of (3*S*,4*S*)-4-β-D-glucopyranosyloxy-3-methyloctanoic acid (**8-107**).

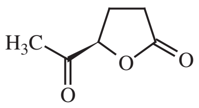


8-106, (3*S*,4*S*)-whisky lactone

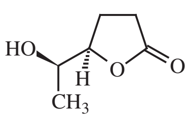


8-107, (3*S*,4*S*)-whisky lactone precursor in oak wood

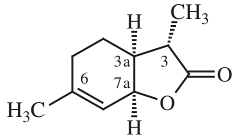
An important γ-lactone in wines is 5-oxohexano-4-lactone known as solerone, which recalls the smell of wine. It occurs as a mixture of (*R*)- (**8-108**) and (*S*)-enantiomers. The reduced form of solerone with a fruity odour, 4,5-dihydroxyhexano-4-lactone, is known under the trivial name of solerole or sherry lactone as it occurs in sherry-type wines, as a mixture of (4*R*,5*R*)- (**8-109**) and (4*S*,5*S*)-diastereoisomers. The almost racemic composition of solerone and solerole is attributed to racemisation during wine storage. An important lactone related to phthalides is 3*a*,4,5,7*a*-tetrahydro-3,6-dimethyl-3*H*-benzofuran-2-one, also known as 3*H*-benzofuran-2-one or wine lactone (**8-110**). Of the eight possible stereoisomers, only the (3*S*,3*aS*,7*aR*)-isomer with a lactonic, herbal and sweet odour is found in white wines in amounts of 0.07–0.2 μg/l, but the odour threshold concentration is very low (0.000 01-0.00 004 ng/l in air). Many foods contain 2-hydroxy-3-methylpent-2-eno-4-lactone, also known as 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one or sotolon (the trade name). Sotolon is a key odorant of fenugreek (*Trigonella foenum-graecum*, Fabaceae), lovage and sake and occurs



8-108, (*R*)-solerone



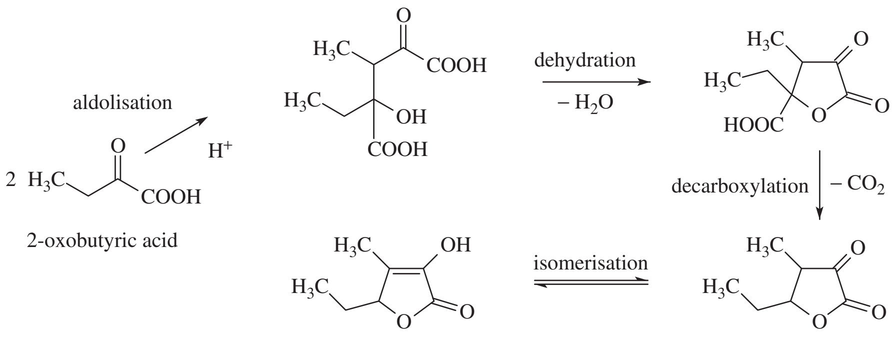
8-109, (4*R*,5*R*)-solerole



8-110, (3*S*,3a*S*,7a*R*)-wine lactone

as a flavouring component of meat, bread and roasted coffee, white wines, sherry, Madeira and Port type wines. Sotolon can result from a number of precursors. In acid protein hydrolysates, sotolon may arise from pyruvic and 2-oxobutyric acids analogously to the formation of abhexon that is produced from two molecules of 2-oxobutyric acid (Figure 8.52). A parallel mechanism responsible for the low concentrations of sotolon found in prematurely aged white wines could be an aldol condensation between 2-oxobutyric acid and acetaldehyde. Another possibility is the formation from biacetyl and glycolaldehyde (Figure 8.53). The precursor of sotolon in fenugreek seeds and in the Maillard reaction is 3-amino-4,5-dimethyl-5*H*-furan-2-one. 3-Amino-4,5-dimethyl-5*H*-furan-2-one arises from pyruvic acid and formaldehyde (or glyoxylic acid and acetaldehyde) and any amino acid. Its hydrolysis yields sotolon (Figure 8.54).

Certain 2-hydroxy substituted γ-lactones (3-hydroxy furan-2-ones) derived from γ-crotonolactone, however, have a specific odour. Typically 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one (sotolon) has an aroma resembling fenugreek or curry at higher concentrations, and caramel, maple syrup or burnt sugar at lower concentrations. Sotolon occurs as a mixture of (−)-(*R*)- and (+)-(*S*)-enantiomers (**8-111**). The perception threshold of (*S*)-sotolon (0.8 μg/l) in a model wine solution was 100 times lower than that of the (*R*)-enantiomer (89 μg/l), indicating that mainly (*S*)-sotolon contributes to the characteristic aroma of wines. The key component of acid protein hydrolysates is the higher



5-ethyl-3-hydroxy-4-methyl-5*H*-furan-3-one

Figure 8.52 Formation of lactones from 2-oxocarboxylic acids.

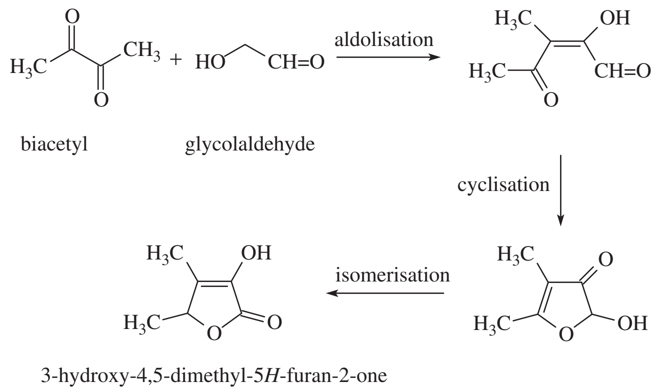


Figure 8.53 Formation of sotolon from biacetyl and glycolaldehyde.

homologue of sotolon, 5-ethyl-3-hydroxy-4-methyl-5*H*-furan-2-one, also known as maggi lactone, maple furanone or under the trade name abhexon. (−)-(*R*)-Abhexon (**8-112**) has an intense typical hydrolysate and maple syrup-like odour; (+)-(*S*)-abhexon has a less intense odour. In acid protein hydrolysates, abhexon is produced from reaction sequences analogous to those for sotolon (Figure 8.52), but from two molecules of 2-oxobutyric acid. Its content in acid protein hydrolysates is 1–4 mg/l.

8-111, (*R*)-sotolon **8-112**, (*R*)-abhexon

Dimethylsubstituted unsaturated γ-lactones that result from the autoxidation or photooxidation products of furan fatty acids are called bovolides. Bovolides have been found in some plants, butter, cooked meats and seafood. The especially important odour-active compounds are 3,4-dimethyl-5-pentylidene-5*H*-furan-2-one, called bovolide (Figure 8.55), and 3,4-dimethyl-5-pentyl-5*H*-furan-2-one that is known trivially as dihydrobovolide. Both compounds are characterised by their smell, which resembles celery. The mechanism of autoxidation of fatty acids is described in detail in Section 3.8.1.8.2.

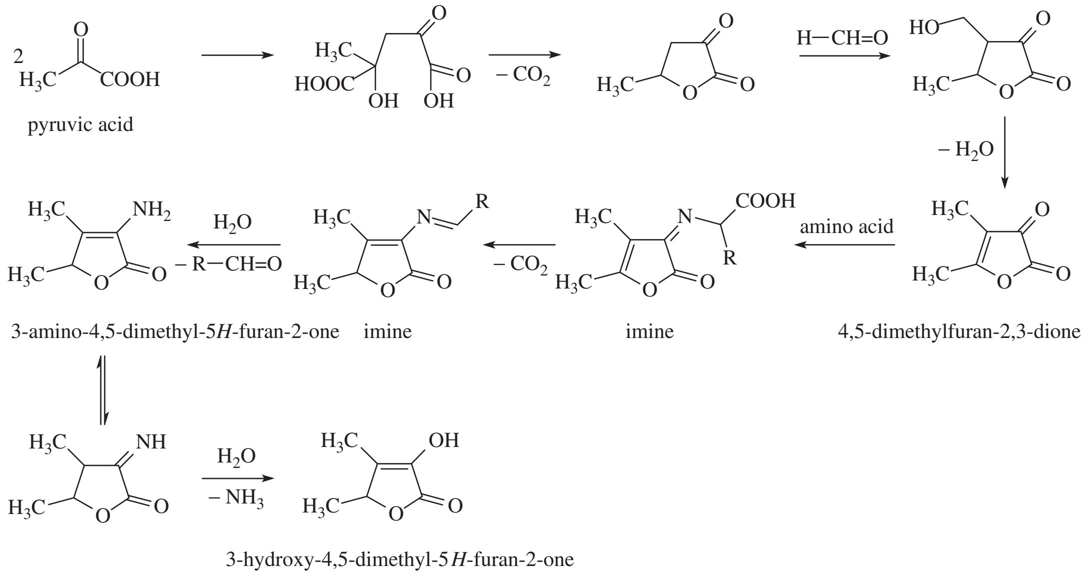

Figure 8.54 Formation of sotolon from pyruvic acid, formaldehyde and amino acids.

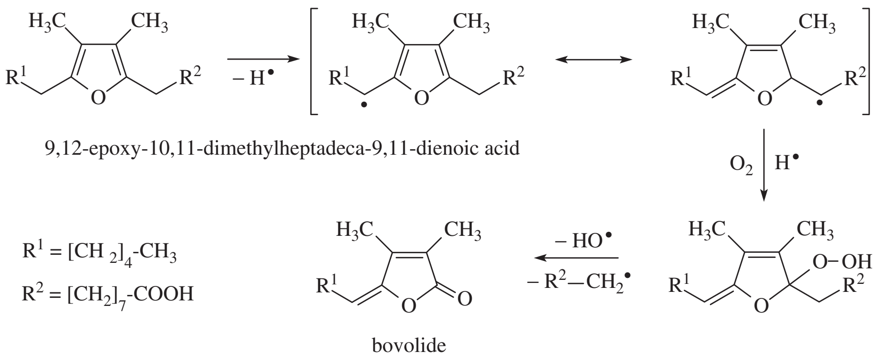

Figure 8.55 Formation of bovolide.

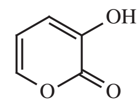
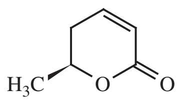
Important taste- and odour-active substances also include some δ-substituted lactones. 3-Hydroxypyran-2-one (3-hydroxy-2*H*-pyran-2-one), also known as isopyromucic acid (**8-113**) is the main degradation product of ascorbic and dehydroascorbic acids. Its aroma, which is reminiscent of liquorice and caramel, can be detected, for example, in dehydrated orange juices. The so-called parasorbic acid (**8-114**), that is (*S*)-2-methyl-2,3-dihydropyran-6-one or (*S*)-hex-2-en-5-olide, has certain biological (mutagenic and carcinogenic) effects. By heating in solutions, parasorbic acid yields sorbic acid via dehydration of 5-hydroxyhex-2-enoic acid that arises by opening the lactone ring. Parasorbic acid is found in rowan berries (*Sorbus aucuparia*, Rosaceae).



8-113, 3-hydroxy-2*H*-pyran-2-one

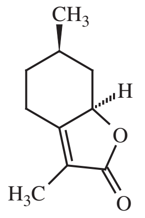


8-114, parasorbic acid

Other lactones

An example of terpenoid lactones that widely occur in plants is monoterpenic lactone (6*R*,7a*R*)-3,6-dimethyl-5,6,7,7a-tetrahydro-4*H*-1-benzofuran-2-one, known as mint lactone (**8-115**), with mint, herbaceous and coumarinic odours that is found together with related lactones in the essential oil of peppermint (*Mentha x piperita*, Lamiaceae), pennyroyal (*M. pulegium*) and other mint oils.

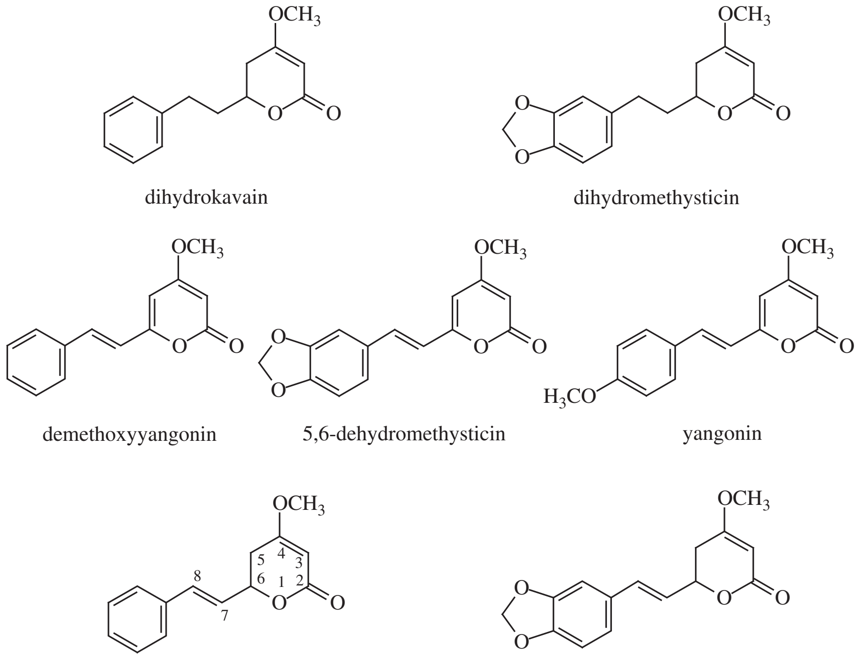
Typical polyketides related to lignans and flavonoids are styrylpyrones derived from cinnamic acids (the corresponding acyl-CoAs). An example of styrylpyrones is (2*R*,1′*E*)-4-methoxy-2-(2′-phenyleth-1′-en-1′-yl)-2,3-dihydropyran-6-one, better known as kavain or kawain and formerly as genosan (**8-116**). Kavain, along with more than 18 related compounds called kava pyrones (kava lactones), is present in kava-kava (*Piper methysticum*, Piperaceae) that grows on the islands of Micronesia and Polynesia. The other major constituents are methysticin, demethoxyyangonin, yangonin, dihydrokavain, dihydromethysticin and 5,6-dehydromethysticin (**8-116**), which belong to three different systems A–C. The A system is characterised by the absence of double bonds in both the positions 5,6 and 7,8; B is a completely unsaturated system; and C has a double bond in the 7,8 position. A drink possessing narcotic effects that is called kava or kava-kava is prepared from the rhizomes, which contain about 12% kava pyrones in the dry state. Phytochemicals based on kava-kava are sold worldwide for the treatment of nervous anxiety, tension and restlessness.



8-115, mint lactone

Phthalides

Phthalides are unique components of aromatic vegetables of the carrot family Apiaceae. They are a group of related γ-lactones, (3*H*)-isobenzofuran-1-ones. The benzene ring of phthalides may be partially or fully unsaturated (in hexahydrophthalides, tetrahydrohydrophthalides and dihydrohydrophthalides) and there can



dihydrokavain, dihydromethysticin, demethoxyyangonin, 5,6-dehydromethysticin, yangonin, kavain, methysticin

8-116, kava lactones

be alkyl or alkylidene substituents in position C-3 of the heterocyclic ring.

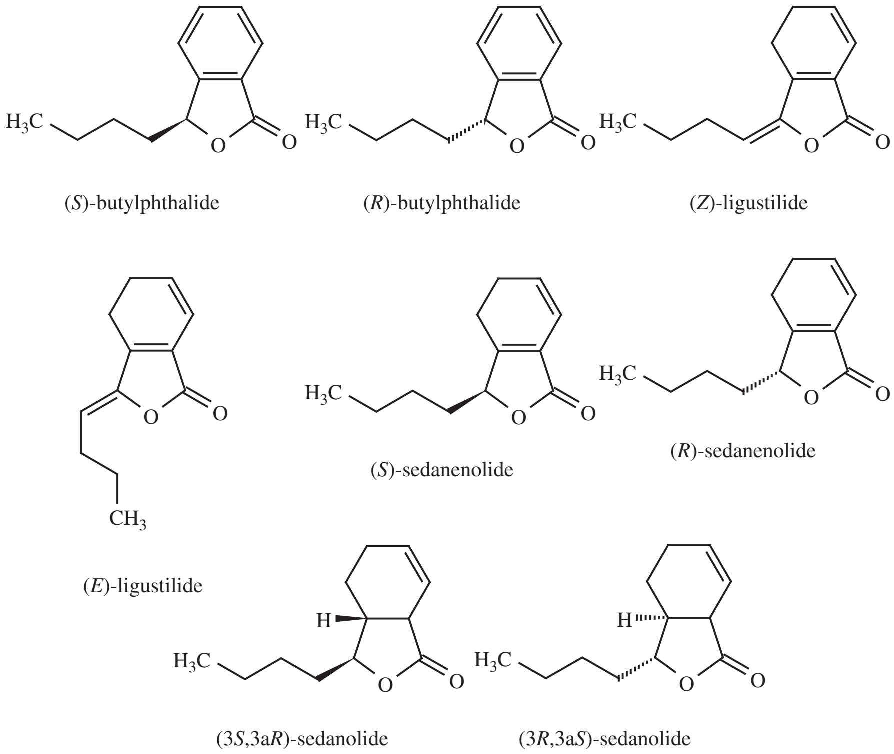
Biosynthesis of phthalides is associated with biosynthesis of styrylpyrones, as both types of compounds are ketides, but phthalides are derived from aliphatic carboxylic acids (the corresponding acyl-CoAs). Phthalides in plants have various regulatory functions at the cellular level. They exhibit spasmolytic, hypotensive, sedative and diuretic effects.

In particular, phthalides are found in celeriac (*Apium graveolens* var. *rapaceum*), celery (*A. g.* var. *dulce*) and lovage (*Levisticum officinale*). In smaller quantities, phthalides are present as aromatic components of garden parsley (*Petroselinum hortense*), dill (*Anethum graveolens*), coriander (*Coriandrum sativum*), fennel (*Phoeniculum vulgare*) and other highly aromatic and flavourful plants of the Apiaceae family that have culinary and medicinal uses. The main components present in celery are 3-butyl-4,5-dihydrophthalide (also known as sedanenolide or senkyunolide, **8-117**), 3-butyl-3a,4,5,6-tetrahydrophthalide (also known as sedanolide or neocnidilide), 3-butylphthalide and 3-butylidene-4,5-dihydrophthalide called (*Z*)-ligustilide. Other dihydro-, tetrahydro- and hexahydrophthalides are present in small quantities. The main fragrant component of lovage is (*Z*)-ligustilide and another important compound is sedanenolide. The main phthalides of the leaves and roots of parsley cultivars are sedanenolide, (*E*)-ligustilide and 3-butylphthalide, sedanolide is the main phthalide of dill and coriander.

Isomeric phthalides have an odour reminiscent of celery or acid protein hydrolysates, but the key component of protein hydrolysates is maggi lactone, known as abhexon. Phthalides occur as numerous isomers in varying amounts in various plants. For example, the content of 3-butylphthalide (with the celery stem-like odour typical of celery and celeriac) in tubers of celery is about 4 wt% and about 88% of this amount is the (*S*)-isomer and 12% the (*R*)-isomer, which has about 1000 times less intense flavour (0.01 μg/l). The amount of 3-butylphthalide in bulb-like stem bases of fennel is only about 0.01%, but the main isomer (64%) is (*R*)-3-butylphthalide. The odour of (−)-(*S*)-sedanenolide (odour threshold of 0.14 μg/l) resembles celery stem, while the odour of (+)-(*R*)-sedanenolide (odour threshold of 0.6 μg/l) is more celery leaf-like. The (−)-(3*S*,3a*R*)-sedanolide has natural celery leaf odour (odour threshold of 0.01 μg/l in 1% ethanol), while the (+)-(3*R*,3a*S*)-sedanolide has more celery seed odour with a weak hint of celery, but its odour threshold is higher (0.03 μg/l in 1% ethanol).

Coumarins

A special group of δ-lactones formally derived from the hydroxycinnamic acids are coumarins with a skeleton of 2*H*-benzopyran-2-one, which is also called chromen-2-one or 5,6-benzo-2-pyrone (**8-99**). More than 1000 coumarins are found in nature, but only the basic member of the homologous series of coumarins performs as an aromatic compound: this is called coumarin. Plant materials also contain a number of non-volatile coumarins substituted with hydroxyl and methoxyl groups and their glycosides. These and other coumarins, generally taking on the role of phytoalexins, such as isocoumarins, furanocoumarins and pyranocoumarins, are described in Section 10.3.2.5.2. Some isocoumarins are intensely sweet (such as phyllodulcin) or bitter substances (such as 6-methoxymellein),



8-117, phthalides

while 3-phenylcoumarins and 4-phenylcoumarins are coloured compounds that are classified as isoflavones and neoflavonoids, respectively. Most of the coumarins are biologically active substances that are normally classified as toxic food components.

Coumarin is found in many fresh plant tissues. Natural coumarin is obtained from the seeds of the tree *Dipteryx odorata* (syn. *Coumarona odorata*, Fabaceae), known as tonka beans, which is native to northern South America. The aromatic bark of an evergreen tree native to South Asia called Chinese cinnamon or cassia (*Cinnamomum aromaticum*, Lauraceae), which is used as a spice, contains high quantities of coumarin. European health agencies have warned against consuming large amounts of cassia, as the tolerable daily intake may be exceeded in consumers with a high intake of this spice containing high levels of coumarin (on average 2100–4400, but also up to 10 000 mg/kg). In larger quantities, coumarin occurs in the haulm of yellow sweet clover (yellow melilot; *Melilotus officinalis*, Fabaceae) and white sweet clover (white melilot; *M. albus*), sweet woodruff (*Galium odortum*, Rubiaceae) and some grass species, such as sweet grass (*Hierochloe odorata*, Poaceae). Coumarin is also found in small amounts in strawberries, apricots, liquorice rhizome (*Glycyrrhiza glabra*, Fabaceae) and other fruits and plant materials.

Plants only contain the β-D-glucoside of (*E*)-2-hydroxycinnamic (*o*-coumaric) acid, called melilotin or melilotoside (Figure 8.56) precursor of coumarin, which accumulates in the vacuoles along with the glucoside of (*Z*)-2-hydroxycinnamic (coumarinic) acid. Coumarin is only produced by plants during tissue injury when glucosides of coumaric and coumarinic acids come into contact with β-glucosidase. The glucoside of coumaric acid is isomerised to the glucoside of coumarinic acid by 2-coumarate β-D-glucoside isomerase, but the *trans–cis* isomerisation also occurs spontaneously by means of UV light. The last step is the spontaneous cyclisation (lactonisation) of coumarinic acid to coumarin, which can be further transformed into dihydrocoumarin and melilotic acid.

The coumarin scent vaguely recalls fresh clover and vanilla and is thus added to tobacco products, artificial vanilla substitutes in perfumes, cosmetic products and alcoholic beverages (such as Polish Zubrovka, which is flavoured with a stem of sweet grass). Coumarin was banned as a food additive in the 1950s because of its moderate toxicity (LD_{50} of 275 mg/kg) manifested by liver damage (hepatotoxicity) and kidneys damage (nephrotoxicity) and is on the list of substances of Regulation (EC) No. 1334/2008, which should not be added as such to foods as flavourings. The maximum level of naturally occurring coumarin in traditional and seasonal bakery products is restricted to 50 mg/kg and in fine bakery (containing a reference to cinnamon in the labelling) to 15 mg/kg, in breakfast cereals to 20 mg/kg and in desserts to 5 mg/kg. According to the German Federal Institute for Risk Assessment, its amount in food must not exceed the tolerable daily intake of 0.1 mg per kg body weight.

8.2.7.1.3 Nitriles

Only nitriles (**8-118**) are found in food; isomeric isonitriles (isocyanides) are not. Precursors of volatile nitriles are almost exclusively glucosinolates that occur in cruciferous plants of the family Brassicaceae. Nitriles (together with a number of other

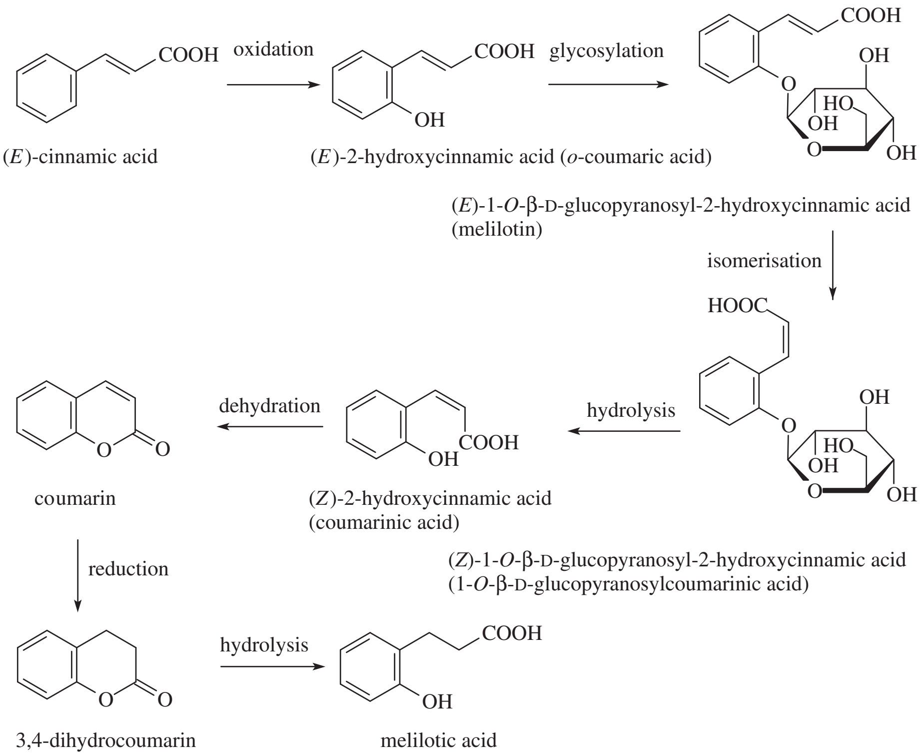


Figure 8.56 Biosynthesis of coumarin.

products) are formed by their enzymatic and thermal degradation. The main products are isothiocyanates (see Section 10.3.2.4.2).

8-118, nitriles

A common nitrile produced during processing of the vast majority of *Brassica* vegetables is but-3-enenitrile (allyl cyanide, **8-118**, R=CH=CH_2), which arises by degradation of glucosinolate sinigrin. For example, but-3-enenitrile acts, along with other compounds, as an odour-active compound in cooked cabbage and in sauerkraut. Other volatile nitriles include pent-4-enenitrile (but-3-en-1-yl cyanide, **8-118**, R=CH_2–CH=CH_2), which contributes considerably to the typical aroma of cabbage and some types of mustard pastes made from black and brown mustard seeds (*Brassica nigra* and *B. juncea*, respectively), and its higher homologue hex-5-enenitrile (pent-4-en-1-yl cyanide, **8-118**, R = CH_2CH_2CH=CH_2). These nitriles are formed from glucosinolates with aliphatic substituents known as gluconapin and glucobrassicanapin, respectively. Different cyanoepithioalkanes, glucosinolates with hydroxyalkenyl substituents, are formed as minor glucosinolate hydrolysis products, For example, progoitrin yields hydroxyalkenylnitriles and cyanohydroxyepithioalkanes.

An example of important non-volatile nitriles is 4-hydroxybenzyl cyanide, which is found in mustard pastes made from white mustard seeds (*Leucosinapis album*) containing glucosinolate sinalbin. Non-volatile nitriles also include cyanogenic glycosides, cyanogenic lipids and amino acids that contain the cyano group.

8.2.7.2 Properties and reactions

8.2.7.2.1 Esters

The organoleptic properties of some esters, which are important components of fruits, spices and fragrant flowers, are given in Table 8.25. One of the most important reactions of esters is hydrolysis (usually enzymatic hydrolysis), which usually has a negative effect on the flavour of many foods, especially fruits, where esters are important components of the primary flavour. Water is present in large excess in most foods, therefore heating or storage of foods usually leads to the hydrolysis of esters, even in the absence of hydrolytic enzymes. Chemical hydrolysis of esters is faster in alkaline solutions where salts of carboxylic acid are formed. Hydrolytic reactions of esters in foods are of great importance in materials rich in lipids and also in many other cases. For example, hydrolysis of pectins alters their ability to form gels and produces methanol.

In enzymatically inactive foods continual reactions proceed between acids, alcohols and esters. Owing to low reaction rates, these reactions never reach the equilibrium state. During heating or prolonged storage, less volatile acids bound in esters may be displaced by more volatile acids, by a process called acidolysis. A common example is the reaction of an ester with an alcohol, which is called alcoholysis. Alcoholysis helps improve the flavour of alcoholic beverages (especially fruit spirits) during long-term storage known as aging. One reason is the reaction of ethanol, which is present in large excess, with esters, the constituents of which are fusel oil alcohols.

8.2.7.2.2 Lactones

Generally, lactones with five-membered and six-membered rings are not too reactive. They are relatively stable in acidic solutions, where they typically arise by spontaneous dehydration of hydroxycarboxylic acids. In aqueous solutions, particularly in alkaline solutions, the lactone ring opens with the formation of a salt of the hydroxycarboxylic acid. The original lactone may result after acidification, especially on heating. Lactones react with alcohols to form esters and, similarly, the lactone ring opens on reaction with amino compounds to form amides.

8.2.7.2.3 Nitriles

Addition reactions to the nitrile group and hydrolysis of nitriles to the corresponding carboxylic acids may, to a certain extent,

Table 8.25 Organoleptic properties of important esters.

Ester	Odour character	Ester	Odour character
Allyl capronate	Pineapple	Ethyl lactate	Mandarin
Amyl acetate	Pear	Ethyl 2-methylbutyrate	Strawberries
Ammyl cinnamate	Cacao	Geranyl acetate	Rose
Ammyl formiate	Black currents, plum	(*Z*)-Hex-3-en-1-yl isovalerate	Rum
Amyl caprylate	Brandy, whisky	(*Z*)-Hex-3-en-1-yl butyrate	Apple
Butyl acetate	Pineapple	Isopulegyl acetate	Green apple
Butyl isobutyrate	Pineapple	Methylphenyl acetate	Mint
Butyl valerate	Apple	Methyl isovalerate	Honey
Cyclohexyl formiate	Sour cherry	Methyl capronate	Apple
Diethyl malonate	Apple	Methyl *N*-methylanthranilate	Pineapple

take place in foods containing nitriles. Nitriles occurring in trace amounts in rapeseed oils can be reduced to the corresponding amines during oil hydrogenation.

8.2.8 Phenols

8.2.8.1 Classification structure, terminology and occurrence

Phenols are components of virtually all foods. They are a very heterogeneous group of compounds, some of which may act also as odour-active compounds such as certain simple phenols formed as the degradation products of phenolic acids and products of their reduction, such as aldehydes and alcohols. Phenols are also important compounds influencing the taste of foods (simple phenols and polyphenols known as condensed tannins, called flavolans, that are responsible for astringent taste). Phenolic compounds include also many natural dyes (some quinones, lignans, flavonoids and related stilbenes, xanthones and other compounds). Particular phenols exhibit significant biological effects, and therefore act as the defensive substances of plants, called phytoalexins, as natural antioxidants and natural toxic compounds. These phenols are discussed elsewhere in this book. An overview of the basic groups of phenolic compounds occurring in foods is given in Table 8.26.

Phenols, which in foods act as aromatic substances, are either primary food components of some essential oils or are produced as secondary substances in food processing. The primary components are phenols structurally related to the corresponding alkyl aryl ethers (see Section 8.2.3.1.2). Secondarily formed phenols are produced mainly from phenolic acids and lignin during thermal processes and by the action of microorganisms. Particularly important compounds are derived from phenol, guaiacol (2-methoxyphenol) and syringol (2,6-dimethoxyphenol) (**8-119**).

Simple alkyl phenols derived from phenol, found as constituents of essential oils, include two major monoterpenes with a similar odour, carvacrol (5-isopropyl-2-methylphenol, **8-119**) and thymol (2-isopropyl-5-methylphenol, **8-119**). These phenols occur, for example, in the essential oil of thyme. Chavicol, also known as 4-prop-2-en-1-ylphenol or 4-allylphenol (**8-119**) is a component of the essential oil of basil. A number of other phenols are derived from guaiacol. Isoeugenol also occurs in the essential oil of basil as the (*E*)-isomer, (*E*)-2-methoxy-4-(prop-1-en-1-yl)phenol (**8-119**),

Table 8.26 Main types of food phenols.

Number of C atoms	Basic skeleton type	Groups of phenolic compounds
6	C_6	Simple phenols, benzoquinones
7	C_6-C_1	Benzoic acids
8	C_6-C_2	Acetophenones, phenylacetic acids
9	C_6-C_3	Phenylpropanoids, phenylpropenes, chromones, isochromenes, cinnamic acids, coumarins
10	C_6-C_4	Naphthoquinones

8-119, phenol,methoxy substituted phenols and their alk(en)yl derivatives

and clove essential oil contains as a key aroma compound eugenol, also known as 2-methoxy-4-(prop-2-en-1-yl)phenol (**8-119**). Eugenol and chavicol (along with myrcene) are major components of the essential oil of allspice (pimento).

3-Alkatrienyl, 3-alkadienyl, 3-alkenyl and 3-alkyl phenols, collectively known as cardanol, occur in the cashew nutshell liquid at a level of 10% (see Section 10.2.3.4). The main components of this mixture are (8*Z*,11*Z*)-3-(pentadeca-8,11,14-trien-1-yl)phenol, (8*Z*,11*Z*)-3-(pentadeca-8,11-dien-1-yl)phenol, (8*Z*)-3-(pentadeca-8-en-1-yl)phenol and 3-pentadecyl phenol. Derivatives of cardanol find applications as polymeric resins, dyestuffs, plasticisers, surface-active agents and pesticides (see Section 8.2.6.1.6). Phenols resulting from pyrolysis of lignin or phenols occurring in liquid smoke (used for smoking foods) are typically found in smoked foods. Pyrolysis of softwood gives rise mainly to guaiacols (2-methoxyphenols, **8-119**), while pyrolysis of hardwood yields a mixture of guaiacols and syringols (2,6-dimethoxyphenols, **8-119**). They not only affect the flavour of smoked products, but stabilise their colour and act as preservatives. The content of phenols in the smoked meat, depending on the smoking process, is around 40 mg/kg. Phenolic substances in alcoholic beverages (such as whisky) are extracted from lignin from oak barrels by ethanol.

Phenolic compounds produced by degradation of phenolic acids or lignin by the activity of microorganisms occur as byproducts of lactic and alcoholic fermentations. Instances of these products are ferulyl alcohol (coniferyl alcohol) and other related alcohols. For example, phenol occurs in sour cream and butter (in butter in an amount of 9–16 μg/kg), and other phenols are present in lower concentrations, especially *m*-cresol (3-methylphenol), *p*-cresol (4-methylphenol) and guaiacol. The content of phenols in alcoholic beverages is highly variable. Concentrations of phenols are relatively low, but they also have low odour detection thresholds (usually within the range of 0.1 to 0.3 mg/l). Phenols only rarely carry an unusual after-taste or off-taste. Higher amounts of phenols are found in various speciality beers (such as beers made from malt directly dried by flue gas), sherry type wines (Table 8.27) and in spirits which are aged in oak barrels. The main phenols in whisky are eugenol, vanillin, guaiacol, phenol, cresols and some other compounds.

Roasting of coffee, nuts or almonds, drying malt, bread baking, production of vegetable oils and other thermal processes generate sensory active volatile phenols that mainly arise from phenolic acids. As an example, the mechanism of phenols formation from ferulic acid is shown in Figure 8.57. At temperatures around 200 °C the main products formed are fragments resulting from the gradual degradation of the three-carbon side-chain at position C-4, its oxidation and partly by recombination of radicals. The composition of these phenols is shown in Table 8.28. The majority of the pyrolytic fragments are produced in the temperature range 360–410 °C. This includes again the cleavage of C–C bonds in the side chain (as at lower temperatures, but to a greater extent than at 200 °C), but the methoxyl group also splits off as a methoxyl radical. The results are three basic structures that represent, in addition to compounds derived from guaiacol, phenol and catechol derivatives. The main guaiacols are 4-ethylguaiacol and 4-vinylguaiacol. The main phenols are 2-methyl-4-vinylphenol, 2-methyl-4-ethylphenol, 4-vinylphenol, 4-ethylphenol, 2,4-dimethylphenol and 4-methyl-2-methylphenol. The main catechols are 4-vinyl-, 4-ethyl, 4-methylpyrocatechols and pyrocatechol.

Recombinations and disproportionations of radicals give rise to other radicals and other products. Some of these reactions are illustrated by the following equations:

$$2CH_3^\bullet \rightarrow CH_3{-}CH_3$$
$$CH_3{-}CH_3 \rightarrow CH_3{-}CH_2^\bullet + H^\bullet$$
$$CH_3{-}CH_2^\bullet \rightarrow CH_2 = CH_2 + H^\bullet$$
$$H_3C^\bullet + H^\bullet \rightarrow CH_4$$
$$H_3CO^\bullet + H^\cdot \rightarrow CH_3OH$$

Analogous products are also formed from cinnamic acid and its derivatives, such as 4-coumaric, caffeic and syringic acids.

Table 8.27 Main phenols contents in selected alcoholic beverages (μg/l).

Compound	Beer	Sherry	Whisky
Phenol	Traces	Traces–100	Traces–12
o-Cresol (2-methylphenol)	Traces	Traces	0–75
m-Cresol (3-methylphenol)	–	10 000	0–35
p-Cresol (4-methylphenol)	–	10 000	9–50
2-Ethylphenol	–	50 000	2
4-Ethylphenol	90	350 000	35–39
2-Methoxyphenol (guaiacol)	10–50	–	0–12
2-Methoxy-4-methylphenol (4-methylguaiacol)	Traces–90	Traces	Traces–5
4-Ethyl-2-methoxyphenol (4-ethylguaiacol)	0–300	80 000	2–36
4-Vinylphenol	5–170	20	–
2-Methoxy-4-vinylphenol (4-vinylguaiacol)	7–100	50	–
4-Allyl-2-methoxyphenol (eugenol)	80	10 000	11–195
4-Ethyl-2,6-dimethoxyphenol	30–1200	40 000	–

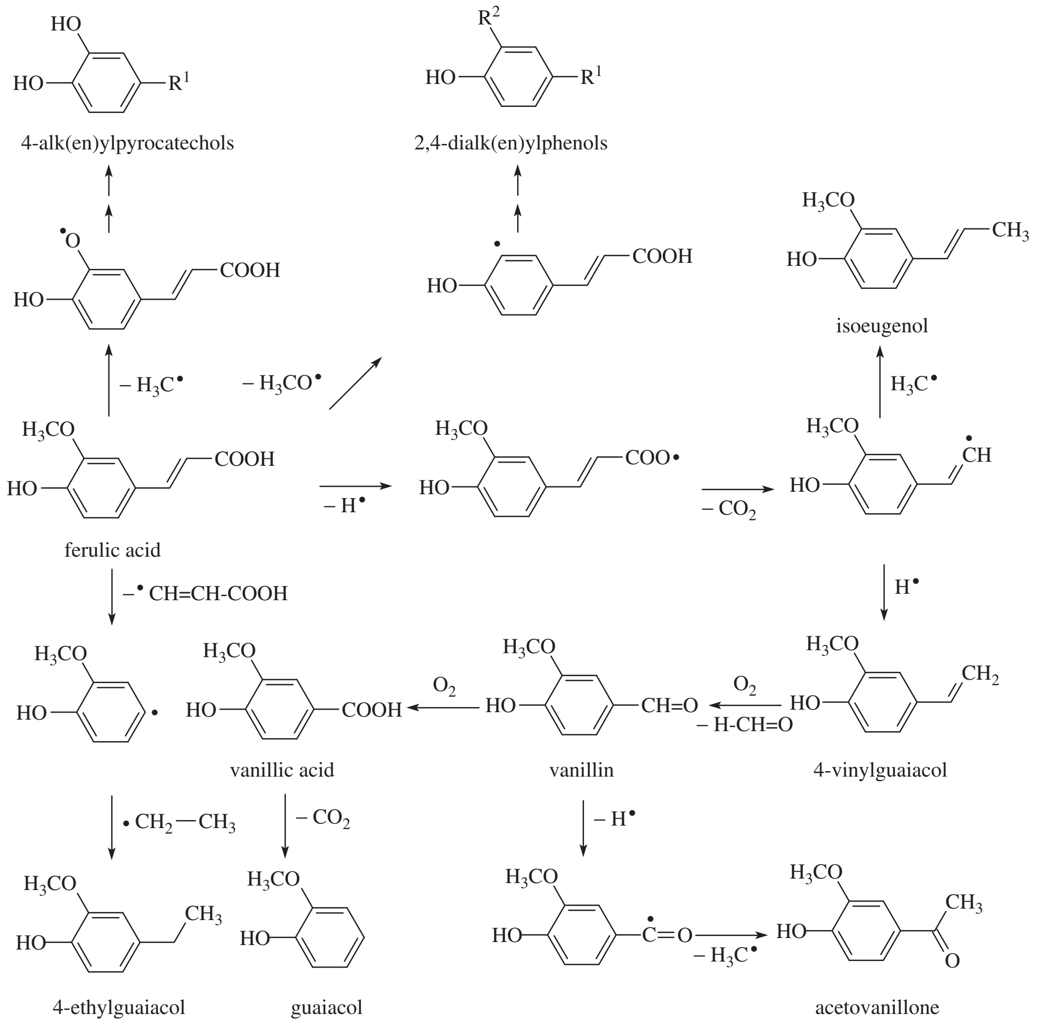

Figure 8.57 Ferulic acid pyrolysis.

Table 8.28 Pyrolysis products of ferulic acid in air at 200 °C.

Product	Composition (%)	Product	Composition (%)
4-Vinylguaiacol	79.9	4-Ethylguaiacol	5.5
Vanillin	6.4	Acetovanillon	2.6
Guaiacol	3.1	Isoeugenol	2.5

For example, the main phenol with antioxidative and antimutagenic activities that occurs in crude canola oil is 2,6-dimethoxy-4-vinylphenol known as canolol, which is produced from syringic acids. The major products of caffeic acid pyrolysis at 225 °C are pyrocatechol, 4-vinylpyrocatechol and 4-ethylpyrocatechol (see Section 8.3.4). A more complex mixture of products arises by pyrolysis of lignin. In the smoke condensates used in the meat industry, more than 150 different phenols, and dozens of aromatic alcohols, phenolic acids and hydroxylated heterocyclic compounds have been identified.

8.2.8.2 Properties and reactions

At higher concentrations, simple phenols are toxic substances that block oxidative phosphorylation. They also exhibit nephrotoxic effects and can act as co-carcinogens. Some alkyl and alkenyl derivatives of phenol, catechol and resorcinol may cause allergic dermatitis.

The most important reaction of natural phenols in foods is oxidation. In many plant foods the enzyme-catalysed oxidation of monophenols to *o*-diphenols (1,2-dihydroxybenzenes) and oxidation of the formed *o*-diphenols to *o*-quinones proceed. These and subsequent reactions belong to the set of enzymatic browning reactions described in Section 9.12.

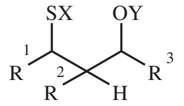
8.2.9 Sulfur compounds

8.2.9.1 Classification structure, terminology and occurrence

Sulfur compounds are an important group of aroma components of foods that determine or significantly affect the desired flavour. However, they may also cause various undesirable off-flavours. Sulfur compounds are often the primary aromatic substances of vegetable foodstuffs (e.g. diallyl disulfide is the characteristic substance of the garlic-like aroma, allyl isothiocyanate that gives the typical aroma of horseradish and 2-isobutylthiazole is a major characteristic component of fresh tomato aroma). Sulfur compounds are formed either from the precursor by enzymatic reactions in damaged plant tissues as primary aromatic substances, or during the heat treatment of foods of plant and animal origin by non-enzymatic reactions as secondarily produced aromatic substances. Sensory active sulfur compounds occur, for example, as important components of the aroma of meat and coffee, but also of many other foodstuffs. A number of sulfur compounds have beneficial effects on human health, especially antimicrobial, antioxidant and anticarcinogenic effects.

Among the most important volatile sulfur compounds are hydrogen sulfide (sulfan), various thiols, sulfides, isothiocyanates and heterocyclic sulfur compounds. Precursors of volatile sulfur compounds are usually non-volatile, sensory indifferent sulfur compounds, especially sulfur-containing amino acids cysteine, cystine, methionine and their derivatives, such as *S*-alk(en)yl cysteine sulfoxides, glucosinolates, thiamine and other compounds. An important sulfur compound is also sulfur dioxide, which is used as a preservative and an inhibitor of enzymatic browning reactions or the Maillard reaction. It also occurs in a small amount as a metabolite in fermentation processes. Sulfur compounds may be accompanied by their selenium analogues at very low concentrations.

Very intense-smelling sulfur compounds with low thresholds of perception often act as key aromatic compounds. They often have very similar structures and contain an important odorophore (a group responsible for the odour character), which is sulfur and oxygen in positions 1 and 3 of the molecule (**8-120**). This structure occurs in mercaptans, thioacetals, mercapto ethers, mercapto ketones, alkylthio esters and other compounds listed in the following sections.



8-120, structure of *S*-compounds with an intense odour

8.2.9.1.1 Sulfane

Sulfane (hydrogen sulfide) is present in all foods containing proteins (bound cysteine or cystine) during prolonged storage or heat treatment through the reaction known as desulfuration, or as a byproduct of the Strecker degradation of sulfur-containing amino acids. Sulfane is also formed by degradation of isothiocyanates via carbonyl sulfide and by microbial reduction of sulfates and sulfites. It also occurs in some mineral waters. The human body produces sulfane in trace amounts and uses it as a signalling molecule. Sulfane has a very low odour threshold (below 1 μg/l in air). The odour increases as sulfane becomes more concentrated, and its smell then resembles rotten eggs up to a concentration of about 30 μg/l. Higher concentrations of sulfane in foods that are rich in protein are associated with putrefactive processes. Sulfane is a very reactive compound that produces a number of volatile odour-active products, especially with carbonyl compounds.

8.2.9.1.2 Thiols

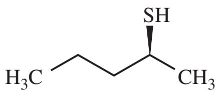
Compounds containing a carbon-bonded mercapto group (sulfhydryl group, –SH), called mercaptans or thiols, are the sulfur analogues of hydroxy compounds. Altogether, lower aliphatic thiols are compounds exhibiting an intense, often penetrating,

unpleasant and repulsive smell, but at low concentrations they are often important components of the aroma of many foods.

The basic member of the homologous series of thiols is methanethiol (methyl mercaptan, **8-121**), which is produced during the thermal processing of foods, mainly by Strecker degradation of methionine via the unstable primary reaction product methional. Propane-1-thiol (**8-121**) is an important component of leeks and onion flavours, while prop-2-en-1-thiol (allyl mercaptan, **8-121**) is generated during the processing of garlic by dismutation of diallyl disulfide, which is formed from the amino acid alliin via disulfide allicin. At lower concentrations it shows a typical garlic and meat-like aroma. It is also the main active component of 'garlic breath' after eating garlic.

8-121, thiols
methanethiol, R = H
propane -1-thiol, R = CH_2CH_3
prop-2-ene -1-thiol, R = $CH{=}CH_2$
3-methylbutane-1-thiol, R = $CH_2CH(CH_3)_2$
3-methylbut-2-ene-1-thiol, R = $CH{=}C(CH_3)_2$

Foods contain many other aliphatic thiols. The tropical aroma of the guava fruit (*Psidium guava*, Myrtaceae) is credited to (*S*)-pentane-2-thiol (**8-122**), while its higher homologue (*S*)-heptane-2-thiol is a flavour compound found in bell peppers. 3-Methylbut-2-ene-1-thiol (1-mercapto-3-methylbut-2-ene, **8-121**), which arises from prenyl alcohol and hydrogen sulfide, is an important component of roasted coffee aroma. Prenyl alcohol (3-methylbut-2-ene-1-ol) occurs in green coffee at levels of about 0.5 mg/kg. However, the same thiol, 3-methylbut-2-ene-1-thiol (also known as skunky thiol), is a carrier of an off-flavour in beer known as light-struck flavour that appears on exposure of the beer to light (see Section 8.2.12.8.1). Its precursor is the cause of bitter beer taste, iso-α-acids (isohumulones), derived from hops. 3-Methylbut-2-ene-1-thiol results from exposure of beer to UV light and also in a photosensitised reaction (on exposure to sunlight or visible light), where, in the first instance, riboflavin acts as a photosensitiser (see Section 8.3.4.1.4). 3-Methylbut-2-ene-1-thiol in well-stored beer occurs a level of 1–5 ng/l, but in the light its content increases up to 0.01–1.05 μg/l. At present modified (hydrogenated) iso-α-acids are produced, enabling cold-hopping and providing increased resistance against the formation of this compound after irradiation of the beer. For example, the major volatile components of the anal sac secretion from North American skunks are similar mercaptans, namely (*E*)-but-2-ene-1-thiol (**8-123**) and 3-methylbutane-1-thiol (**8-121**) that comprise 18–66% of the secretion.



8-122, (*S*)-pentane-2-thiol

8-123, (*E*)-but-2-ene-1-thiol

Not all thiols have unpleasant odours. A component of raw and heat-treated onion with a very intense aroma is 3-mercapto-2-methylpentan-1-ol (2-methyl-1-hydroxypentan-3-thiol, see Section 8.2.12.6.4). The characteristic sulfur note of blackcurrants is caused by the presence of 4-methoxy-2-methylbutan-2-thiol (4-methoxy-2-methyl-2-mercaptobutane), called blackcurrant mercaptan (**8-124**), which occurs in aromatic juices at concentrations of 0.2 μg/l and higher. It seems that it can be used to express a fruity aroma to tropical fruit juices, coffee and other products. The same compound is also found in virgin olive oils at levels of about 2 μg/l. Its odour threshold is 0.045 μg/kg in oil. Another component resembling blackcurrant aroma is 4-mercapto-4-methylpentan-2-one, the so-called cat ketone (**8-125**). The same compound also occurs in small amounts in grapefruits, Japanese green tea, some hop cultivars, basil and certain aromatic wines (such as Sauvignon Blanc), which contributes to their musky aroma. In passion fruit (*Passiflora edulis*, Passifloraceae) contributions to the aroma come from 3-mercaptohexan-1-ol along with a number of other sulfur compounds, such as 3-mercaptohexyl acetate, 3-mercapto-3-methylbutan-1-ol and 3-mercapto-3-methylbutyl acetate. Both enantiomers of 3-mercaptohexan-1-ol also occur in some white wines. The two enantiomers differ in their odour, the (*S*)-enantiomer (**8-126**) smells more of passion fruit, while the (*R*)-enantiomer is fruitier and reminiscent of grapefruit. The odour threshold is 0.08 ng/l in air. Alicyclic thiols are also significant aromatic compounds. The characteristic flavour component of grapefruit is monoterpene *p*-mentha-1-ene-8-thiol. Another related thiol, (1*S*,4*R*)-*p*-methane-8-thiol-2-one (see Section 8.2.13.1.1) is a key component of the scent of blackcurrant.

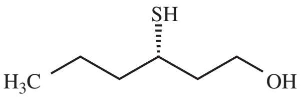
8-125, 4-mercapto-4-methylpentan-2-one



8-126, (+)-(*S*)-3-mercaptohexan-1-ol

Volatile thiols are present in fruits and vegetables in combined forms, as *S*-cysteine and *S*-glutathione conjugates, and are released from these precursors by the action of L-cysteine-*S*-conjugate thiol-lyase (deaminating) during fermentation (Figure 8.58). For example, the precursors of 3-mercaptohexan-1-ol in passion fruit and wines are the individual diastereomers of 3-*S*-(hexan-1-ol)-L-cysteine and in wines, correspondingly, diastereomers of 3-*S*-glutathionylhexan-1-ol. The precursor of 4-mercapto-4-methylpentan-2-one in wines is 4-*S*-glutathionyl-4-methylpentan-2-one.

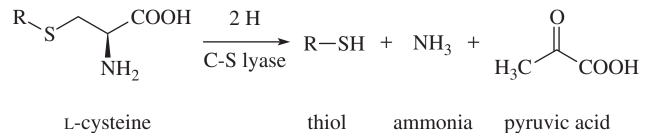


Figure 8.58 Formation of thiols by degradation of cysteine conjugates.

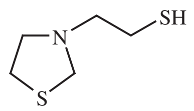
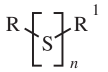
Thiols arising in the Maillard reaction, mostly derived from heterocyclic compounds, such as furan, thiophene, thiazole and other heterocycles, are important flavour-active components of meat, coffee and many other foods. For example, 2-furanmethanethiol (furan-2-ylmethanethiol, furfuryl mercaptan) has an odour resembling roasted coffee, *N*-(2-mercaptoethyl)-1,3-thiazolidine (**8-127**), which is formed in the reaction of fructose with cysteamine, and has a very strong odour resembling popcorn. Its odour threshold is 0.005 ng/l in air.



8-127, 3-(2-mercaptoethyl)-1,3-thiazolidine

8.2.9.1.3 Sulfides and oligosulfides

In foods, a range of aliphatic sulfides, disulfides, trisulfides (**8-128**) and higher oligosulfides, but also some cyclic sulfides, are important compounds. Sulfides and oligosulfides have an unpleasant odour at higher concentrations, but in low concentrations they contribute to the characteristic full flavour of many foods, such as onion, garlic, cheese, meat, vegetables (especially *Brassica* vegetables) and chocolate, and are used in various flavour compositions.



8-128, sulfides

sulfides, $n = 1$

trisulfides, $n = 3$
dimethyl sulfide, $n = 1$, $R = R^1 = CH_3$
dimethyl disulfide, $n = 2$, $R = R^1 = CH_3$
dimethyl trisulfide, $n = 3$, $R = R^1 = CH_3$
di(prop-2-en-1-yl)trisulfide, $n = 3$, $R = R^1 = CH{=}CH{-}CH_3$

Dialkyl sulfides are sulfur analogues of ethers. They are formed in foods (along with dialkyl trisulfides) mainly by disproportionation of disulfides. The homolytic S–R bond cleavage of disulfides proceeds by photolysis or heating:

$$R{-}S{-}S{-}R \rightarrow R{-}S{-}S^{\bullet} + R^{\bullet}$$
$$R{-}S{-}S{-}R + R^{\bullet} \rightarrow R{-}S{-}R + R{-}S^{\bullet -}$$
$$R{-}S{-}S{-}R + R{-}S^{\bullet} \rightarrow R{-}S{-}S{-}S{-}R + R^{\bullet}$$

The basic member of the homologous series of dialkyl sulfides is dimethyl sulfide, presenting an odor threshold of 0.12 μg/l in water, which has a characteristic sulfurous, cabbage-like smell at low concentrations, similar to that of dimethyl disulfide, which also has garlic-like notes. Dimethyl trisulfide odour is described as sulfurous, alliaceous, cooked, savoury, meaty, eggy and vegetative, with a fresh, green and onion top note. Dimethyl sulfide (**8-128**, $R{=}R^1{=}CH_3$, $n{=}2$) arises by disproportionation of dimethyl disulfide (e.g. in garlic and cruciferous vegetables). In many vegetables (such as cooked cabbage, celery and some other vegetables), dimethyl sulfide forms by decomposition of *S*-methylmethionine during food storage and/or thermal treatment. *S*-Methylmethionine, known as vitamin U (Figure 8.59), is a natural component of *Brassica* and other vegetables (see Section 5.15). In cruciferous vegetables, dimethyl disulfide and trisulfide result from degradation of *S*-methylcysteine sulfoxide. Dimethyl sulfide is an important aromatic component of tea, coffee, cocoa and other foods; however, in certain foods it causes an unpleasant off-flavour (as in beer and milk). For example, sulfides contribute to an off-flavour of aged beer resembling cooked vegetables, especially creamed maize, cabbage and tomato, and shellfish/oyster-like in high concentrations. The main undesirable compounds responsible for this off-flavour include dimethyl disulfide (first perceived at concentration of about 30 μg/l), diethyl sulfide, diisopropyl sulfide, dimethyl sulfide and other compounds at considerably lower concentrations. Dimethyl disulfide and trisulfide (**8-128**) are, along with degradation products of glucosinolates, important components of cruciferous vegetables aroma. Dimethyl trisulfide contributes significantly to the flavour of chicken, cabbage and garlic.

Ethyl methyl disulfide, along with other sulfur compounds, is a flavour-active component of the highly prized fruit durian (*Durio zibethinus*, Bombacaceae), native to Indonesia and Malaysia, whose odour is reminiscent of rancid meat. Allyl-, propyl-, methyl- and

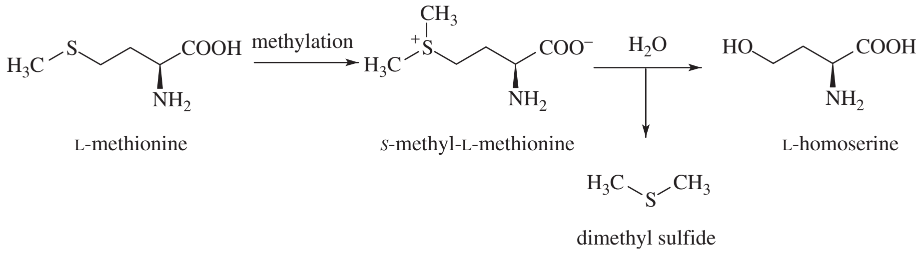

Figure 8.59 Formation of dimethyl sulfide from *S*-methyl methionine.

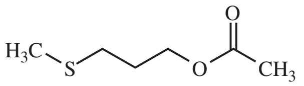
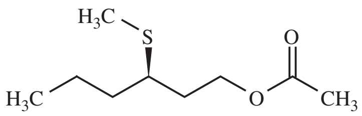
prop-1-en-1-yl sulfides (mono-, di-, tri- and tetrasulfides) are some of the most important sensory active components of bulb vegetables, such as garlic, chives, leeks, onions, shallots and other varieties of onions, where they arise by enzymatic (and also by thermal) decomposition of *S*-alk(en)ylcysteine sulfoxides, mainly via the corresponding thiosulfinates.

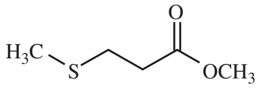
An important sulfide is methional (**8-37**). Methional in beer and wine is formed by the activity of microorganisms. It is partly reduced to the corresponding alcohol methionol (**8-13**) and reaction with acetyl-CoA yields 3-methylthiopropyl acetate (**8-129**), which is an important component of various fermented foods. Another ester of acetic acid 3-(methylthio)hexyl acetate is a component that posseses attractive tropical fruity notes on dilution. The less odoriferous (−)-(*R*)-enantiomer (**8-130**) is reminiscent of passion fruit, while the (+)-(*S*)-form has a more herbaceous odour. The odour thresholds of these thiols in air are 0.10 ng/l and 0.03 ng/l, respectively. Both isomers have been found in passion fruit (*Passiflora edulis*, Passifloraceae), guava (*Psidium guajava*, Myrtaceae) and aromatic white wines. Methyl-3-(methylthio)propionate, or pineapple mercaptan (**8-131**), has a flavour reminiscent of pineapple. *S*-Methylthiohexanoate (**8-132**) is a component of the durian fruit smell. Condensation of methional with ethanol yields (*Z*)-2-(methylthio)methylbut-2-enal also known as 2-ethylidenemethional (**8-133**), which is an important component of potato chips aroma. It also occurs in



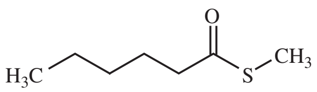
8-129, 3-(methylthio)propyl acetate



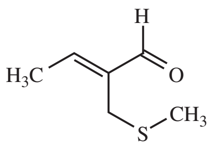
8-130, (*R*)-3-(methylthio)hexyl acetate



8-131, methyl 3-(methylthio)propionate

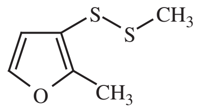


8-132, *S*-(methylthio)hexanoate



8-133, (*Z*)-2-(methylthiomethyl)but-2-enal

coffee, cocoa and other foods. Methyl (2-methyl-3-furyl) disulfide (**8-134**) is a component of meat volatiles, and also of chocolate aroma. Many other sulfides are, similarly, important components of foods.



8-134, methyl(2-methyl-3-furyl)disulfide

Cyclic disulfides, for example, dithiines (see Section 8.2.12.6.4), are components of garlic aroma. The mushroom shiitake (*Lentinula edodes*), native to East Asia, with a sulfurous aroma, contains 4,4,7,7-tetramethyl-1,2,3,5,6-pentathiepan known as lenthionine (see Section 8.2.12.9) as a characteristic component.

8.2.9.1.4 Thiosulfinates

Thiosulfinates of a general structure R–SO–S–R, also known as alkanethiosulfinic acid esters, are the basic group of oxidised disulfides. In foods, thiosulfinates may result from oxidation of disulfides, for example, by fatty acid hydroperoxides, as in the case of cystine (see Section 2.5.1.1.1). Precursors of a number of acyclic and cyclic thiosulfinates and other volatile sulfur compounds in plants are *S*-alk(en)ylcysteine sulfoxides (see Section 2.2.1.2.2) that typically occur in garlic, onion and other plants of the *Amarillidaceae* family. These amino acids are decomposed enzymatically to alk(en)ylsulfenic acids under the catalysis of C–S lyases (cysteine sulfoxide lyase known as alliinase that is found in garlic and other Alliums). Alk(en)ylsulfenic acids then undergo very facile self-condensation to dialk(en)ylthiosulfinates. Dimethylthiosulfinate is produced in Amarillidaceae family vegetables and also in plants of the Brassicaceae family vegetables from *S*-methylcysteine sulfoxide via methylsulfenic acid. A well known thiosulfinate is diallylthiosulfinate, which is di(prop-2-en-1-yl)thiosulfinate (called allicin), which is formed via (prop-2-en-1-yl)sulfenic acid from *S*-allylcysteine sulfoxide (alliin) found mainly in garlic. Allicin is a chiral compound, but occurs naturally only as a racemate. Analogously, but to a lesser extent, other thiosulfinates are also found in garlic, for example dimethylthiosulfinate, allylmethylthiosulfinate and methylallylthiosulfinate. Another important thiosulfinate is di(prop-1-en-1-yl)thiosulfinate, which is found mainly in onion via (*E*)-(prop-1-en-1yl)sulfenic acid from (*E*)-*S*-(prop-1-en-1-yl)cysteine sulfoxide (isoalliin). The general mechanism for the formation of dialk(en)ylthiosulfinates is given in Figure 8.60.

Dialk(en)ylthiosulfinates are relatively labile compounds. Their degradation is rapid even under room temperature and is influenced by various factors. For example, the half-life of allicin in water is 30–40 days at 23 °C. In non-polar media, such as organic solvents and vegetable oils, allicin is transformed into the corresponding main products dithiines (about 70%), diallyl disulfide and diallyl oligosulfides (about 18%), 4,5,9-trithiadodeca-1,6,11-triene 9-oxides known as ajoenes (ajo is the Spanish word for garlic) and certain other products (Figure 8.61). Vinyldithiines occur as regioisomers, 2-vinyl-4*H*-1,3-dithiine (the main product)

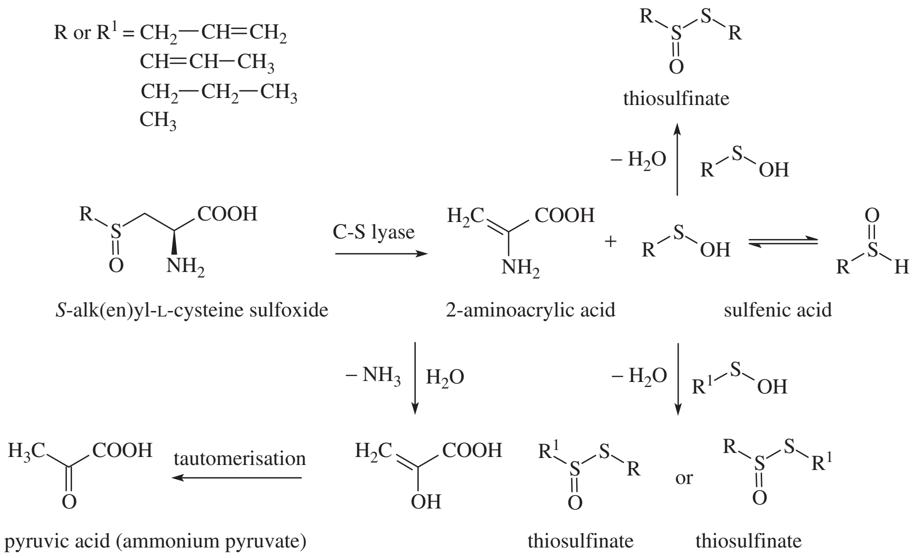


Figure 8.60 Formation of dialk(en)ylthiosulfinates by enzymatic decomposition of *S*-alk(en)ylcysteine sulfoxides.

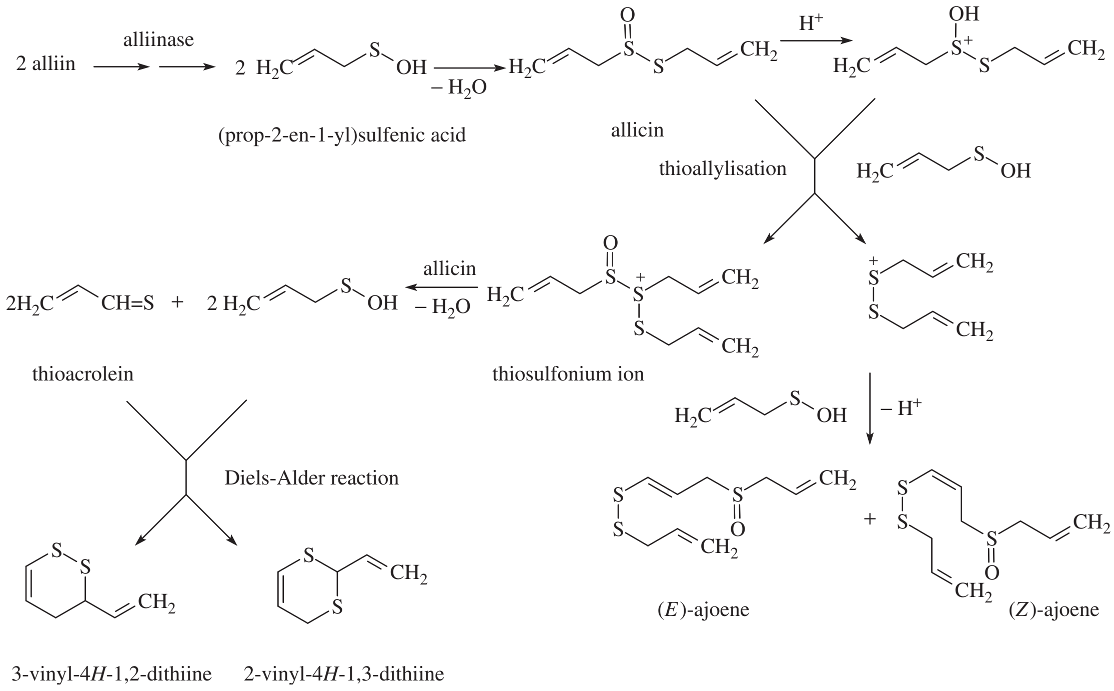

Figure 8.61 Transformation of allicin to dithiines and ajoenes in non-polar media (see Figure 8.57). Block, Dane, Thomas and Cody, 2010, fig 1. Reproduced by permission of the American Chemical Society.

and 3-vinyl-4*H*-1,2-dithiine, with (*E*)-ajoene usually present in double the amounts of (*Z*)-ajoene.

The main products of alliin transformation in polar media are sulfides. At room temperature or on heating, allicin is converted by water into diallyl disulfide, diallyl trisulfide and diallyl polysulfides, which are the principal components of garlic essential oil and aged garlic (Figure 8.62). Other reaction products are allyl alcohol, sulfur dioxide and propene. Disproportionation of thiosulfinates in aqueous (polar) solutions also leads to disulfides and thiosulfonates of general formula R–SO_2–S–R. For example, disproportionation of allicin yields diallylthiosulfonate (pseudoallicin) and diallyl disulfide, which subsequently give diallyl sulfide and diallyl trisulfide. In addition to alliin, garlic contains lesser amounts of methiin and isoalliin, which decompose by alliinase to the corresponding alk(en)ylsulfenic acids. These acids can self-condense to the corresponding dialk(en)ylthiosulfinates or react with allicin to yield mixed alk(en)ylthiosulfinates.

The (*E*)-(prop-1-en-1-yl)sulfenic acid derived from the related amino acid occurring in onion and known as isoalliin behaves differently. It isomerises on catalysis with enzyme LF-lyase

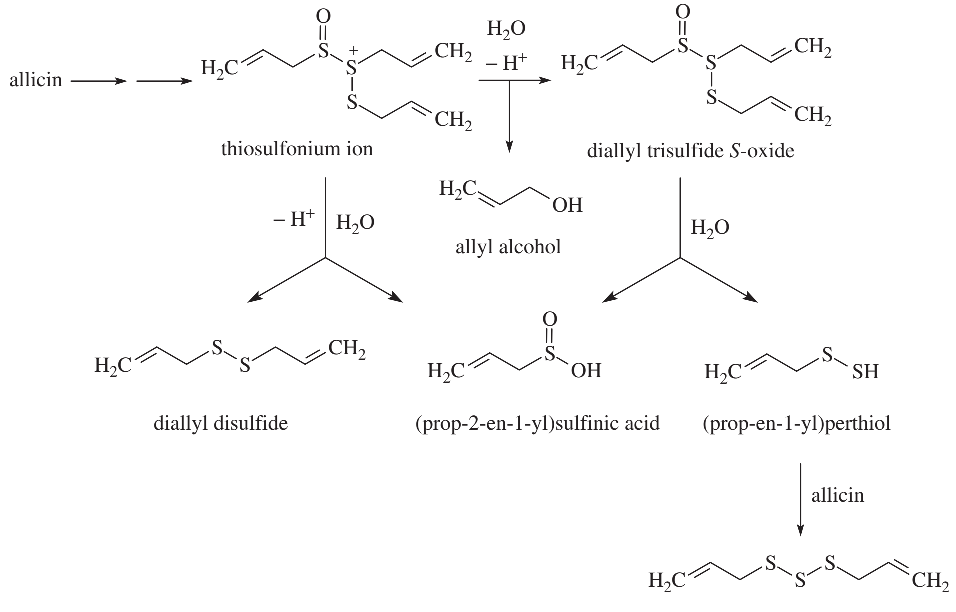

Figure 8.62 Transformation of allicin to oligosulfides and allyl alcohol in polar media (see Figure 8.58). Block, Dane, Thomas and Cody, 2010, fig 1. Reproduced by permission of the American Chemical Society.

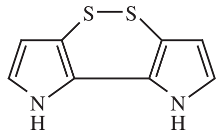
(Lachrymatory Factor-lyase), absent in garlic, to (*Z*)-thiopropanal *S*-oxide (thiopropanal sulfoxide), which is a lachrymatory substance that causes tears when cutting onions (Figure 8.63). Leek and chives contain the same sulfur-containing amino acids as onion; only the propiin content is somewhat higher at the expense of isoalliin, which is the major cause of much lower lachrymatory properties of these vegetables. (*E*)-(Prop-1-en-1-yl)sulfenic acid or (*Z*)-thiopropanal sulfoxide yield (*Z*,*Z*)-2,3-dimethyl-1,4-butanedithial 1,4-dioxide, which is also known as bis-sulfine. Dehydration of two molecules of (*E*)-(prop-1-en-1-yl)sulfenic acid produce (prop-1-en-1-yl)thiosulfinate, which is the precursor of 2,3-dimethyl-5,6-dithiabicyclo[2.2.1]hexane 5-oxides, known as zwiebelanes (Zwiebel is the German word for onion). The main product is (*E*)-zwiebelane, which is a chiral isomer. Spontaneous cyclisation of isoalliin in raw and cooked onion gives (1*S*,3*R*,5*S*)-3-carboxy-5-methyl-1,4-thiazan-*S*-oxide, also known as cycloalliin (see Section 2.2.1.2.7).

Technological processing of garlic, onions and leeks (e.g. cutting, preservation in salt or drying) often leads to the formation of undesirable intensely coloured compounds that are pink to deep red with onions and leeks, and dark green or green–blue with garlic. These pigments are not stable and are slowly converted into yellow–brown or brown pigments within a few days of storage. It was found that the pinking of onions and leeks and the greening of garlic are chemically very similar reactions consisting of enzymatic and non-enzymatic processes. The primary precursor is the sulfur amino acid isoalliin (see Section 2.2.1.2.2). In disrupted tissues, isoalliin is, along with other *S*-substituted cysteine derivatives, degraded by the enzyme alliinase to form (prop-1-en-1-yl)thiosulfinate, $H_3C–CH=CH–S(=O)–S–CH=CH–CH_3$, or mixed thiosulfinates, $H_3C–CH=CH–S–S(=O)–R$ ($R=CH_2CH=CH_2$ or CH_3). These compounds then react with free amino acids to form pigment precursors, *N*-substituted 3,4-dimethylpyrroles. Molecules containing a 3,4-dimethyl pyrrole ring are then cross-linked by an allyl group of allicin (or with thioacrolein formed from allicin, Figure 8.61) to form conjugated reddish-purple pigments (Figure 8.63). *N*-Substituted 3,4-dimethylpyrroles derived from alanine and valine have been identified in onion. A colour shift towards blue to green can be expected as the cross-linking reaction continues to form, for example, tri- or tetrapyrrole compounds.

Most of the species of the subgenus *Melanocrommyum* of the genus *Allium* are characterised by a deep orange to red ichor (fluid discharge) occurring after damage of the cells. This red pigment, 3,3′-dithio-2,2′-dipyrrole (**8-135**), forms spontaneously from (R_C,S_S)-*S*-(pyrrol-3-yl)cysteine sulfoxide (see Section 2.2.1.2.2) via 2-lactyl-3′-pyrrolyl sulfoxide.



8-135, 3,3′-dithio-2,2′-dipyrrole

8.2.9.1.5 Isothiocyanates

Isothiocyanates (formerly known as mustard oils, **8-136**) are compounds with a cumulated system of double bonds belonging to the heterocumulenes, compounds that are formally derived from the hydrocarbon allene ($H_2C=C=CH_2$). In small quantities, isothiocyanates are often accompanied by isomeric thiocyanates. Related cyanates and isocyanates do not occur in foods.

Precursors of isothiocyanates in food are the sulfur-containing glycosides known as glucosinolates that are found in the

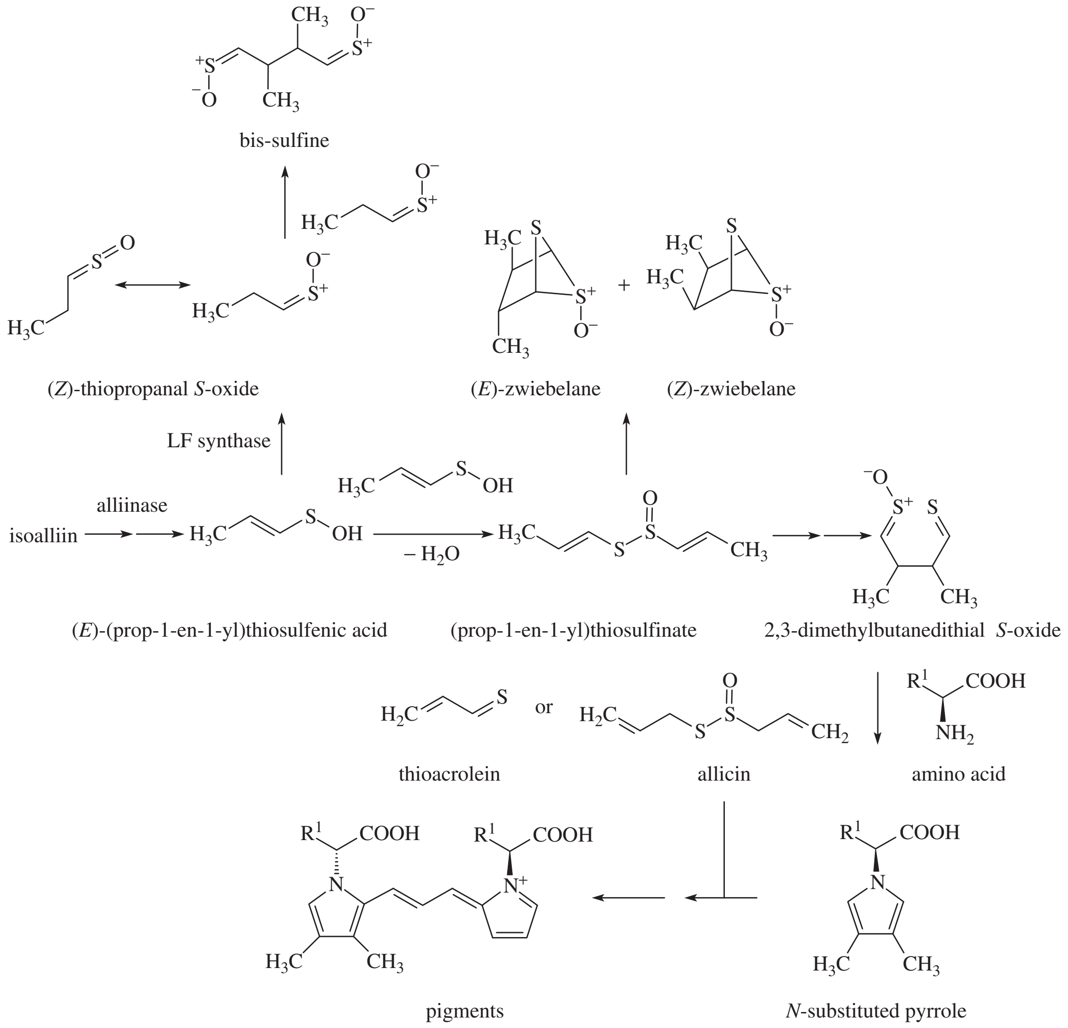


Figure 8.63 Transformation of isoallicin to (*Z*)-thiopropanal *S*-oxide, zwiebelanes and coloured products. Block, Dane, Thomas and Cody, 2010, fig 1. Reproduced by permission of the American Chemical Society.

8-136, isothiocyanates

cruciferous plant family (Brassicaceae) in particular. When the plant is damaged, for example by cutting or masticating, the released enzyme β-glucosidase is released to catalyse the glucosinolate degradation to isothiocyanates and a number of other substances. Isothiocyanates are substance with a very intense and sharp odour and taste. One of the major representatives of this group of substances is allyl isothiocyanate (prop-2-en-1-yl isothiocyanate, **8-136**, R=CH_2–CH=CH_2), which is an active component of hot horseradish, pastes made from brown and black mustard seeds and a number of *Brassica* vegetables.

8.2.9.2 Properties and reactions

Sulfur compounds are reactive and enter into reactions with other food components. Most sulfur compounds are substances with characteristic intense flavours that contribute to the odour and taste of many foods.

8.2.9.2.1 Sulfane, thiols and sulfides

Sulfane and thiols react readily with the carbonyl groups of carbonyl compounds (Figure 8.26) and they often undergo addition reactions to double bonds of unsaturated compounds. Unlike alcohols, thiols are easily oxidised by atmospheric oxygen to disulfides. The reaction mechanism is given in Section 2.5.1.1.1. Like methionine, cysteine and cysteine, simple sulfides and disulfides are also oxidised to sulfoxides, sulfones and other products. Fatty acid hydroperoxides are important oxidation reagents generated in the autoxidation of unsaturated fatty acids. An important reaction of oligosulfides is the interchange reaction that also proceeds in peptides and proteins containing bound cystine:

$$R–S–S–R + R^1–S–S–R^1 \rightarrow 2R–S–S–R^1$$

In veterinary science, it is known that onion and garlic are oxidatively toxic to erythrocytes resulting in haemolytic anaemia

in domestic animals, such as dogs, cats, horses, sheep and cattle. The causative agents have been identified as di(prop-2-en-1-yl) trisulfide (**8-128**), tetrasulfide and pentasulfide, di(prop-2-en-1-yl)thiosulfonate (R–SO_2–S–R, R = prop-2-en-1yl) and other transformation products of isoalliin.

8.2.9.2.2 Thiosulfinates

Aliphatic thiosulfinates formed by enzymatic decomposition of *S*-alk(en)yl cysteine sulfoxides show antimicrobial and antiaggregatory activity with human blood platelets, but are rather unstable. They are mainly oxidised to less active thiosulfonates. Thiosulfinates derived from vegetables such as garlic and onions can freely permeate cell membranes and rapidly react with reduced glutathione (G–SH) to form intracellular mixed-disulfide conjugates of the type G–S–S–R, where R = allyl or propyl. Analogous conjugates with cystine are found in extracellular fluids. Conjugation reactions of thiosulfinates in the presence of free thiols, including those in proteins, also occur in foods. Some conjugates of thiosulfinates with cysteine and degradation products of thiosulfinates have demonstrable biological activities. For example, *S*-allylmercaptocysteine (Cy–S–S–allyl) is believed to be a major bioactive component in aged garlic extract and has antioxidant, antiproliferative, apoptosis-inducing and antimetastatic activities. Another active compound is *S*-allylmercaptoglutathione (G–S–S–allyl). Decomposition products of thiosulfinates similarly have various physiological effects, such as lowering of blood pressure, cholesterol and blood sugar levels, antimutagenic and anticarcinogenic activities.

8.2.9.2.3 Isothiocyanates

Isothiocyanates are not only flavour-active compounds, but also have some antibacterial and fungicidal effects and a certain toxicity, such as mild strumigenic and cytotoxic activities. These properties are found especially in methyl isothiocyanate and allyl isothiocyanate, which are used as pesticides as their insecticidal, herbicidal, fungicidal and nematocidal effects can control soil-borne plant pathogens and parasitic nematodes. Allyl isothiocyanate have found use in the canning industry in modified atmospheres to extend the shelf life of packaged food (e.g. of meat products). The ability of some isothiocyanates of cruciferous vegetables to inhibit chemically induced cancer has also been demonstrated. These isothiocyanates are therefore classified as natural anticarcinogenic agents. In this respect, particular attention has been paid to sulforaphane (4-methylsulfinylbutyl isothiocyanate), which arises from its precursor, glucoraphanin, in broccoli and radishes (see **10-88**).

In aqueous solutions, isothiocyanates rearrange into thiocyanates. The rearrangement takes place via various mechanisms, usually by heterolytic or homolytic cleavage of the molecule (Figures 8.64 and 8.65). Allyl isothiocyanate preferably isomerises via the six-membered cyclic allyl thiocyanate intermediate (**8-137**). Isothiocyanates are extremely reactive substances, due to the electrophilic nature of their functional group, and enter into reactions with a number of nucleophilic reagents. Particularly important reactions in foods are the reactions of isothiocyanates with mercapto, amino and hydroxyl groups of amino acids and proteins. Some reactions of isothiocyanates with amino acids also produce coloured products (see Section 2.5.2.4).

$$R{-}N{=}C{=}S \rightleftharpoons R^+ + [{}^-S{=}C{=}N \longleftrightarrow {}^-S{-}C{\equiv}N] \rightleftharpoons R{-}S{-}C{\equiv}N$$

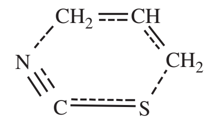
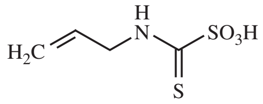
$$R{-}S{-}C{\equiv}N \rightleftharpoons R\bullet + SCN\bullet$$
$$R\bullet + R{-}N{=}C{=}C \rightleftharpoons R\bullet + R{-}S{-}C{\equiv}N$$

Figure 8.65 Homolytic cleavage of isothiocyanates.



8-137, cyclic intermediate involved in the isomerisation of allyl isothiocyanate to allyl thiocyanate (transition state)

Additions of various nucleophilic reagents to the isothiocyanate functional group are shown in Figure 8.66. The nucleophilic reagent can be water (hydroxyl ions), which yields thiocarbamoic acid salts, whereas alcohols give thiocarbamic acid esters, sulfane gives dithiocarbamoic acid salts, thiols give dithiocarbamoic acid esters, ammonia gives *N*-substituted thioureas and amines give *N,N′*-disubstituted thioureas. Reactions are usually complex and depend on pH and other factors. The main reactions of allyl isothiocyanate in aqueous solutions are shown in Figure 8.67. The main product in weakly acidic solutions (pH 4) is carbon disulfide and allylamine. In slightly alkaline solutions (pH 8) allylamine, allyldithiocarbamate, diallylthiourea and carbon disulfide form as the main products. Diallyl disulfide and other products are also produced in small amounts. For example, diallyl disulfide imparts a faint odour resembling garlic to older mustard pastes. In the presence of hydrogen sulfites (HSO_3^- ions), sometimes used as preservatives, allyl isothiocyanate yields allylaminothiocarbonylsulfonic acid (**8-138**).



8-138, allylaminothiocarbonyl sulfonic acid

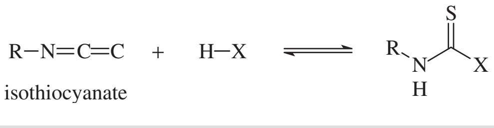


Figure 8.66 Reaction of isothiocyanates with nucleophilic reagents: HX = water (H_2O) – thiocarbamoic acid, alcohol (R^1–OH) – thiocarbamate, sulfan (H_2S) – dithiocarbamoic acid, ammonia (NH_3) – *N*-alkylthiourea, amine (R^1-NH_2) – *N,N*[1]-dialkylthiourea.

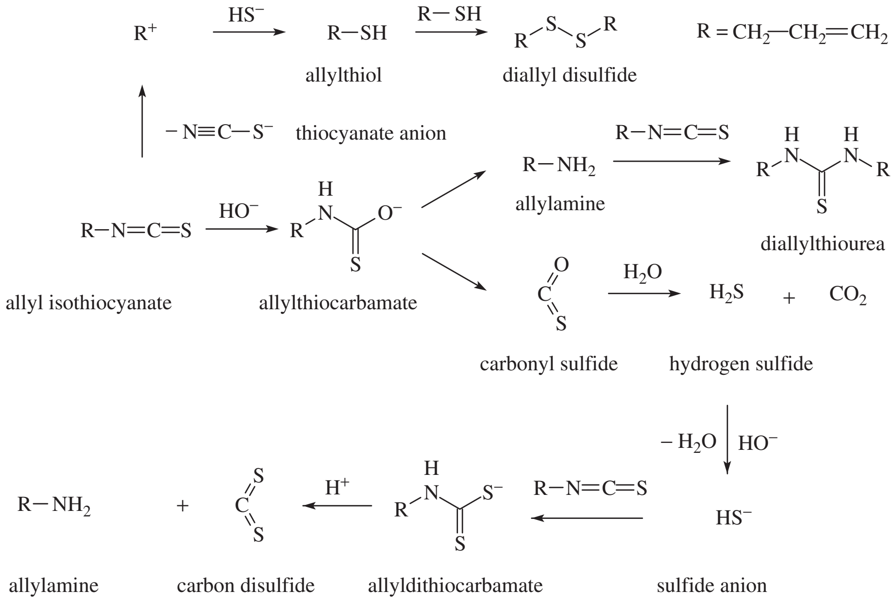

Figure 8.67 Decomposition of allyl isothiocyanate in aqueous solutions.

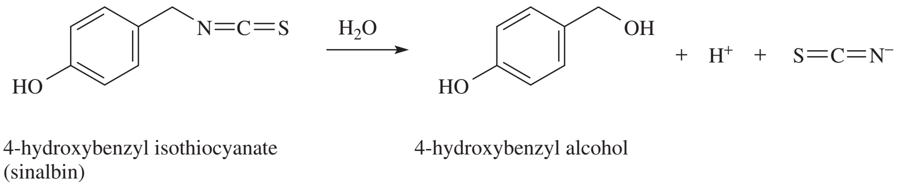

Figure 8.68 Hydrolysis of sinalbin.

Aromatic and heterocyclic isothiocyanates are unstable and easily hydrolyse to the corresponding alcohols. For example, 4-hydroxybenzyl isothiocyanate (the degradation product of sinalbin, which occurs in the seeds of white mustard, *Leucosinapis album*, Brassicaceae) decomposes in normal table mustard to 4-hydroxybenzyl alcohol and thiocyanate ions (Figure 8.68). Isothiocyanates derived from indolyl glucosinolates behave similarly.

8.2.10 Nitrogen compounds

8.2.10.1 Classification, structure, terminology and occurrence

Ammonia, volatile amines imines and amides and, in particular, heterocyclic compounds containing nitrogen, have certain importance as flavour-active substances in non-acidic foods.

8.2.10.1.1 Ammonia

Ammonia (NH_3) is found in foods mainly as a product of free nucleotide deamination, such as deamination of adenosine 5′-monophosphate (AMP) to inosine 5′-monophosphate, and as a product of deamination of the amino acid amides asparagine and glutamine. In acidic foods, ammonia is present almost exclusively in the form of ammonium salts.

8.2.10.1.2 Amines

Amines are structurally derived from ammonia by substitution. The basic amine groups are primary amines (RNH_2), secondary amines (RR^1NH), tertiary amines (RR^1R^2N) and quaternary amines with the general structure $RR^1R^2R^3N^+(OH^-)$. Tertiary amines can form *N*- oxides of the type $RR^1R^2N^+(O^-)$.

Primary amines in foods most often arise as products of enzymatic reactions that include decarboxylation of amino acids catalysed by non-specific decarboxylases or enzymatically catalysed amination or transamination of aldehydes (Figure 8.69).

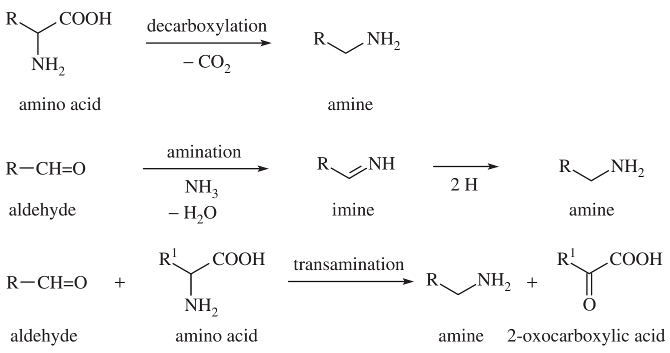

Figure 8.69 Main reactions of amine formation.

The decarboxylation of amino acids takes place mainly in materials of animal origin, while the formation of aldehydes and amines occurs largely in plant materials. Common products are aliphatic amines. In aromatic compounds, such as benzylamine (**8-139**), the amino group is bound in the side-chain. Amines are present in virtually all foods, and therefore can also be found in fruits, alcoholic beverages and so on, but they act as odour-active substances only in some non-acidic foods of animal origin, especially in cheeses, fish, other aquatic animals and meat. In acidic foods, amines are present in the form of non-volatile salts. In plants and fungi, amines often have a function of insect attractants. An overview of major amine precursors is given in Table 8.29. The common volatile amines contents in selected foods are shown in Table 8.30. The enzymatic decarboxylation also occurs in amino acids other than those listed in Table 8.29. Sulfur amino acids and hydroxyamino acids are decomposed with the formation of non-volatile amines. For example, cysteamine (2-mercaptoethylamine, **8-140**) is produced from cysteine, homocysteamine (3-mercaptopropylamine, **8-133**) from homocysteine, 3-(methylthio)propylamine (**8-141**) from methionine, ethanolamine (2-aminoethanol, **8-142**) from serine and (−)-(*R*)-1-aminopropan-2-ol, (**8-142**, R=CH_3) from threonine. Ethanolamine also results from the hydrolysis of some glycerophospholipidis, for example from (3-*sn*-phosphatidyl)ethanolamine.

Some aliphatic, aromatic and heterocyclic amines and diamines formed by decarboxylation of basic, aromatic and heterocyclic amino acids are biologically active substances called biogenic amines. Subsequent enzymatic transformations of biogenic amines yield other biologically active products that play important roles in living organisms, such as adrenal hormones called catecholamines (see Section 10.3.2.10.1).

homocysteamine, $n = 1$

8-141, 3-(methylthio)propylamine

ethanolamine (*R*)-1-aminopropan-2-ol

8-142, amino alcohols

Decarboxylation of amino acids can also proceed as a non-enzymatic reaction. Analogously to the enzyme catalysed decarboxylations, amines are formed as byproducts of the Strecker degradation of amino acids and by thermal decarboxylation of amino acids, especially of sulfur amino acids, hydroxyamino acids and aromatic amino acids. For example, thermal decarboxylation and subsequent reactions of cysteine and cystine produce ammonia

Table 8.29 Precursors of volatile amines in foods.

Amine	Precursor		Amine	Precursor

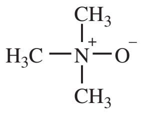
Butylamine	-	-	3.7	<0.07	Benzylamine	3.8	2.8	-	-

and ethylamine and ethylamine, pentylamine and crotylamine (but-2-en-1-ylamine) arise from methionine. A number of aromatic and heterocyclic amines that have the amino group attached to the aromatic (heterocyclic) ring may be formed by pyrolysis of amino acids and proteins in the Maillard reaction, especially in the presence of creatinine. Some of these amines (e.g. aminoimidazoazaarenes), described in Section 12.2.1.1, are mutagenic and probably carcinogenic compounds.

Secondary and tertiary amines are formed from precursors other than amino acids. Dimethylamine results from degradation of choline (which is present in some phospholipids), some alkaloids (e.g. in beer it is produced from gramine (see **10-198**) present in germinating barley grains and also in non-enzymatic browning reactions from methylamine and formaldehyde or by decarboxylation of sarcosine. Trimethylamine, together with dimethylamine, methylamine and ammonia, is an odorous compound of fish and other aquatic animals. It is formed by reduction of the sensory indifferent trimethylamine oxide (trimethylaminoxide, **8-143**) in tissues post mortem.

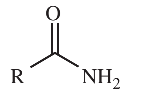


8-143, trimethylamine oxide

8.2.10.1.3 Amides

Amides derived from carboxylic acids (**8-144**) and the corresponding *N*-substituted (**8-145**) and *N*,*N*-disubstituted amides (**8-146**) are polar compounds of low volatility, yet some of them may participate in the aroma of non-acidic foods. Commonly occurring compounds are mainly amides derived from formic and acetic acids. For example, beer contains hundredths to tenths mg/kg *N*-methylformamide (**8-145**, $R = H$, $R^1 = CH_3$), *N*-methylacetamide (**8-145**, $R = R^1 = CH_3$), *N*,*N*′-dimethylacetamide (**8-146**, $R = R^1 = R^2 = CH_3$), *N*-(2-methylbutyl)acetamide, where $R = CH_3$, $R^1 = CH_2CH(CH_3)CH_2CH_3$, its isomer *N*-(3-methylbutyl)acetamide, $R^1 = CH_2CH_2CH(CH_3)_2$ and *N*-(2-phenylethyl)acetamide (**8-147**), which are produced by condensation of carboxylic acids with amines followed by decarboxylation (Figure 8.70). Many non-volatile *N*-substituted formamides and acetamides are also produced in the Maillard reaction. Decarboxylation of asparagine catalysed by decarboxylases yields 3-aminopropionamide (**8-148**), which may become a precursor of acrylamide (see Section 12.2.2).

In addition to aliphatic amides, significant components of the aroma of shrimps, crabs, other marine crustaceans, molluscs and other marine animals include cyclic amides (lactams), such



8-144, carboxylic acid amide

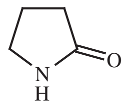
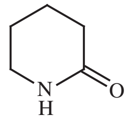
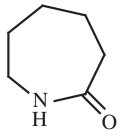
as 2-pyrrolidone (also known as γ-butyrolactam or butane-4-lactam, **8-149**), 2-piperidone (δ-valerolactam or pentane-5-lactam, **8-150**), 2-perhydroazepinone (ε-caprolactam or hexane-6-lactam, **8-151**) and their *N*-methyl-substituted analogues. Cyclic amides are formed by dehydration of the corresponding amino acids.



8-149, 2-pyrrolidone



8-150, 2-piperidone



8-151, 2-perhydroazepinone

As well as aspartic and glutamic acid amides (glutamine and asparagine), foods contain a number of other non-volatile amides derived almost exclusively from glutamine or glutamic acid. An example is the amino acid L-theanine (see Section 2.2.1.2.3) in tea leaves.

Substituted amides derived from amino acids (biogenic amines) and cinnamic acids are also frequent components. Amides derived from biogenic amines are constituents of cell walls of higher

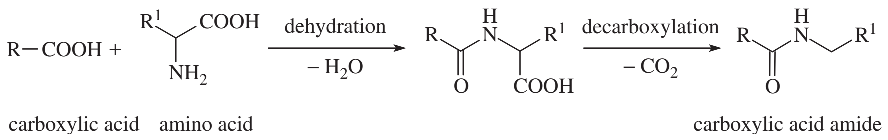


Figure 8.70 Formation of amides from carboxylic acids and amino acids.

plants that are often classified as alkaloids. It is assumed that tyramine amides, such as (*E*)-*N*-sinapoyltyramine (**8-152**), act as a barrier against the penetration of pathogens in the plant cell walls, because they increase tissue rigidity and reduce its digestibility. Another amide derived from tyramine and ferulic acid (**8-152**), exhibiting antioxidant effects, occurs in black pepper. Some other amides are derived from dopamine, phenylethylamine and octopamine. For example, (*E*)-*N*-*p*-coumaroyloctopamine and (*E*)-*N*-feruloyloctopamine (**8-152**) occur in garlic skin as major antioxidants. Also active as an antioxidant is the amide derived from the pepper alkaloid piperine via opening of the 1,3-dioxol ring and methylation of one hydroxy group (**8-153**). Unlike piperine and other pepper alkaloids (see Section 10.3.2.1.2), this amide is odourless and does not cause a burning sensation.

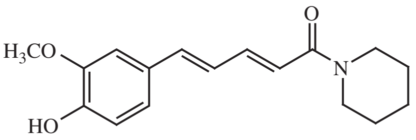
8-152, cinnamic acids amides

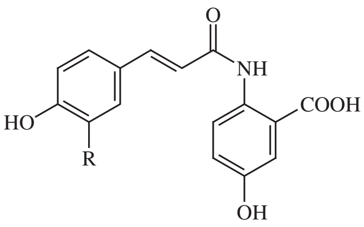


8-153, piperine derived amide with antioxidant properties

A group of about 40 amides derived from 5-hydroxyanthranilic or 5-hydroxy-4-methoxyanhranilic acids and cinnamic acids, trivially named avenanthramides, are important phytoalexins unique to oat grains (*Avena sativa*, Poaceae). The dominant compounds are derivatives of 5-hydroxyanthranilic acid: avenanthramide Bp derived from *p*-coumaric acid (also called avenanthramide A, **8-154**), avenanthramide Bc derived from caffeic acid (also called avenanthramide C) and avenanthramide Bf derived from ferulic acid (also called avenanthramide B). The main compound (40–132 mg/kg) is avenanthramide Bf (**8-154**). Approximately 6% of oat antioxidants are anthramides derived from caffeic acid.

Related amides are vanillylamides, such as capsaicin and dihydrocapsaicin, which are derived from vanillylamine and fatty acids. Vanillylamides are the main hot substances of peppers. A similar compound in peppers is capsaicinol, which does not create a burning sensation, but is effective as an antioxidant (see Section 10.3.2.1.7).

$^{\beta}N$-Alkanoyl-5-hydroxytryptamides occurring in the wax layer of coffee beens are derived from serotonin and $C_{22:0}$ to $C_{24:0}$ fatty acids. It has been shown that all these amides are responsible for the



8-154, avenanthramide Bp, R = H
avenanthramide Bc, R = OH
avenanhramide Bf, R = OCH_3

stomach irritation caused by stimulation of gastric juice secretion after ingestion of coffee brews.

8.2.10.2 Properties and reactions

Aldehydes and ketones react with ammonia and primary amines to form imines. Reaction with aldehydes yields aldimines, and ketimines arise in reactions with ketones (Figure 8.28). Imines derived from aliphatic carbonyl compounds are generally unstable and are transformed to more stable products, such as amines, diamines and others. Secondary amines react with aldehydes and ketones with the formation of enamines (Figure 8.29). Imines are similarly flavour-active compounds derived from furan-2-carbaldehyde. For example, the aromas of *N*-furfuryl(isobutylidene)amine, *N*-(furfuryl)isopentylideneamine (**8-155**) and *N*-(furfurylidene)isobutylamine (**8-156**) reportedly resemble chocolate.

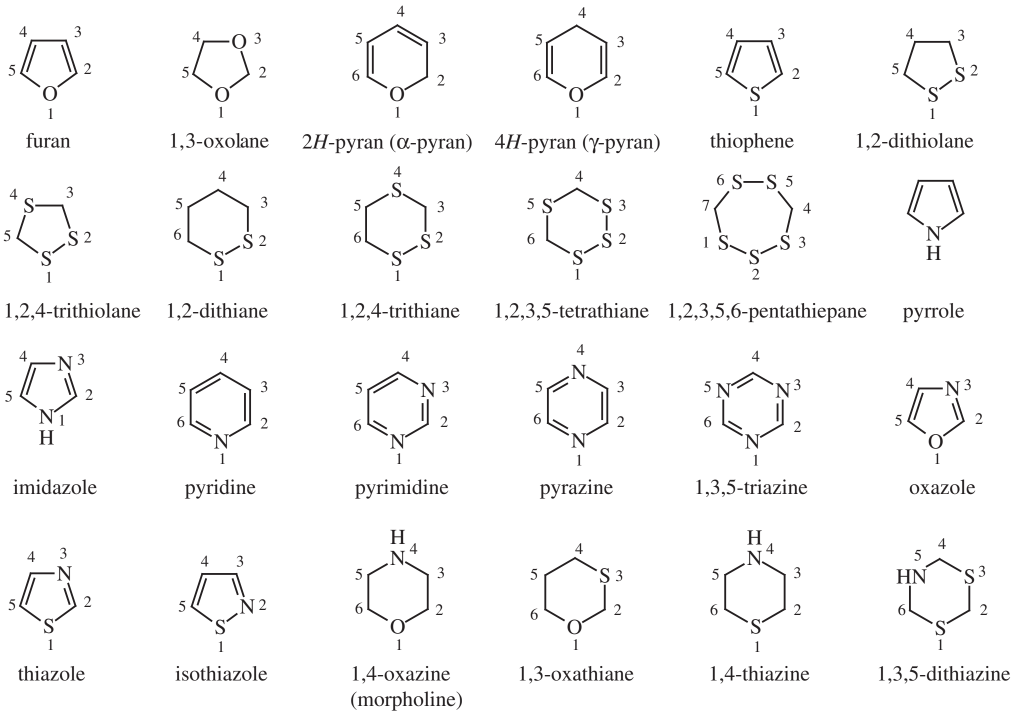
8-156, *N*-(furfurylidene)isobutylamine, R = $CH(CH_3)_2$
N-(furfurylidene)isopentylamine, R = $CH_2CH(CH_3)_2$

8.2.11 Heterocyclic compounds

Heterocyclic compounds are those in which one or more carbon atoms in the ring are replaced by another element, which is called a heteroatom. Most common in foods are five-membered and six-membered heterocyclic compounds containing as the heteroatom oxygen, sulfur or nitrogen. Also common are heterocycles containing more of the same or different heteroatoms. Heterocyclic compounds are important odour- and taste-active components of many foods. The basic structures of most oxygen, sulfur and nitrogen heterocycles are shown in formulae **8-157**. More important than these basic heterocycles, however, are their



8-157, structures of basic heterocyclic compounds

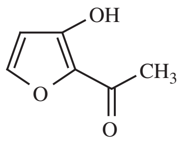
derivatives, particularly alkyl, acyl, hydroxy, oxo and certain others. A number of important aromatic compounds are derived from dihydro, tetrahydro or hexahydro derivatives of these heterocyclic compounds. Some heterocyclic compounds exhibit different physiological effects. Heterocycles containing polar functional groups are non-volatile, such as virtually all imidazole and pyrimidine derivatives, but they often have other functions in living organisms.

Heterocyclic compounds are formed mainly in non-enzymatic browning reactions, especially in food surface layers during the thermal processing of foods by baking, frying and roasting. They also arise by pyrolysis of proteins, carbohydrates, lipids and other food components; some heterocyclic compounds result from reactions catalysed by enzymes.

8.2.11.1 Classification, structure, terminology and occurrence

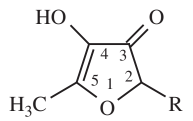
8.2.11.1.1 Furans

A large number of furan derivatives are produced in non-enzymatic browning reactions as dehydration products of carbohydrates and related compounds, such as ascorbic acid (γ-lactones can also be considered furan derivatives). Most furans are common to many thermally processed foods. Higher levels of these compounds are also present in acid protein hydrolysates. Furan-2-carbaldehyde has the characteristic pleasant woody aroma resembling nuts, which arises from pentoses and ascorbic acid, and 5-methylfuran-2-carbaldehyde, which is a product of 6-deoxyhexoses. A fatty herbal type flavour is provided by 5-hydroxymethylfuran-2-carbaldehyde arising from hexoses. 2-Acetylfuran arising from hexoses and pentoses is an important component of a number of foods, such as fruits, wine and beer, with a sweet, balsamic flavour. 2-Acetyl-3-hydroxyfuran known as isomaltol (**8-158**) has a caramel-like flavour. Isomaltol is formed from hexoses and 4-*O*-substituted glucoses at higher concentrations.



8-158, isomaltol

The most important furans in major food commodities are 4-hydroxy-2*H*-furan-3-ones (**8-159**), which are characterised by a planar arrangement of molecules and the same configuration of the enol, hydroxyl and oxo groups. Furanones occur as racemic mixtures because of their keto–enol tautomerism (Figure 8.71). Some other compounds have analogous structures as furanones, such as maltol, 3-hydroxy-2*H*-pyran-2-one and cyclopentenolones. All compounds with this structure resemble more or less the caramel



8-159, 4-hydroxy-5-methyl-2*H*-furan-3-one (norfuraneol), R = H

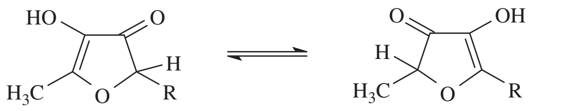

Figure 8.71 Structure of compounds with caramel flavour.

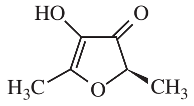
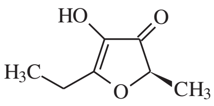
flavour with sugary and sweet notes; this is different, however, if the hydroxyl group is methylated or completely missing.

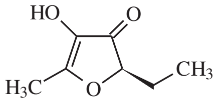
An important compound is 4-hydroxy-5-methyl-2*H*-furan-3-one, known as norfuraneol. Norfuraneol occurs in caramel, roasted chicory root and also in meat broth. 4-Hydroxy-2,5-dimethyl-2*H*-furan-3-one, known as furaneol, strawberry furanone or pineapple furanone, arises in the Maillard reaction from L-rhamnose (Figure 4.39) and in a reaction of methylglyoxal with hydroxyacetone (Figure 4.41). It occurs, for example, in strawberries, pineapple, roasted almonds, popcorn, meat broth and a number of other foods as a racemic mixture. The structure of (+)-(*R*)-furaneol responsible for the characteristic odour is given in formula **8-160**. The odour of furaneol is sugary, jammy and reminiscent of strawberries and, at higher concentrations, caramel (threshold concentration is 1–4 μg/l in air). Racemic homofuraneol exists in two tautomeric forms through the keto–enol isomerisation, as 5-ethyl-4-hydroxy-2-methyl-2*H*-furan-3-one (homofuraneol I) or 2-ethyl-4-hydroxy-5-methyl-2*H*-furan-3-one (homofuraneol II). Homofuraneol I and homofuraneol II occur in a ratio of 1 : 3 to 1 : 2, which are in equilibrium with each other. Structures of (+)-(*R*)-isomers are given in formulae **8-161** and **8-162**, respectively. Only one isomer, (*R*)-homofuraneol I was found to have a strong roasted sweet scent. The other isomers have sweet, less roasted odour. Homofuraneol is found, for example, in soy sauce.



8-160, (+)-(*R*)-furaneol



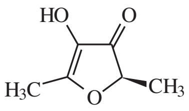
8-161, (+)-(*R*)-homofuraneol I



8-162, (+)-(*R*)-homofuraneol II

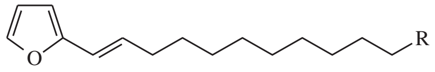
An example of a furanone with methylated hydroxyl in position C-4 is 4-methoxy-2,5-dimethyl-2*H*-furan-3-one, also known as mesifurane, which is derived from furaneol. (+)-(*R*)-Mesifurane (**8-163**) has a burnt and caramel-like odour, but is more subtle and mellow than the odour of furaneol. Mesifurane accompanies furaneol in fruits (such as pineapple, raspberry, strawberry and grape) and other foods. 2,5-Dimethyl-2*H*-furan-3-one, which does not contain the C-4 hydroxy group occurs as a constituent of bread and coffee flavour; its odour resembles bread.

Autoxidation of linoleic and linolenic acids yields 2-pentylfuran, isomeric 2-(pent-2-en-1-yl)-furans are produced from linolenic



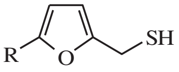
8-163, (+)-(*R*)-mesifurane I

acid with a specific type of rancidity called reversion. They, along with other oxidation products in soybean oil and some other oils, possess a green odour resembling beans, which is known as reversion flavour (see Section 3.8.1.10.1). Avocados (*Persea americana*, Lauraceae) and other *Persea* species contain a group of furans commonly referred to as avocadofurans that are substituted at C-2 with various saturated or unsaturated side chains. The first two avocadofurans identified from avocado fruit and seeds were 2-(tridec-12-yn-1-yl)furan (avocadodyenofuran) and 2-(tridec-12-en-1-yl)furan (avocadodienofuran) (**8-164**). Since then, many other avocadofurans with growth inhibitory and insecticidal activities have been identified.

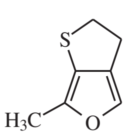


8-164, avocadienofuran, R = CH=CH$_2$
avocadynenofuran, R = C≡CH

Some furans containing a sulfur atom in the aliphatic side chain, and also some thienofurans, contribute significantly to the aroma of roasted coffee. Examples of compounds of the first group are 2-furanmethanethiol (furfuryl mercaptan), its 5-methyl derivative (**8-165**) and 2-methyl-3-furanthiol which are found in coffee. The presence of 2-furanmethanethiol and 2-methyl-3-furanthiol has also been reported in certain wines. On the other hand, 2-methyl-3-furanthiol can contribute to stored orange juice off-flavor. A representative of the second group of compounds is diterpene kahweofuran, also known by the systematic name of 2-methyl-3-oxa-8-thiabicyclo[3.3.0]octa-1,4-diene or 2,3-dihydro-6-methylthieno[2,3-*c*]furan (**8-166**), which is only found in roasted coffee. All these compounds have very low odour thresholds. A number of other furan derivatives containing sulfur in the molecule arise as thermal degradation products of thiamine, which is, therefore, used as an ingredient for simulating meat aroma, together with proteins, sugars (such as ribose) and sulfur amino acids (e.g. cysteine) in the so-called reaction flavours, also known as process flavours. Possibly the best known commercial



8-165, 2-furanmethanethiol, R = H
5-methyl-2-furanmethanethiol, R = CH$_3$

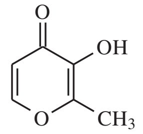


8-166, kahweofuran

reaction flavour is 2,5-dimethyl-3-hydroxy-2*H*-furan-3-one (furaneol), obtained by heating L-rhamnose with L-proline.

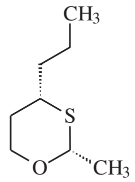
8.2.11.1.2 Pyrans

Pyrans occurring in foods are hypothetically derived from α-pyran or γ-pyran, or from α- or γ-pyrones, respectively. δ-Lactones can also be considered derivatives of α-pyran. An important α-pyrone is 3-hydroxypyran-2-one, also known as 3-hydroxy-2-pyrone or 3-hydroxy-2*H*-pyran-2-one, which is a δ-lactone of 2,5-dihydroxypenta-2,4-dienoic acid with a caramel-like flavour, which arises from ascorbic acid (see Section 5.14.6.2.2). Undoubtedly, the most important γ-pyrone is 3-hydroxy-2-methylpyran-4-one, which is known as maltol (**8-167**), featuring a caramel (or malt) smell and taste. A large number of other γ-pyrones are formed in non-enzymatic browning reactions, but as flavourings they are of little consequence.



8-167, maltol

Additionally, aroma components of some foods are six-membered heterocycles containing an oxygen atom and sulfur in the molecule. An example of such a compound is (2*R*,4*S*)-2-methyl-4-propyl-1,3-oxathiane (**8-168**), also known as *cis*-tropathiane, which occurs in the yellow passion fruit (*Passiflora edulis*, f. *flavicarpa*, Passifloraceae), pineapple (*Ananas comosus*, Bromeliaceae), whisky and white wines.



8-168, (2*R*,4*S*)-2-methyl-4-propyl-1,3-oxathiane

8.2.11.1.3 Thiophenes

Thiophenes are found in many foods and often contribute significantly to their organoleptic properties. They are important as aromatic components of meat, roasted coffee, roasted nuts, onions and other foods. For example, while unsubstituted thiophene has an odour reminiscent of benzene, 2-methyl substituted thiophenes positively affect the flavour of canned meat. 2-Methylthiophene odour is described as green, heated onion, sulfurous and sweet; dimethylthiophenes are important components of fried onion aroma, 2-acetyl-3-methylthiophene is reminiscent of honey and roasted nuts and 3-acetyl-2,5-dimethylthiophene has a sulfurous odour.

Thiophenes are formed by different reactions. The general reaction is that of furan derivatives with hydrogen sulfide (Figure 8.72). This mechanism is assumed, for example, in the formation of some thiophene derivatives from 4-hydroxy-2*H*-furan-3-ones. Alkylthiophenes substituted in positions C-2 and C-3 may arise in reactions of 2-mercaptoethanal with unsaturated aldehydes, such as acrolein or but-2-enal (Figure 8.73). 2-Mercaptoethanal is a product of Strecker degradation of cysteine.

The characteristic components of the fried onion aroma are 2,4-dimethylthiophene and 3,4-dimethylthiophene. They are produced from di(prop-1-en-1-yl)disulfide (Figure 8.74), which is formed from isoalliin via the corresponding thiosulfinate, in the same way as diallyl disulfide gives alliin via allicin.

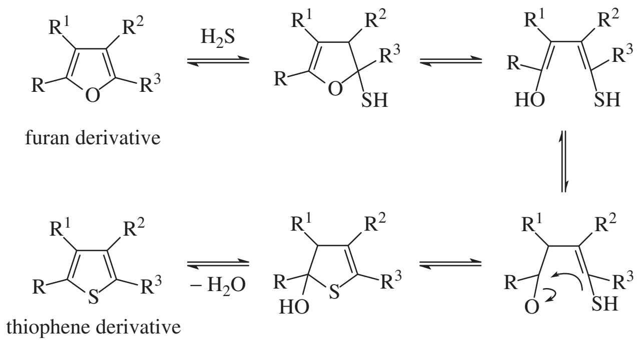


Figure 8.72 Formation of thiophenes from furans.

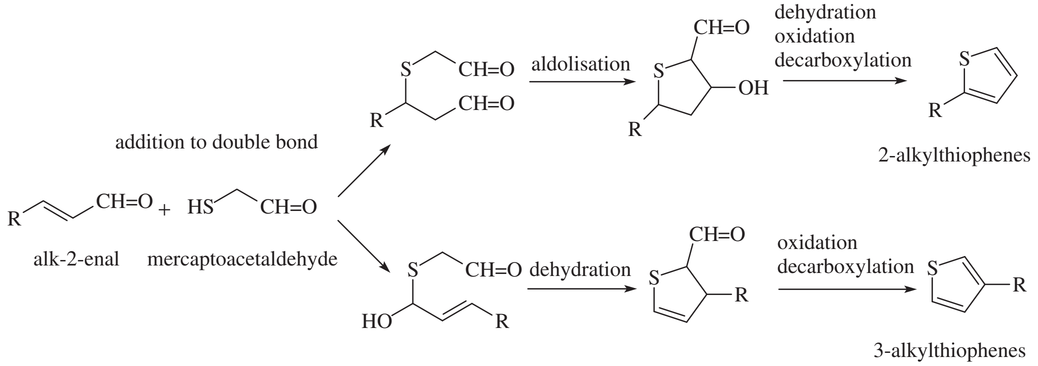

Figure 8.73 Formation of 2-alkylthiophenes and 3-alkylthiophenes.

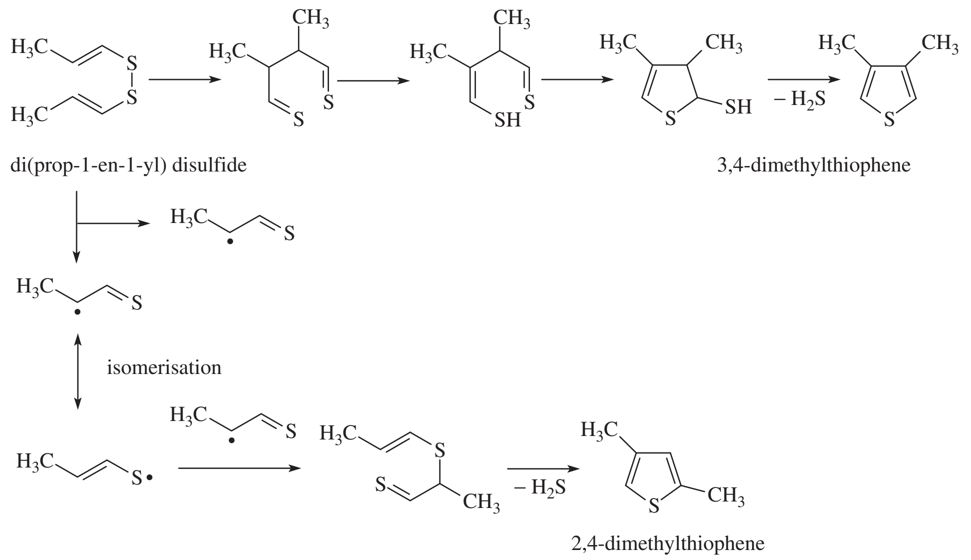

Figure 8.74 Formation of 2,4-dimethylthiophene and 3,4-dimethylthiophene in roasted onion.

Common compounds generated by the thermal processes are also thienothiophenes (**8-169**); these are, for example, components of roasted coffee volatiles.

thieno[2,3-*b*]-thiophene thieno[3,2-*b*]-thiophene

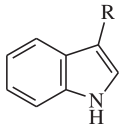
8-169, thienothiophenes

8.2.11.1.4 Pyrroles

Pyrroles generally have an intense and unpleasant odour, but the odour of some pyrroles and derived compounds resembles caramel, nuts, bread or chocolate upon dilution. A non-volatile pyrrole derivative is 5-oxopyrrolidine-2-carboxylic acid, produced by heating glutamic acid or glutamine.

Many pyrroles arise mainly as products of the Maillard reaction of carbohydrates and proline. Unsubstituted pyrrole and some alkylsubstituted pyrroles also result from pyrolysis of other amino acids. For example, pyrrole appears in the pyrolysate of glycine, serine, threonine or proline, 1-methylpyrrole arises from hydroxyproline, and 2-methylpyrrole and 3-ethyl-4-methylpyrrole are products of serine and threonine degradation. In general, pyrroles may arise in reactions of furans with ammonia (Figure 8.75), analogous to the reaction of furans with sulfane, which yields thiophenes. Pyrroles acylated in position C-2 of the nuclei are formed in reactions of amino acids with 2-acylfurans (Figure 8.76) and the corresponding pyridines are similarly produced. A particularly important compound is 2-acetyl-1-pyrroline, which is a characteristic aroma component of white bread crust, basmati rice and popcorn (see Section 8.2.12.4.1)

Indoles (4,5-benzopyrroles) are components of a generally undesirable odour of certain foods. Typical compounds are indole and 3-methylindole, which is trivially called skatole (**8-170**). At higher concentrations, these compounds have a faecal smell (as they are also found in faeces), but in low concentrations, they have a flowery smell. Both indoles are the result of degradation of tryptophan by microorganisms (also in the digestive tract of animals) or by pyrolysis of tryptophan. For example, these compounds contribute to a specific boar odour in pork meat and the typical odour of cooked beef tripe (see Section 8.2.12.1). For this reason, the traditional



8-170, indole, R = H
3-methylindole (skatole), R = CH_3

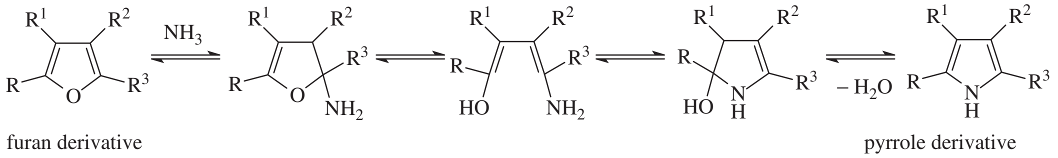


Figure 8.75 Formation of pyrroles from furans.

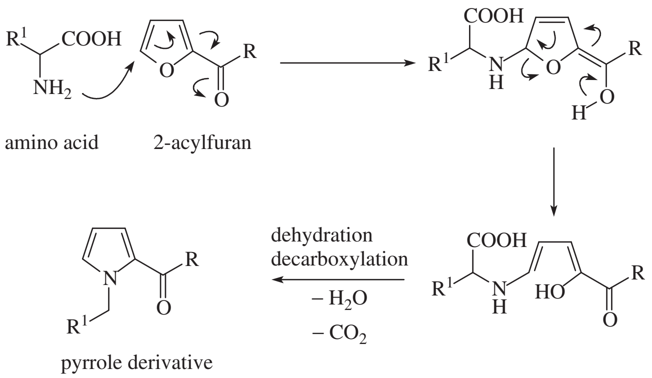

Figure 8.76 Formation of 2-acylpyrroles.

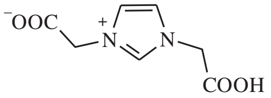
way of cooking tripe soup includes heating-up and removal of the first broth. The threshold concentration of skatole is very low (0.006 μg/l in water), and the acceptable concentration in pork fat is 0.15–0.25 mg/kg.

8.2.11.1.5 Imidazoles

Imidazoles are virtually non-volatile compounds and therefore do not act as odour-active substances. The main reaction leading to the formation of simple imidazoles is that of α-dicarbonyl compounds with aldehydes and ammonia (Figure 8.77). The basic member of the homologous series, unsubstituted imidazole (Figure 8.77, $R^1 = R^2 = R^3 = H$), thus arises from glyoxal, formaldehyde and ammonia, 4-methylimidazole (Figure 8.77, $R^1 = CH_3$, $R^2 = R^3 = H$) is analogously formed from methylglyoxal, formaldehyde and ammonia and the precursors of 2-methylimidazole (Figure 8.77, $R^1 = R^2 = H$, $R^3 = CH_3$) are glyoxal, acetaldehyde and ammonia. 4-Methylimidazole is found in large quantities (50–700 mg/kg) in caramel (see Section 4.7.6), when ammonia or ammonium salts are used as catalysts. Common dark beers and cola drinks may contain more than 250 μg/kg of 4-methylimidazole. It acts as a convulsant (an agent that causes convulsions) for some animals at very high doses and is a probable carcinogen; therefore in the European Union the legal limit was established at 250 mg/kg of caramel.

Similar effects were observed for 2-methylimidazole that is also found in caramel, together with polyhydroxy-substituted imidazoles that are produced from glycosuloses, 3-deoxyglycosuloses and ammonia. These imidazoles are unstable and at higher temperatures decompose to imidazole, its methyl derivatives and the corresponding glycols. An example of these compounds is 2-acetyl-4-(*arabino*-1,2,3,4-tetrahydroxybutyl)imidazole.

Non-volatile imidazoles that result from amino acids in reactions with α-dicarbonyl compounds, aldehydes and ammonia are betaines. The basic member of the homologous series of these imidazoles is 3-carboxymethyl-1-imidazolium ethanoate, which arises as the main product in the reaction of glycine with glyoxal and ammonia (**8-171**).



8-171, 3-carboxymethyl-1-imidazolium ethanoate

8.2.11.1.6 Pyridines

Descriptive terminologies for the odours of pyridines use terms such as green, bitter, astringent, roasted, burnt, pungent, solvent and fishy, none of which could be considered desirable. Their presence in some food commodities, such as beer and whisky, is disagreeable and associated with a cardboard, oxidised and harsh flavour. In roasted coffee, pyridines may contribute to a pleasant smell that is, however, less pleasant than the smell of pyrazines.

Some pyridines may arise, like thiophenes and pyrroles, in reactions of amino compounds with 2-acylfurans (Figure 8.78). Many pyridines are formed by thermal degradation of amino acids, proteins and other nitrogenous compounds. For example, a large number of pyridines present in roasted coffee result from the pyrolysis of alkaloid trigonelline. During the roasting process, trigonelline breaks down in two ways (Figure 8.79). The first pathway is the migration of the *N*-methyl group, which gives rise to methyl nicotinate (about 7%). Its content in roasted coffee is about 6 g/kg. In the presence of water, methyl nicotinate is hydrolysed to nicotinic acid. About 88% of trigonelline is decomposed via the second pathway (decarboxylation) to a number of pyridines. An important volatile product is unsubstituted pyridine, produced at a concentration of

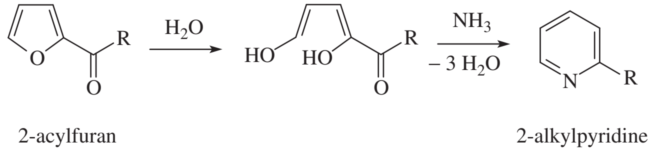


Figure 8.78 Formation of 2-alkylpyridines from 2-acylfurans and ammonia.

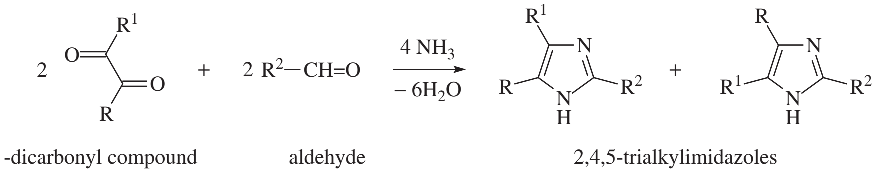

Figure 8.77 Formation of imidazoles from α-dicarbonyl compounds, aldehydes and ammonia.

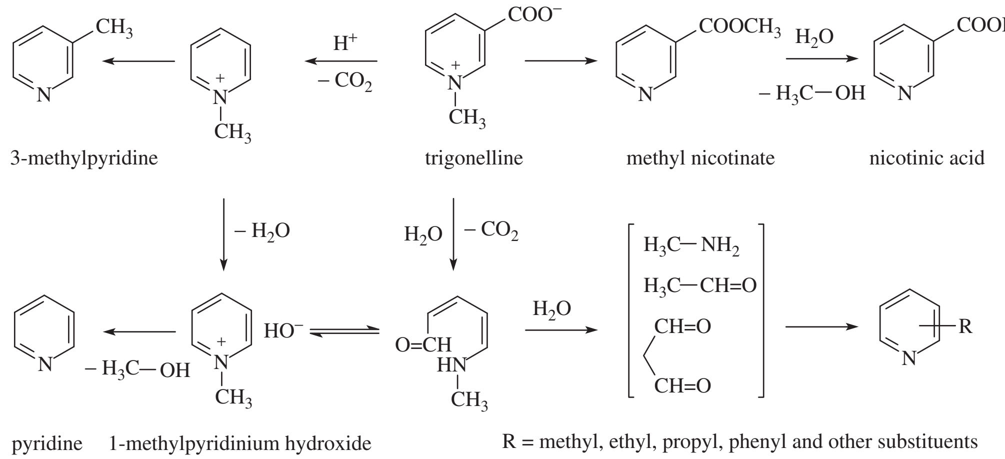

Figure 8.79 Main products of trigonelline pyrolysis.

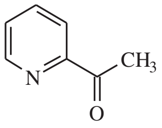
about 200 mg/kg (5.3% of degraded trigonelline). Higher amounts of pyridine in coffee cause an unpleasant aroma. Another major product is 3-methylpyridine (0.25%). An important intermediate is considered to be 1-methylpyridinium hydroxide, which decomposes to give methylamine, acetaldehyde and malondialdehyde. The *N*-methylpyridinium ion shows chemopreventive effects. Reactions of these and certain carbonyl compounds and other fragments yield large quantities of different products, in particular various alkylpyridines and arylpyridines, of which 4-phenylpyridine, formed at a level of about 5 g/kg, is particularly significant.

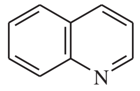
A significant alkyl pyridine is 2-pentylpyridine, which is found, for example, in meat. It may be formed by ring closure of deca-2,4-dienals by ammonia. Important components of cocoa, bread, aromatic rice, popcorn and other cereal products are 2-acetylpyridine (**8-172**) and 6-acetyl-1,2,3,4-tetrahydropyridine, which occurs in tautomeric equilibrium with 6-acetyl-2,3,4,5-tetrahydropyridine. Tetrahydropyridines develop together with 2-acetyl-1-pyrroline during the baking process (see Section 8.2.12.4.1).



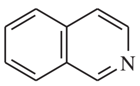
8-172, 2-acetylpyridine

Further flavour components of coffee (and other foods) are different quinolines (**8-173**) and isoquinolines (**8-174**), which result from trigonelline. Some pyridines (aminoimidazopyridines) and quinolines (aminoimidazoquinolines) produced in the Maillard reaction are classified as processing food contaminants (see Section 12.2.1).

Pyridines and pyrazines, such as 2-ethylpyridine, 2,3,5-trimethyl pyridine, 2-ethyl-3,5-dimethyl pyridine, 2,3-dimethylpyrazine and 2,5-dimethylpyrazine, are the most prominent classes of odorous compounds identified as being responsible for the odour of a cigar smoker's breath. They may be generated during cigar pyrrolysis by cleavage of nicotine or by Maillard reaction.



8-173, quinoline



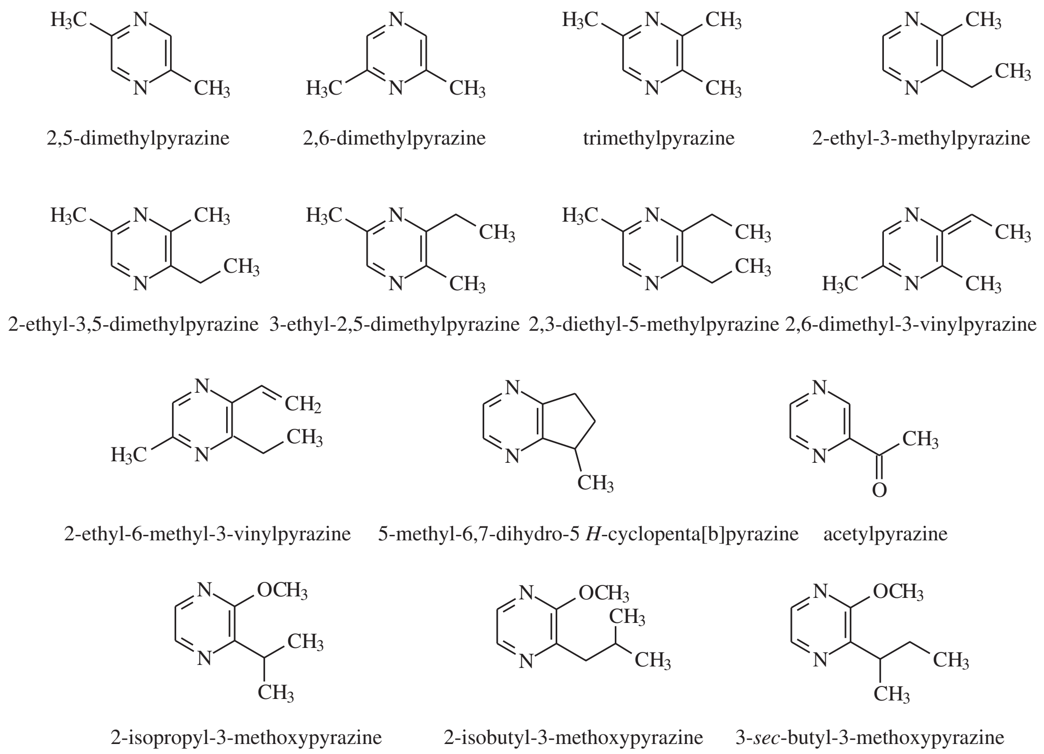
8-174, isoquinoline

8.2.11.1.7 Pyrazines

Pyrazine derivatives (alkylpyrazines, acylpyrazines, alkoxypyrazines and other derivatives, **8-175**) are present in virtually all heat processed foods (such as meat, bread, cocoa, roasted coffee and nuts), where they are the major carriers of the characteristic burnt, roasted and nutty odour. Pyrazines arise mostly as products of the Maillard reaction and by pyrolysis of some amino acids. 2-Alkyl-3-methoxypyrazines, which are odour components of various vegetables, are formed as primary odorous compounds through enzymatic reactions.

The general scheme of formation of pyrazines as byproducts of Strecker degradation of amino acids with α-dicarbonyl compounds is shown in Figure 8.80. For example, the main product of glyoxal reaction with amino acids is unsubstituted pyrazine, the reaction of amino acids with a mixture of glyoxal and methylglyoxal yields methylpyrazine and the reaction of methylglyoxal itself gives 2,5-dimethylpyrazine as the main reaction product. 2,5-Dimethylpyrazine is likewise produced by pyrolysis of threonine via the corresponding 2,5-dioxopyrazine. From simple alkylpyrazines, the methyl and ethyl substituted derivatives (Figure 8.81) are produced on reaction with formaldehyde and acetaldehyde, respectively. Recently an alternate route to pyrazine formation was proposed, which is based on dimerisation of azomethine ylids formed in the reaction of amino acids with 2-oxo acids. Simple alkylpyrazines may also form as pyrolysis products of non-volatile polyhydroxyalkyl-substituted pyrazines, which are reaction products of reducing sugars with amino acids. 2,3-Dimethylpyrazine and 2,5-dimethylpyrazine have also been identified as important odorous constituents responsible for the odor of a cigar smoker's breath.

Many pyrazines are synthesised and used to flavour foods, such as instant coffee, ice creams, potato products and many



8-175, selected important pyrazines

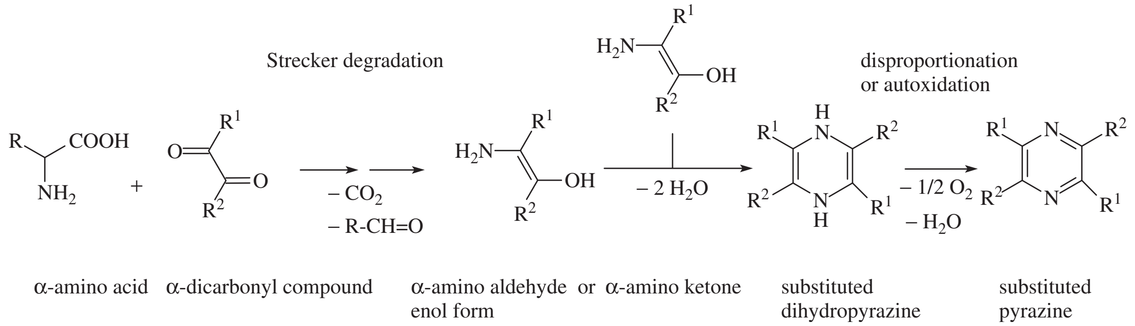


Figure 8.80 Formation of alkylpyrazines from α-dicarbonyl compounds and amino acids.

others. For example, the odour of 2,5-dimethylpyrazine resembles roasted hazelnuts, and 2,6-dimethylpyrazine and trimethylpyrazine have a chocolate-like odour. Important components of coffee aroma include a number of pyrazines, such as 2,3-diethyl-3-methylpyrazine, 2-ethyl-3,5-dimethylpyrazine, 2,6-dimethyl-3-vinylpyrazine and 2-ethyl-6-methyl-3-vinylpyrazine. The flavour-active components of popcorn and white bread are acetylpyrazine, 2-ethyl-3-methylpyrazine, 3-ethyl-2,5-dimethylpyrazine and 5-methyl-6,7-dihydro-5*H*-cyclopenta[*b*]pyrazine. Cyclopentapyrazines, specifically 6,7-dihydro-5*H*-cyclopenta[*b*]pyrazines, are formed in reactions of cyclopentenolones with aminoketones and ammonia.

In some plants and microorganisms, tetramethylpyrazine occurs as a product of metabolism. 2-Alkyl-3-methoxypyrazines are important odorous components of many types of vegetables. For

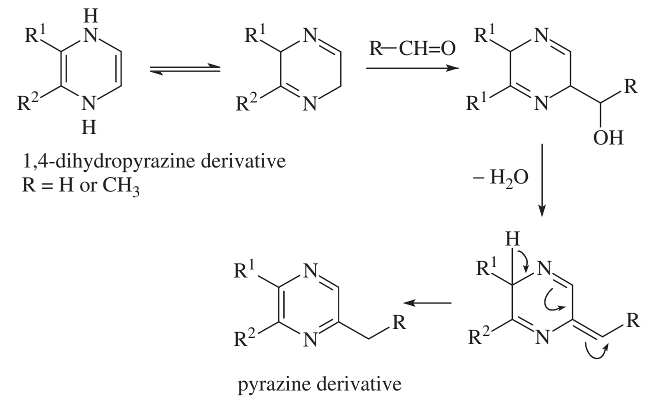

Figure 8.81 Formation of methylsubstituted and ethylsubstituted pyrazines.

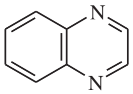
the aroma of parsley, peas, peanuts or potatoes, 2-isopropyl-3-methoxypyrazine is an important compound, for the aroma of pepper 2-isobutyl-3-methoxypyrazine and for the aroma of parsley, peas and salad beet 2-*sec*-butyl-3-methoxypyrazine. 2-Alkyl-3-methoxypyrazines are also significant substances in the varietal character of wines, such as Cabernet Sauvignon and Sauvignon Blanc. The predominant compound is 2-isobutyl-3-methoxypyrazine, which occurs in these wines in concentrations of 3–56 ng/l, while its odour threshold concentration is 1 ng/l. Its content depends on the degree of maturation of grapes and with advancing maturity its concentration decreases and increases in grapes grown in a cool climate and low levels of sunlight. On the other hand, 2-isopropyl-3-methoxypyrazine has been suggested to be one of the key compounds responsible for the off-flavor produced by Asian lady beetle (*Harmonia axyridis*) in Frontenac and Leon Millot wines produced in Minnesota, and 2-methoxy-3,5-dimethylpyrazine was found to be responsible for the unpleasant, musty and moldy aroma of wine corks in Australian wines, which is similar to that produced by 2,4,6-trichloroanisole.

Thermal reactions, such as coffee roasting, also produce various quinoxaline (benzopyrazine) derivatives (**8-176**). Other quinoxalines (aminoimidazoquinoxalines) that arise in the Maillard reaction are classified as processing contaminants (see Section 12.2.1).



8-176, quinoxaline

8.2.11.1.8 Oxazoles

From the olfactive point of view, an unsubstituted oxazole odour is reminiscent of pyridine; alkylsubstituted oxazoles resemble melons with very ripe kiwi notes and with other more or less aggressive nuances and pungent notes. Oxazolidines, oxazolines and oxazoles (like other heterocycles) arise as reaction products of amino acids and reducing sugars, especially in the Maillard reaction, and occur as aroma components of roasted coffee, cacao, meat and other commodities. An important reaction is the Strecker degradation of cysteine. Formation of alkyloxazoles can be explained by condensation of aminoketones (products of the Strecker degradation of amino acids with α-dicarbonyl compounds) or hydroxyketones and ammonia with aldehydes via oxazolines that are oxidised to oxazoles with the elimination of water (Figure 8.82). For example, 4,5-dimethyloxazole (Figure 8.82, $R^1 = R^2 = CH_3$, $R^3 = H$) results from biacetyl and glycine (precursor of formaldehyde) and in an even greater amount as a product of formaldehyde and 2-aminobutan-3-one, which is a product of the Strecker degradation of amino acids with biacetyl. 2,4,5-Trimethyloxazole (Figure 8.82, $R^1 = R^2 = R^3 = CH_3$) arises from 2-aminobutan-3-one and acetaldehyde, 2,5-dimethyl-4-ethyloxazole (Figure 8.82, $R^1 = CH_2CH_3$, $R^2 = R^3 = CH_3$) and 2,4-dimethyl-5-ethyloxazole (Figure 8.82, $R^1 = R^3 = CH_3$, $R^2 = CH_2CH_3$) are products of pentane-2,3-dione and acetaldehyde and 2,4,5-trimethyl-3-oxazoline is formed as a reaction product of acetoin, acetaldehyde and ammonia (Figure 8.83). Analogously, 2-acetyloxazole is produced from serine and methylglyoxal.

8.2.11.1.9 Thiazoles and other sulfur heterocycles

Thiazole itself is smelling like pyridine, but substituted thiazoles, such as 2-acetylthiazole and 2,4-dimethyl-5-vinylthiazole, generally have a desirable odour, frequently described as nutty, green, roasted and vegetable-like. For example, the Strecker degradation of cysteine by methylglyoxal yields 2-acetylthiazole in thermally processed foods (Figure 8.83). A possible intermediate of this reaction is 2-acetyl-2-thiazoline with an intense aroma of fresh bread crust, which is similar to the odour of 2-acetyl-1-pyrroline. 2-Acetyl-2-thiazoline has been identified among the volatiles of beef broth and was reported as being an important component of roasted beef (14–28 μg/kg) and other foods. The reaction pathways leading to 2-acetyl-2-thiazoline involve the cysteine decarboxylation product cysteamine and the participation of sugar degradation products, such as methylglyoxal. The reaction mechanism (Figure 8.84) involves the condensation of cysteamine with methylglyoxal, isomerisation of the condensation product, its cyclisation to 2-(1-hydroxyethyl)-4,5-dihydrothiazole and isomerisation to 2-(1-hydroxyethylene)thiazolidine, which is oxidised by atmospheric oxygen in the presence of transition metals via hydroperoxide (with elimination of hydrogen peroxide) to 2-acetyl-2-thiazoline. Alternative mechanisms of oxidation of 2-(1-hydroxyethylene)thiazolidine (or 2-acetylthiazolidine) have also been suggested. In addition to the pathway involving methylglyoxal, another suggested pathway starts with cysteamine and 4-deoxy-D-*glycero*-hexo-2,3-diulose, which provides, on elimination of formaldehyde and glycolaldehyde, the necessary three carbons for the formation of 2-acetyl-2-thiazoline.

2-Methylthiazole and particularly 2-isobutylthiazole have an odour resembling vegetables, with the latter typically having the smell of fresh tomatoes and tomato leaves. Its biosynthesis requires leucine and cysteine (Figure 8.85). Related 2-isopropyl-4-methylthiazole (**8-177**), synthesised from cysteine and valine, is an odorous component of durian (*Durio zibethinus*, Bombacaceae).

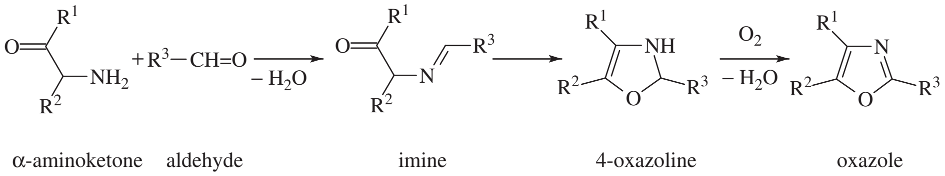


Figure 8.82 Formation of alkyloxazoles.

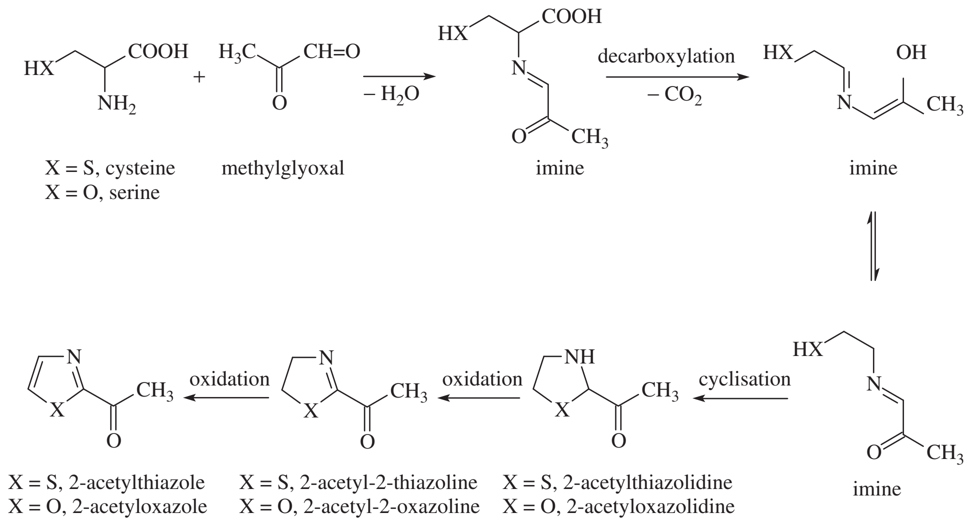

Figure 8.83 Formation of 2-acetyloxazole and 2-acetylthiazole.

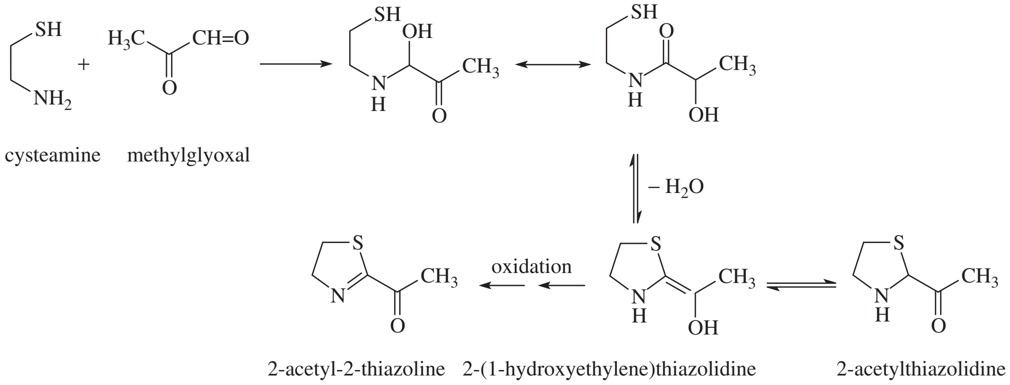

Figure 8.84 Formation of 2-acetyl-2-thiazoline.

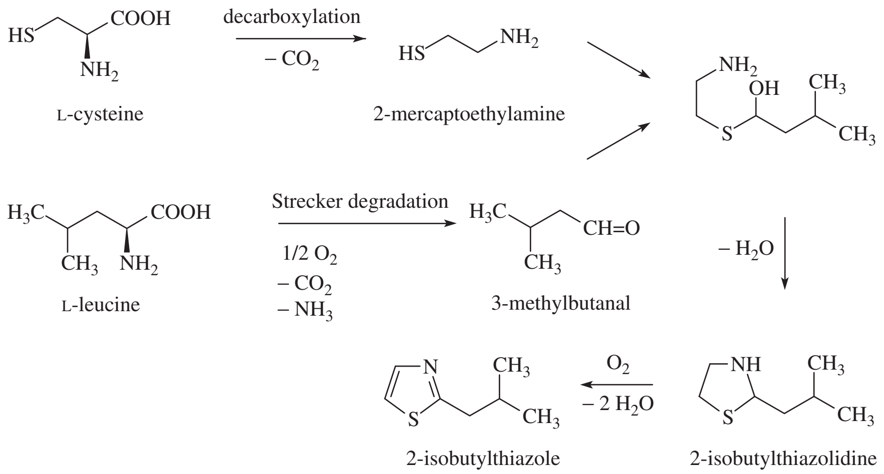

Figure 8.85 Biosynthesis of 2-isobutylthiazole.

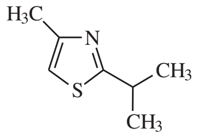
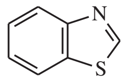
Some thiazoles arise from degradation of other sulfur-containing compounds. An example of these thiazoles is non-volatile 4-methyl-5-(2-hydroxyethyl)thiazole that is formed by degradation of thiamine either by the action of thiaminases or by non-enzymatic reactions. Its dehydration, however, yields 4-methyl-5-vinylthiazole, which is a constituent of cocoa aroma.



8-177, 2-isopropyl-4-methylthiazole

Thiazoles are substances found in many thermally processed foods. They are present in coffee, boiled meat and boiled potatoes in high concentrations. A number of thiazoles can be synthesised and used to flavour various foods. Thiazoles are also carriers of undesirable odours and tastes, such as 2-acetylthiazole in beer, 2-acetyl-2-thiazoline (Figure 8.83) or benzothiazole (**8-178**) in condensed and powdered milk.



8-178, benzothiazole

8.2.11.2 Properties and reactions

Reactions of heterocyclic compounds are very complex. Significant reactions are discussed in the chapters dealing with the individual heterocyclic compounds; other important reactions are related to the Maillard reaction.

8.2.12 Aromatic substances of foods

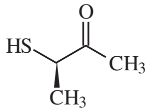
8.2.12.1 Meat and meat products

Hundreds of compounds contribute to the taste and odour of meat. These include non-volatile substances, which mainly affect the taste, and volatile substances, which particularly affect the odour. Raw meat has only a weak, faint odour, and aromatic substances are mainly the result of thermal processing of various precursors, largely from water-soluble compounds found in raw meat. Many of these precursors are formed during aging of meat due to important chemical, structural and functional changes in tissues. The characteristic flavour of cooked meat derives from thermally induced reactions occurring during heating, principally the Maillard reaction and degradation of lipids. Aroma character depends on the type of meat (pork, beef, mutton and chicken, each having their own different, distinctive odour) and the method of heat treatment (e.g. cooking, baking, frying or grilling), which is related to the water and fat content in the material and the temperature during the treatment. Parameters such as diet, sex, age, differences between muscles and storage conditions also play a significant role in determining the overall flavour sensation. For example, because of differences in the digestive systems between ruminants and non-ruminants, pork meat typically has more linoleic acid than beef or lamb, and pork and poultry meat contain higher amounts of polyunsaturated fatty acids than beef and lamb.

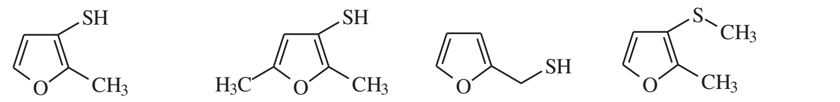
Lipid oxidation products and their reaction products with amino acids (proteins) have a considerable influence on the typical odour and taste of meat. Particularly significant aminocarboxylic acids include glutamic acid, alanine, threonine and lysine, guanidine compounds (creatine and creatinine), quaternary ammonium compounds (choline and carnitine), peptides (β-alanylhistidine peptides and some products of proteolysis), free nucleotides, nucleosides and their bases (especially inosine 5′-monophosphate, IMP), proteins, carboxylic acids (especially lactic acid), sugars (mainly glucose, fructose and their phosphates, ribose formed by hydrolysis of free nucleotides) and some vitamins (especially thiamine). Some of these compounds, such as glutamic acid and IMP, are additionally used as food additives, namely as flavour enhancers.

Another important reaction that leads to flavour-active compounds in meat is the Maillard reaction and the Strecker degradation of amino acids in particular. Many secondary compounds are formed by reactions of primary degradation products (hydrogen sulfide, methanethiol and ammonia) with Strecker aldehydes and carbonyl compounds being formed from lipid oxidation. Active aromatic substances include numerous alcohols, aldehydes, ketones, carboxylic acids, esters, lactones, various aliphatic sulfur compounds and oxygen, sulfur and nitrogen heterocycles. Not all volatile compounds are equally important to the meat aroma, but the resulting flavour is always determined by a relatively large number of different compounds.

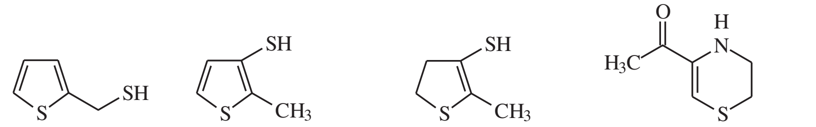
Particularly important substances for the basic flavour of baked and cooked meat are aliphatic thiols (such as methanethiol), sulfides (such as dimethyldisulfide, dimethytrisulfide and dimethyltetrasulfide), aldehydes (such as acetaldehyde, 2-methylpropanal and 3-methylbutanal), furans, pyridines and thiophenes with a mercapto group in position C-3 and their corresponding disulfides and some other aliphatic and heterocyclic sulfur compounds. Examples of important aliphatic thiols are 3-mercaptobutan-2-one (**8-179**) and 3-mercaptopentan-2-one found in cooked beef. A mixture of 3-mercapto-2-methylpentane-1-ol diastereoisomers (Figure 8.86) has a broth-like, sweaty and leek-like flavour. Very low odour threshold concentrations and an odour reminiscent of roasted meat are found in 2-methylfuran-3-thiol (**8-180**), which also occurs in beef broth, roasted coffee and other foods, 2,5-dimethylfuran-3-thiol, their corresponding disulfides and 2-furanmethanethiol (furfuryl mercaptan). The typical aroma of roast beef is found in 2-methylthiophene-3-thiol and 4,5-dihydro-2-methylthiophene-3-thiol. Important sulfur compounds in beef are 2-methyl-3-methylthiofuran, along with the other heterocyclic compounds 2-pentylpyridine, thiophene-2-thiol and 5-acetyl-2,3-dihydro-1,4-thiazine. Significant odorous components of heat-treated beef also



8-179, (*R*)-3-mercaptobutan-2-one



2-methylfuran-3-thiol 2,5-dimethylfuran-3-thiol 2-furfurylmethyl mercaptan 2-methyl-3-methylthiofuran



2-thienylmethyl thiol 2-methylthiophene-3-thiol 2.3-dihydro-5-methyl-thiophene-4-thiol 5-acetyl-2,3-dihydro-1, 4-thiazine

8-180, selected heterocyclic odorous substances in meat

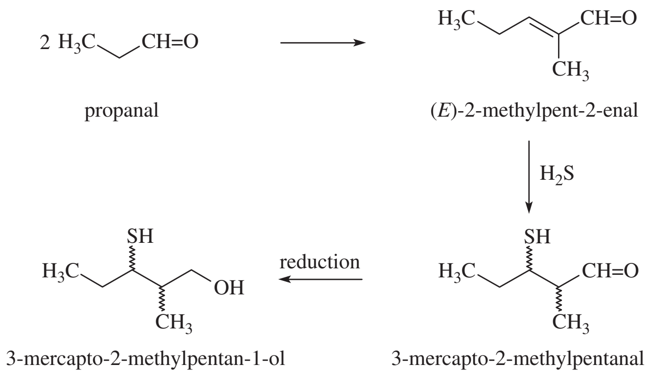


Figure 8.86 Formation of 3-mercapto-2-methylpentan-1-ol from propanal and hydrogen sulfide.

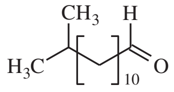
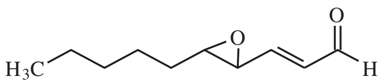
include 2-acetyl-2-pyrroline, which is otherwise an important component of bread crust flavour, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol), its lower homologue 4-hydroxy-5-methyl-2*H*-furan-3-one (norfuraneol), lactone 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one (sotolon).

Some compounds formed from meat lipids have an important role. Such compounds include some carbonyl compounds, such as oct-1-en-3-one, hexanal, octanal, nonanal, (*Z*)- and (*E*)-non-2-enal, (2*E*,6*Z*)-nona-2,6-dienal, (2*E*,4*Z*)-deca-2,4-dienal and 12-methyltridecanal (**8-181**). Other important fatty acid oxidation products include (*E*)-4,5-epoxydec-2-enal (**8-182**), (*Z*)-octa-1,5-dien-3-one, (2*E*,6*Z*)-nona-2,6-dienal. Also important



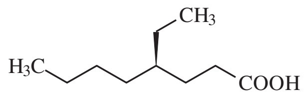
8-181, 12-methyltridecanal



8-182, (*E*)-4,5-epoxydec-2-enal

are higher thiols, 2-alkylpyridines, 2-alkyl-3-formylthiophenes and dihydrothiophenes, 2-alkylthiazoles, 2-alkyl-4-methylthiazoles, 2-alkyl-4,5-dimethylthiazoles, 5-alkyl-4-ethylthiazoles and 2-alkyl-4,5-diethylthiazoles. The alkyl is mostly pentadecyl derived from hexadecanal bound in plasmalogenes. Plasmalogenes also produce aldehyde 12-methyltridecanal (**8-181**) with the aroma of beef stew. The list of sensory active compounds is far from complete and many components of meat flavour are yet unknown.

For example, lamb/mutton has a distinctive aroma, which to some extent determines its lesser popularity. The main aromatic component of heat-treated meat is an unusual, branched fatty acid 4-ethyloctanoic acid (**8-183**) that has a waxy, fatty, creamy, moldy, sour sweaty, cheesy odour with animal-like nuances, and occurs as an almost racemic mixture of the enantiomers. The odour thresholds of the (+)-(*R*)- and (−)-(*S*)-enantiomers are <13 and <6 μg/l in air, respectively. 4-Ethyloctanoic acid (also identified in stewed beef gravy and goat and sheep cheeses) is accompanied by 4-methyloctanoic acid. The 4-ethyloctanoic acid content is approximately the same in raw meat but higher in fat.

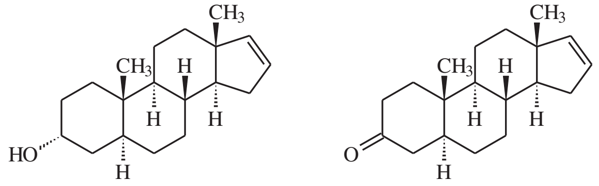


8-183, (*R*)-4-ethyloctanoic acid

For example, in dry-fermented and mold-ripened sausages, such as the Hungarian-type salami, the key aroma compounds are 2-methoxyphenol, eugenol, (*E*)-isoeugenol, 5-methyl-2-methoxyphenol, 4-propyl-2-methoxyphenol, 4-ethyl-2-methoxyphenol and 3-ethylphenol, phenylacetaldehyde, methional, acetic acid and 3-methylbutanoic acid.

A boar taint in processed pork is caused by the presence of the hormone pregnenolone and its metabolic products (**8-184**), which may similarly occur in meat of castrates and sows. The steroid alcohol (+)-(3α,5α)-androst-16-en-3-ol has a musk aroma, the corresponding oxidation product (+)-(5α)-androst-16-en-3-one has a smell resembling urine. A characteristic unpleasant odour then develops during the cooking of meat. Other compounds contributing to the boar taint are skatole, an intestinal degradation

product of tryptofan, which exhibits a faecal-like odor, and 4-phenylbut-3-en-2-one. The source of 4-phenylbut-3-en-2-one is not clear, but its seems to be related to cinnamic acid metabolism and with phenylalanine degradation.



(3α,5α)-androst-16-en-3-ol (5α)-androst-16-en-3-one

8-184, derivatives of androst-16-ene

8.2.12.1.1 Poultry and fish

The volatile components of raw chicken breast muscle include mainly carbonyls, thiols, sulfides and alcohols. The major volatile components of fried chicken are similar to volatiles of the meat of farm animals (e.g. common aldehydes, ketones, hydrocarbons and other compounds). Sulfur-containing compounds generated during thermal processing are also important for the flavour of chicken meat. Saturated and unsaturated aldehydes are very important – these are produced easily by oxidation of lipids and manifest negatively in stored poultry meat, which quickly becomes rancid. Feed plays an important role in imparting certain flavour characteristics to poultry meat.

The characteristic essential flavour-active components of fish and other aquatic animals are amines and other nitrogenous compounds. Trimethylamine arises by reduction of sensorially indifferent trimethylamine oxide (acting in the regulation of osmotic pressure in cells) in the tissue post mortem. The amount of trimethylamine oxide, as well as the amount of a number of simultaneously produced biogenic amines, depends primarily on the species, type and time of storage. Its content in fresh water fish is about 5 mg/kg, and in seafood is 40–120 mg/kg. Other important compounds are dimethylamine and ammonia.

Flavour-active components of fresh fish are further oxidation products of unsaturated fatty acids formed by the action of lipoxygenases. Important compounds are mainly alcohols and carbonyl compounds. For example, oxidation of eicosapentaenoic acid via 12-hydroperoxide yields (3*Z*,6*Z*)-nona-3,6-dienal, (2*E*,6*Z*)-nona-2,6-dienal, (3*Z*,6*Z*)-nona-3,6-dien-1-ol, (*Z*)-octa-1,5-dien-3-ol and (*Z*)-octa-1,5-dien-3-one, while the products of 15-hydroperoxide decomposition include (*Z*)-hex-3-enal, (*E*)-hex-2-enal, (*Z*)-hex-3-en-1-ol and pent-1-en-3-ol.

The fishy and greasy off-flavour appearing in long-term refrigerated storage of fish is almost entirely caused by lipid oxidation products that are present in larger quantities than in fresh fish. The important components are mainly (*Z*)-hex-3-enal, (*Z*)-hept-4-enal, (*Z*)-octa-1,5-dien-3-one and (3*Z*,6*Z*)-nona-3,6-dienal. An chief component is methional, the product of the Strecker degradation of methionine.

8.2.12.2 Milk and dairy products

8.2.12.2.1 Milk

Raw or gently pasteurised milk (e.g. for 10 seconds at 73 °C) has a fine characteristic odour and sweet taste. Typical components present in low concentrations are dimethylsulfide, biacetyl, 2-methylbutan-1-ol, (*Z*)-hept-4-enal and (*E*)-non-2-enal. Milk pasteurised at higher temperatures and Ultra High Temperature (UHT) milk present the so-called cooked flavour, the appearance of which is the first measurable manifestation of the chemical changes that occur in heated milk. The substances responsible for the cooked off-flavour are sulfane and other sulfur compounds. Of particular importance are dimethylsulfide, dimethyldisulfide and dimethyltrisulfide that are produced from proteins contained in the membranes of fat particles and from thiamine. Also relevant are alkane-2-ones (methylketones) generated by thermal decarboxylation of β-oxocarboxylic acids (mainly hexane-2-one, heptane-2-one and nonane-2-one), γ-lactones and δ-lactones produced by dehydration of γ- and δ-hydroxycarboxylic acids (mainly δ-decalactone and γ- and δ-dodecalactones). Important carbonyl compounds include biacetyl, hexanal, 3-methylbutanal, (*Z*)-hept-4-enal and (*E*)-non-2-enal. In the more intensive thermal treatment of milk (sterilisation), products of the Maillard reaction play a role, such as maltol and isomaltol, 5-hydroxymethylfuran-2-carbaldehyde, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) and 2,5-dimethylpyrazine.

Evaporation and drying leads to more extensive reactions than in UHT milk that include degradation of proteins and thiamine, Maillard reaction between proteins (preferably in bound lysine) and lactose, degradation of oxo- and hydroxycarboxylic acids and oxidation of fatty acids. Phospholipids of fat particles are particularly susceptible to oxidation. It is therefore mainly alkane-2-ones, lactones and the Maillard reaction products that are responsible for the odour of condensed and powdered milk. In addition to these compounds, typical aromatic substances are benzaldehyde, acetophenone, 2-aminoacetophenone, furfuryl alcohol and benzothiazole.

Flavour defects of milk and dairy products may be due to different causes. Raw or pasteurised milk products can pass into milk from unsuitable feed, or milk may absorb flavours from the surroundings during storage and distribution.

Chemical defects can occur in both raw and pasteurised milk as endogenous aromatic substances are formed by both enzymatic and chemical reactions. Oxidation of lipids is the major problem during storage of dried milk. Some of the oxidation products of lipids present in larger quantities play a negative role. For example, (*Z*)-hept-4-enal, oct-1-en-3-one and hexanal are important carriers of a full, creamy flavour, but at higher concentrations they confer cardboard, metal and green flavours. Long-term storage of condensed milk is reflected as old flavour, which is due to higher concentrations of normal compounds. Examples are benzothiazole and 2-aminoacetophenone (at a concentration >1 μg/kg) produced by decomposition of tryptophan. Often confused with oxidised flavour is the so-called sunlight flavour (characterised as burnt-protein or medicinal-like) that develops in unprotected milk stored in the light. Photooxidation activates riboflavin, which is

responsible for catalysing the conversion of methionine into sulfur compounds via methional.

Bacterial off-flavours result from the growth of psychrophilic bacteria that are present in milk due to poor sanitation or milk handling practices. Fruit odour is caused by carboxylic acid esters produced by bacteria *Pseudomonas fragii*, and a malt smell (caused by the presence of methylbutanal, 2-methylbutanal and 2-methylpropanal) is produced by bacteria *Streptococcus lactis* var. *maltigenes* and a phenolic odour by bacteria *Bacillus circulans*. Rancid smell, caused by lower fatty acids from butyric to lauric acids, is manifested as a result of lipolysis by milk lipase or bacterial lipases.

8.2.12.2.2 Cream and butter

For cream flavour, the most important components are lactones of hydroxycarboxylic acids, in particular, δ-decalactone, δ-dodecalactone and (*Z*)-dodec-6-eno-γ-lactone, to a lesser extent many other lactones, such as δ-tetradeca-, δ-hexadeca-, γ-tetradeca-, γ-hexadeca-, γ- and δ-octadeca- and γ- and δ-eicosalactones and other compounds (methanethiol, skatole and others).

The aroma of butter made from sweet cream is affected primarily by free fatty acids (especially capric and lauric acids), δ- and γ-lactones, dimethylsulfide, (*Z*)-hept-4-enal and the degradation products of tryptophan (indole and skatole). The butter obtained from sour cream contains mainly metabolic products of microorganisms (so-called starter cultures). Especially important compounds are biacetyl, lactic and acetic acids.

Lipases in stored butter gradually release fatty acids from triacylglycerols, and their presence can be detected as a rancid and soapy flavour when they reach 30–40% of their threshold concentrations, which is a result of their synergism. The reaction is called hydrolytic rancidity. Responsibe for the rancid flavour is mainly butyric acid, followed by caproic acid. Caprylic acid has a rancid soap-like flavour, capric and lauric acids only have soapy flavours. Odour (and taste) threshold concentrations in butter made from sweet cream are 50 (60) mg/kg for butyric acid, 85 (105) mg/kg for caproic acid, 200 (120) mg/kg for caprylic acid, >400 (90) mg/kg for caprinic (capric) acid and >400 (130) mg/kg for lauric acid, respectively. In long term stored butter, active oxidative rancidity products are (*E*)-non-2-enal, (*Z*)-non-2-enal in particular, while less active products are (*Z*)-hept-4-enal, oct-1-en-3-one and others. The rancid and soapy odour in butter can also be caused by contamination with anion active detergents, such as natriumdodecyl sulfate.

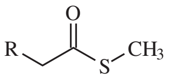
8.2.12.2.3 Fermented dairy products

Characteristic flavouring substances of fermented dairy products are metabolites of lactic acid bacteria, especially biacetyl, acetaldehyde, dimethylsulfide, lactic and acetic acids, various aldehydes, ketones and esters. An important product is carbon dioxide. The acetaldehyde content in good quality yoghurts is 13–16 μg/kg, while the biacetyl content is about four times higher.

8.2.12.2.4 Cheeses

Cheeses contain large amounts of aromatic compounds that differ qualitatively and quantitatively according to types of cheeses. Important components of hard cheeses (Gouda type) include some carboxylic acid esters (ethyl butanoate, ethyl hexanoate), as well as carboxylic acids (acetic, butyric, isobutyric, valeric, isovaleric, 2-methylbutyric and caproic acids). Cheeses manufactured using bacteria of the genus *Propionibacterium* (such as Emmental and Gruyère) contain propionic acid and other lower fatty acids, methyl thioacetate, some oxocarboxylic acids, various alcohols, esters (such as ethyl butanoate), lactones (such as δ-decalactone), amines and other basic compounds (also skatole in addition to aliphatic amines), alkylpyrazines (e.g. 2-sec-butyl-3-methoxypyrazine), 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol), 2-ethyl-4-hydroxy-5-methyl-2*H*-furan-3-one (homofuraneol) and a range of other compounds.

Cheeses with a very pungent aroma caused by bacteria that live in the rind and on the cheese surface (such as Pont l'Eveque, Limburger or Romadur) contain phenol, cresol, acetophenone and methylthioesters of lower fatty acids (**8-185**), such as methyl thioacetate (R = H), methyl thiopropionate (R = CH_3) and methyl thiobutyrate (R = CH_2CH_3) as flavourings. Other important flavouring substances include C_4–C_{10} fatty acids, especially capric acid, alkan-2-ones (methylketones) and alkan-2-ols.



8-185, fatty acid methylthioesters

Camembert-type cheeses with a powdery rind of white mold (*Penicillium camemberti*) smell pleasantly of mushrooms, earth and garlic. The characteristic component of the mushroom-like odour is oct-1-en-3-ol, the floral odour components are primarily 2-phenylethanol and 2-phenylethyl acetate, and 1,3-dimethoxybenzene and methyl cinnamate are responsible for the odour resembling nuts. The garlic note of matured cheese is caused by the presence of sulfur compounds, such as 2-bis (methylthio)methane, also known as bis(dimethylsulfanyl)-methane or 2,4-dithiapentane, tris(methylthio) methane, also known as tris(methylsulfanyl)methane or 3-methylthio-2,4-dithiapentane, methyl (methylthio)methyl disulfide, also known as (methyldisulfanyl) methylsulfanylmethane or 2,3,5-trithiahexane, and bis(methylthiomethyl) sulfide (**8-186**).

tris(methylthio)methane

methyl(methylthiomethyl)disulfide

bis(methylthiomethyl)sulfide

8-186, methylthio and methylthiomethyl compounds

8.2.12.3 Eggs

Fresh eggs contain more than 100 volatile compounds. An important group are the sulfur compounds, mainly dimethylsulfide and dimethyldisulfide, which are characteristic components of egg aroma. Higher levels of these compounds are found in older eggs. Therefore, the long-term storage of eggs produces defects in smell and taste. The degradation products of amino acids, such as indole and lower alkylbenzenes, especially toluene, are also important volatiles. Aldehydes and ketones are present in low amounts (especially acetaldehyde, propionaldehyde, acetone and butanone). A significant proportion of volatiles represent C_7–C_{17} hydrocarbons, with the main hydrocarbon being heptadec-5-ene. Very small amounts of pyrroles and pyrazines are present.

Heat treatment of eggs by cooking and frying creates a variety of other volatile compounds, more from egg yolk than from egg white. The main volatile components are aldehydes, alcohols, free fatty acids, esters and other compounds. Those occurring in the highest quantities are (2*Z*,4*Z*)- and (2*Z*,4*E*)-deca-2,4-dienals, (*Z*)-oct-2-enal, nonanal, hexanal, phenylacetaldehyde and hexyl butyrate. Egg white odour resembles (2*E*,4*Z*,7*Z*)-2,4,7-tridecatrienal, which arises as a product of arachidonic acid autoxidation (see Section 3.8.1.12.1). Its odour threshold was estimated to be 0.07 ng/l air. Sulfane and ammonia are also important protein degradation products.

Some eggs may have an unusual or unacceptable odour or taste, although their appearance is normal. The cause may be age (they are past their 'best'), high storage temperatures, or poor storage conditions, resulting in fishy or other undesirable flavours. The fishy off-flavour, more common in brown-shelled eggs, is caused by the presence of trimethylamine that is produced by microbial decomposition of choline when hens are fed excessive amounts of fishmeals or fish oils and rapeseed and mustard meals. In the case of oilseed meals, trimethylamine arises from sinapine, an ester of choline with sinapic acid. In most breeds of hens, trimethylamine is enzymatically oxidised to odourless trimethylamine oxide, which is excreted from the body.

8.2.12.4 Cereals and cereal products

8.2.12.4.1 Bread and cereal products

Two processes produce aromatic substances from bread. Activities of yeast in the dough give volatiles of breadcrumbs, and baking yields volatiles of bread crust.

The main aroma substances produced by yeast in breadcrumbs are aldehydes, alcohols, acetals and sulfur compounds. The most important components are 2-phenylethanol and 3-methylbutan-1-ol, while the other components present in significant quantities are acetaldehyde, 2-methylpropanal, 3-methylbutanal, ethanol, 2-methylpropan-1-ol, 1,1-diethoxyethane, dimethylsulfide and dimethyldisulfide. In addition, other important volatiles are products of oxidation of fatty acids, especially unsaturated aldehydes (*E*)-non-2-enal and (2*E*,4*E*)-deca-2,4-dienal.

Volatiles of the bread crust arise mainly in the Maillard reaction and caramelisation of sugars. Important precursors of these compounds are the amino acids ornithine, proline, arginine and lysine. Their partners are reducing sugars and their degradation products, for example, methylglyoxal and hydroxyacetone. The basic odorous substances of wheat and rye breads are pyrazines, especially acetylpyrazine and 2-ethyl-3-methylpyrazine. Two key compounds have a major impact on the aroma of bread crust, namely 2-acetyl-1-pyrroline and 6-acetyl-1,2,3,4-tetrahydropyridine, which is in equilibrium with its tautomer 6-acetyl-2,3,4,5-tetrahydropyridine. In wheat bread crust, concentrations of 2-acetyl-1-pyrroline and 6-acetyl-1,2,3,4-tetrahydropyridine were found to be 19–78 and 53 μg/kg, respectively. The precursors of all three compounds are the amino acids proline and ornithine. Ornithine is produced by yeast during fermentation of the dough from glutamic acid, and an alternative route is the formation from proline in a reaction catalysed by ornithine cyclodeamidase. In cases where ornithine is not present, the only precursor is proline. Decarboxylation and oxidation of proline to 1-pyrroline is facilitated by reaction with reactive α-dicarbonyl compounds, such as 1-deoxy-D-*erythro*-hexo-2,3-diulose arising from D-fructose (Figure 4.34), while 1-deoxy-D-*erythro*-hexo-2,3-diulose is via the formation of iminium ion, followed by its decarboxylation and dehydration, transformed into 1,6-dideoxy-D-*glycero*-hexo-2,4,5-triulose (acyclic form of diacetylformoin, Figure 4.40). 1-Pyrroline then condenses with hydrated methylglyoxal to yield 2-(1,2-dioxopropyl)pyrrolidone, which spontaneously oxidises with air oxygen to the corresponding 1-pyrroline, which undergoes an addition of water with the formation of a hydrate and subsequent semibenzilic rearrangement to a β-ketoacid. Its decarboxylation generates 2-acetylpyrrolidine, which is spontaneously oxidised to 2-acetyl-1-pyrroline. The immediate precursor of 2-acetyl-1-pyrroline from ornithine is 4-aminobutanal, which is produced in the Strecker degradation of ornithine, but also as a product of ornithine catabolism by yeast. Ornithine is first decarboxylated to putrescine by ornithine decarboxylase and putrescine transamination yields 4-aminobutanal with catalysis of aminotransferase. A hypothetical mechanism of formation of 2-acetyl-1-pyrroline is outlined in Figure 8.87.

The formation of tetrahydropyridines starts with reaction of 1-pyrroline with hydroxyacetone (acetol, 1-hydroxypropan-2-one), which gives rise to 2-(1-hydroxy-2-oxopropyl)pyrrolidine. The ring enlargement requires opening of the pyrrolidine ring with the formation of 7-aminoheptane-2,3-dione, which finally cyclises to 6-acetyl-1,2,3,4-tetrahydropyridine (Figure 8.88). Hydroxyacetone is produced in the baking process by thermal decomposition of methylglyoxal.

Additional odorous components, such as 3-ethyl-2,5-dimethylpyrazine, biacetyl, 3-methylbutanal, 2-phenylethanal and others are found in dark rye bread. Toasted bread contains the same compounds that carry the aroma of bread crust and crumb. A key component is again 2-acetyl-1-pyrroline, other major components are methional, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol), (*E*)-non-2-enal and biacetyl, the odour of which resembles butter.

Important flavour components of other cereal products are, as in bread, 2-acetyl-1-pyrroline, 6-acetyl-1,2,3,4-tetrahydropyridine, acetylpyrazine and further compounds. Cereal flours and legume

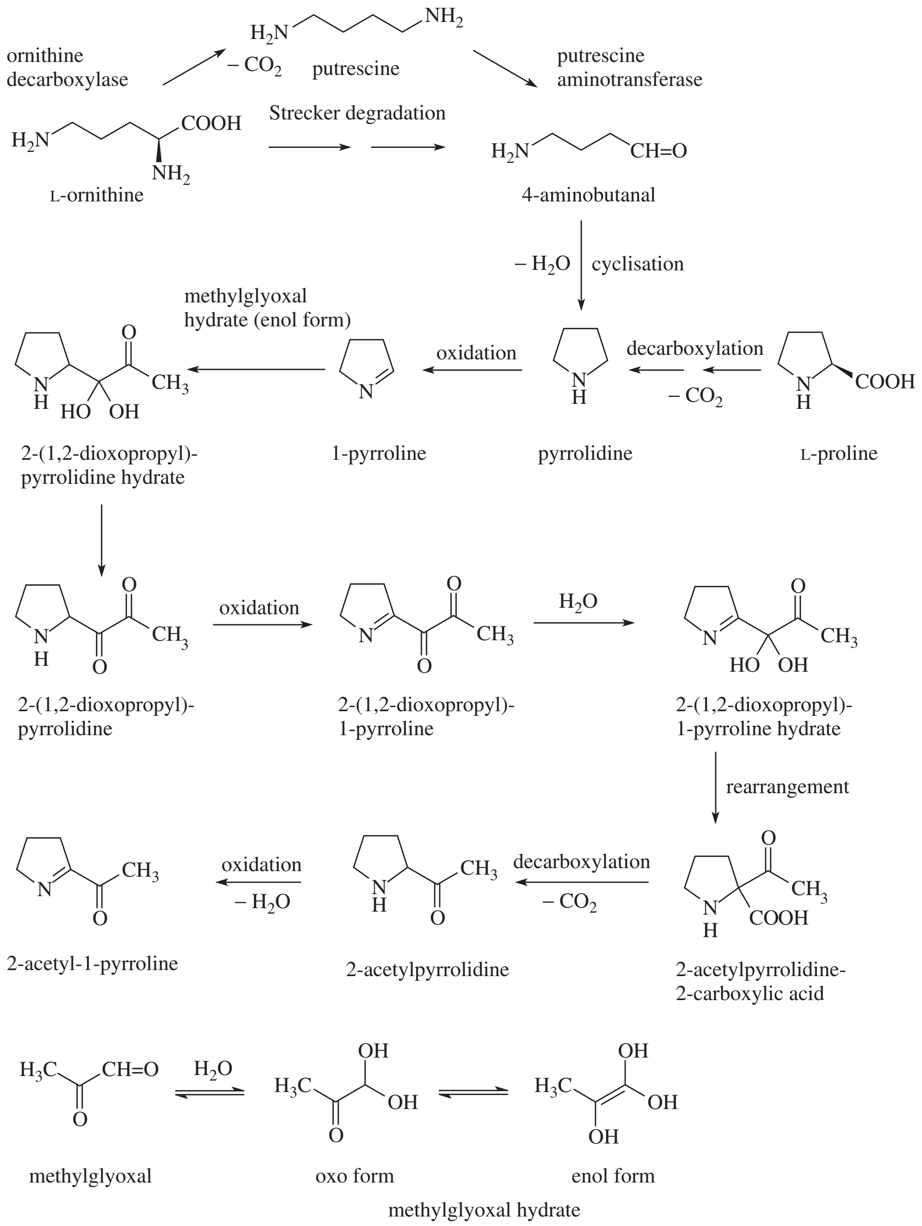

Figure 8.87 Formation of 2-acetyl-1-pyrroline from ornithine and proline.

products, such as soybean products, often assume rancid flavours on prolonged storage. The carriers of this off-flavour are carbonyl compounds (such as hexanal and other aldehydes) produced by oxidation catalysed by lipoxygenases.

8.2.12.4.2 Rice

The aroma of cooked rice (*Oryza sativa*, Poaceae), especially of the aromatic basmati rice, is mainly influenced by the formation of 2-acetyl-1-pyrroline which has the odour of bread crust and popcorn. Its concentration can reach approximately 0.6 mg/kg. Significant compounds are also aldehydes formed by oxidation of fatty acids, especially (2*E*,4*E*)-deca-2,4-dienal, nonanal, hexanal, octanal and (*E*)-non-2-enal, and phenols guaiacol and 4-vinylphenol resulting from the degradation of phenolic acids. Another important compound is 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one (sotolon) with the aroma of protein hydrolysates and 2-aminoacetophenone with a phenolic odour.

8.2.12.5 Fruits

8.2.12.5.1 Apples

The aroma of apples (*Malus pumila*, syn. *M. domestica*, Rosaceae) consists of more than 300 different compounds, of which the most important components are C_5 carboxylic acids, alcohols and esters. Important acids are 2-methylbutyric and 3-methylbutyric (isovaleric) acids, which are found in the fruits in a ratio

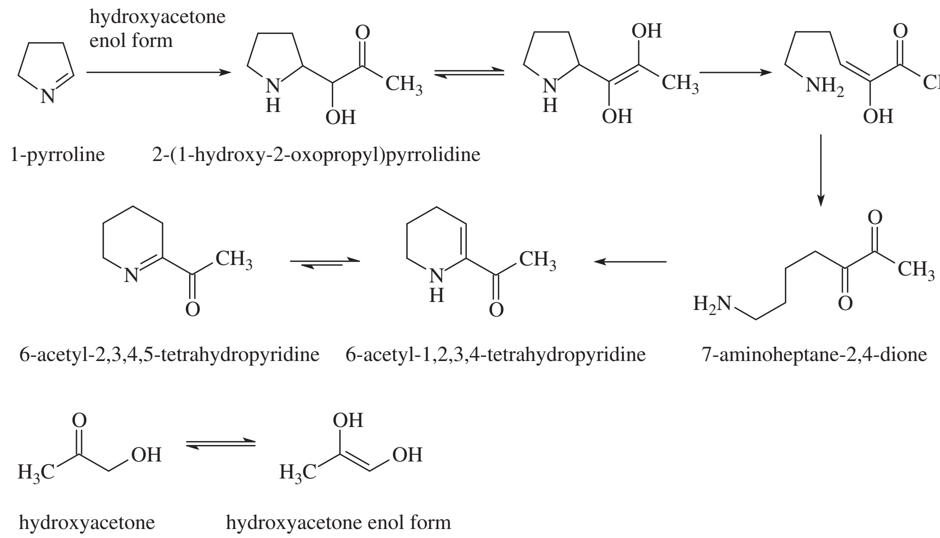

Figure 8.88 Formation of 6-acetyltetrahydropyridines from ornithine and proline.

of about 80 : 20, and in juices in the ratio 99 : 1 due to the activities of microorganisms. In some apple varieties esters predominate, while in others alcohols are in the majority. The key odorous component is ethyl 2-methylbutanoate, but there are other butyanoates and acetates present, such as butyl acetate, 2-methylbutyl acetate and 3-methylbutyl acetate, ethyl butanoate, ethyl 2-methylbutanoate, methyl 2-methylbutanoate, hexyl 2-methylbutanoate and ethylesters of 5-hydroxyoctanoic and 5-hydroxydecanoic acids. Compounds responsible for the green apple aroma are hexanal, (*E*)-hex-2-enal (leaf aldehyde), (*Z*)-hex-3-en-1-ol (leaf alcohol), (*E*)-hex-2-en-1-ol and related esters, such as (*Z*)-hex-3-en-1-yl butyrate. Other alcohols are present, such as butane-1-ol, hexane-1-ol, linalool and 2-phenylethanol. An important flavour-active compound is (*E*)-β-damascenone, resulting from the decomposition of carotenoids, and related compounds, followed by 1-octene-3-one with a mushroom flavour, methional with the aroma of boiled potatoes, and dimethyldisulfide with a sulfurous smell. Cooking of apples causes partial hydrolysis of esters and the formation of lactones from hydroxycarboxylic acids.

8.2.12.5.2 Cherries and plums

A typical component of the flavour in both types of fruits (*Cerasus vulgaris*, syn. *Prunus cerasus* and *Prunus domestica* and other species, Rosaceae) is benzaldehyde. Other important compounds for cherry flavour are linalool, hexanal, (*E*)-hex-2-enal, (2*E*,6*Z*)-nona-2,6-dienal, phenylacetaldehyde and eugenol. During heating of cherry juice and in the preparation of jams and confectionery products, yet more benzaldehyde is produced by hydrolysis of cyanogenic glycosides. Similarly, hydrolysis of linalool glycoside yields linalool. Loss of volatile C_6 aldehydes and nonadienal changes the formerly green aroma to more floral notes. The characteristic aroma components of plums, in addition to benzaldehyde, are linalool, methyl cinnamate, δ-decalactone and aldehydes with green odour. Plum compotes also contain nonanal, benzyl acetate and degradation products of carotenoids.

8.2.12.5.3 Apricots

The aroma of apricots (*Armeniaca vulgaris*, syn. *Prunus armeniaca*, Rosaceae) is composed of a large number of different substances. Important components are monoterpenic hydrocarbons, alcohols and aldehydes (myrcene, limonene, *p*-cymene, terpinolene, α-terpineol, geranial, geraniol and linalool in particular) and aldehydes with green flavour, such as (*Z*)-hex-3-enal and acetaldehyde. Other volatile components include products of oxidation of fatty acids, such as (2*E*,6*Z*)-nona-2,6-dienal, (*Z*)-octa-1,5-dien-3-one, lactones (γ-hexalactone, γ-octalactone, γ-decalactone, γ-dodecalactone, δ-decalactone and δ-dodecalactone), carboxylic acids (especially, 2-methylbutanoic and acetic acids) and degradation products of carotenoids, such as β-ionone.

8.2.12.5.4 Peaches

The basic flavour of peaches (*Persica vulgaris*, syn. *Prunus persica*, Rosaceae) is typified by the presence of γ-lactones (C_6–C_{12}) and δ-lactones (C_{10} and C_{12}). Individual varieties differ mainly in their content of esters and monoterpenoids. As with all stone fruits, an important component is benzaldehyde, while other important compounds include benzyl alcohol, ethyl cinnamate, isopentyl acetate, linalool, α-terpineol, hexanal, (*Z*)-hex-3-enal, (*E*)-hex-2-enal and decomposition products of carotenoids.

8.2.12.5.5 Strawberries

Nowadays, more than 400 compounds forming the large-fruited strawberry (*Fragaria ananassa* and other hybrids, Rosaceae) flavour are known, yet the importance of many of them is not yet fully understood. Besides a number of esters (mainly butanoates) and aldehydes, such as (*Z*)-hex-3-enal, which generally have green and fruity flavours, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol, also known as strawberry or pineapple furanone) and its methyl ether 4-methoxy-2,5-dimethyl-2*H*-furan-3-one

(mesifurane) have special importance for the aroma of ripe fruit. These compounds are present in the order of units of mg/kg. The content of furaneol decreases during ripening and storage of strawberries, but the content of its ether, whose smell is reminiscent sherry type wines, increases. The aroma of strawberry juice reportedly represents a mixture of only furaneol, its methyl ether, (*Z*)-hex-3-enal, methyl and ethyl butanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate (ethyl isobutyrate), biacetyl and acetic and butanoic acids. Sulfur volatiles have also been reported in strawberries and some of them may have an impact on strawberry aroma as concentrations of most sulfur volatiles increase with increasing maturity. In addition to hydrogen sulfide, methanethiol, dimethyl sulfide, dimethyl disulfide and dimethyl trisulfide, sulfur volatiles of straberries include methyl thioacetate, methyl thiopropionate, methyl thiobutanoate, ethyl thiobutanoate, methyl thiohexanoate, methyl (methylthio)acetate, ethyl (methylthio)acetate, methyl 2-(methylthio)butanoate, methyl 3-(methylthio)propionate, ethyl 3-(methylthio)propionate and methyl thiooctanoate, which can be used to distinguish overripe from full ripe and commercially ripened berries.

8.2.12.5.6 Raspberries

The characteristic flavour component of raspberries (*Rubus idaeus* ssp *vulgatus*, Rosaceae) 4-(4-hydroxyphenyl)butan-2-one is known as raspberry ketone (**8-53**). In addition to this compound, other important compounds include in particular methyl cinnamate, non-1-en-3-one, (*Z*)-hex-3-en-1-ol with a green flavour and degraded carotenoids, such as α-ionone, β-ionone and α-irone.

8.2.12.5.7 Blackcurrants

The characteristic aroma of blackcurrants (varieties of *Ribes nigrum*, Grossulariaceae) is mainly a consequence of aliphatic and alicyclic thiols. The bearer of the characteristic cat odour is 4-methoxy-2-methyl-2-thiol, called blackcurrant mercaptan (**8-124**), which occurs also in olive oil and green tea. Other important components are 4-mercapto-4-methylpentan-2-one called cat ketone (**8-125**) and (1*S*,4*R*)-*p*-menthan-8-thiol-2-one (see Section 8.2.13.1.1). Cat ketone is also found in grapefruits, some hop cultivars, basil and some aromatic wines. The leaves contain about 0.7% essential oil, whose main component is *p*-cymol, the sulfur compounds of which contribute to the strong smell, mainly *p*-menthan-8-thiol-2-one.

8.2.12.5.8 Citrus fruits

The main odour-active components of selected citrus fruits, fruits of plants of the genus *Citrus* of the rut family (Rutaceae), are listed in Table 8.31. The aroma of citrus fruits normally consists of between several tens and several hundreds of compounds. For example, it is estimated that lemon oil contains about 300 different substances. Some of these compounds are of fundamental importance for the character of the typical aroma; others have little or no importance. The main component of all citrus fruits is always (+)-limonene, which determines the basic sensory character of essential oils, but its presence is not necessary. Removal of the limonene while leaving other important components (such as citral) produces a more soluble, stronger and more stable oil, which, however, lacks the characteristic freshness associated with the complete oil. Important components of citrus fruit scents are also saturated straight chain C_8 to C_{12} aldehydes (fatty aldehydes), as well as citral, which is always a mixture of two stereoisomers, known as geranial and neral, and the unsaturated aldehyde (*E*)-dec-2-enal. For the aroma of fresh fruit, aldehydes with green odour are important. Limonene readily undergoes autoxidation and is therefore a source of instability in juices and essential oils obtained from citrus fruits (Figure 8.1).

Oranges

Many compounds are responsible for the smell of oranges. The presence of (+)-valencene distinguishes orange and grapefruit aroma from the aroma of other citrus fruits. Acetaldehyde and (*Z*)-hex-3-enal are the main contributors to the smell of fresh fruit. Some aldehydes also influence the aroma of oranges, for example octanal, nonanal and decanal, and deca-2,4-dienals are important components in Spanish oranges. β-Sinensal has a pleasant orange smell (α-sinensal is typical for the aroma of mandarin); other important compounds are citral (mixture of isomers) and vanillin and some ketones, such as pent-1-en-3-one and β-ionone. The aroma of fresh oranges can be substituted by about 15 components that also include some ethyl esters, such as ethyl propionate, ethyl butanoate, ethyl 2-methylpropanoate, (*S*)-ethyl 2-methylbutanoate, ethyl 3-hydroxyhexanoate, neryl acetate and wine lactone. Important alcohols include 3-methylbutan-1-ol, (+)-α-terpineol, (−)-terpinen-4-ol and (+)-linalool. Other significant components are, furthermore, some hydrocarbons, especially β-caryophyllene with spice-like odour, α-pinene and myrcene.

The composition of volatiles of juices and beverages prepared from the oils extracted from citrus fruit peels is slightly different. For example, juices contain ethyl vinyl ketone, (*E*)-pent-2-enal and ethyl butanoate as major aromatic substances.

The main products of limonene oxidation, carvone and carveol, cause a terpenic off-flavour in essential oils and juices. Valencene oxidation products, such as (+)-nootkatone, cause a grapefruit-like off-flavour in orange juices. Large amounts of alcohol (+)-α-terpineol, which arises, for example, during storing of juices by acid catalysed hydration or microbial transformation of limonene, is also perceived as an off-flavour.

Bergamot oranges

The essential oil of bergamot oranges is rich in (+)-limonene, (+)-linalool and (+)-linalyl acetate. The dominant sesquiterpenes are (*E*)-α-bergamotene (0.2–0.4%), and other major sesquiterpenes are β-caryophyllene, germacrene D, α-humulene, β-farnesene and β-bisabolene. The typical aroma of bergamot oranges is attributed to oxygen compounds, such as (−)-guaienol, (+)-spathulenol, nerolidol, farnesol, α-bisabolol and β-bisabolol. Other important trace compounds are aldehydes β-sinensal, lanceal and bergamotenal. Further compounds that make a contribution are sesquiterpenic ketones (+)-nootkatone, (+)-8,9-didehydronootkatone, camphorenone and certain other substances.

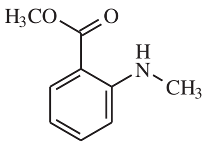
Mandarin oranges

Unlike other citrus essential oils, tangerine essential oil contains about 0.85% of *N*-methyl methylanthranilic acid (**8-187**), which is the key component. Other important substances are terpenic hydrocarbons, such as γ-terpinene and β-pinene, terpenic aldehyde α-sinensal and other terpenoids.



8-187, methyl *N*-methylanthranilate

Grapefruits

The key components of fresh grapefruit juices with a typical grapefruit odour are both isomers of *p*-mentha-1-en-8-thiol (**8-188**). The (+)-(*R*)-enantiomer is present in minute concentrations (less than 1 μg/kg), but has a very low odour threshold concentration. The (−)-(*S*)-*p*-mentha-1-ene-8-thiol has a weak and non-specific smell. Of the other sulfur compounds, 4-mercapto-4-methylpentan-2-one (**8-125**) is significant, and also occurs in blackcurrants, some hop cultivars, aromatic wines and basil. A relatively high content of sesquiterpenoids is also typical. The smell and bitter taste of grapefruits arise from (+)-nootkatone and (+)-8,9-didehydronootkatone. Important odour-active compounds are numerous cyclic ethers, which are likewise found in other essential oils. For example, the essential oil contains about 13% of linalool oxides that arise from linalool via 5,6-epoxide, and another important epoxide is (*E*)-4,5-epoxydec-2-enal. The fresh odour of juices is mainly influenced by aliphatic aldehydes, such as acetaldehyde, (*Z*)-hex-3-enal and decanal, as well as by some esters, such as 2-methylpropanoate, (*S*)-2-methylbutanoate and wine lactone.

(*R*)-*p*-menth-1-ene-8-thiol (*S*)-*p*-menth-1-ene-8-thiol

8-188, *p*-menth-1-ene-8-thiol enantiomers

Lemons

Principal carriers of the smell of lemons are β-pinene, (−)-terpinen-4-ol and citronellol, whose smell is reminiscent of lemon peel, while α-bergamotene contributes significantly to the basic lemon odour. A high content of citral (isomeric aldehydes geranial and neral) and the presence of some alkanals, esters and alcohols, especially geranyl acetate, neryl acetate and α-bisabolol are very important.

The off-flavour of lemon juices may be caused by degradation products of citral (*p*-cymene and α,*p*-dimethylstyrene) that result from reactions catalysed by acids.

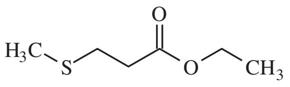
8.2.12.5.9 Bananas

The characteristic aroma components of bananas (*Musa* x *paradisiaca*, Musaceae) are esters. Important components are largely acetic acid esters, and the most significant compound is isopentyl acetate. The typical banana odour comes from esters of pentan-1-ol with acetic, propionic and butyric acids, while esters of butanols and hexanols with acetic and butyric acids generally show a fruity aroma. Other compounds also contribute to the full fine aroma,

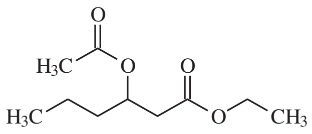
such as eugenol and its derivatives (methyleugenol and elemicin) and other compounds.

8.2.12.5.10 Pineapple

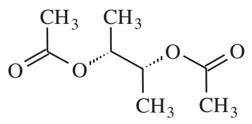
Pineapple (*Ananas comosus*, Bromeliaceae) aroma consists of about 200 alcohols, esters, lactones, aldehydes, ketones, monoterpenes, sesquiterpenes and other volatiles. About 80% of the total volatile substances are esters. The main components in the green fruit are ethyl acetate, ethyl 3-(methylthio)propionate (**8-189**) with a distinctive pineapple aroma and ethyl 3-(acetoxy)hexanoate (**8-190**). The ripe fruit contains, as the main esters, ethyl acetate, (2*R*,3*R*)-butane-2,3-diol diacetate (**8-191**) and ketone 3-hydroxybutan-2-one. An important compound for the typical character of pineapple aroma, as in strawberry aroma, is 2,5-dimethyl-4-hydroxy-2*H*-furan-3-one (furaneol), present as a glycoside, and 2,5-dimethyl-4-methoxy-2*H*-furan-3-one.



8-189, ethyl 3-(methylthio)propanoate



8-190, ethyl 3-(acetoxy)hexanoate



8-191, (2*R*,3*R*)-butan-2,3-diol diacetate

8.2.12.6 Vegetables

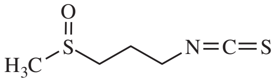
8.2.12.6.1 Cabbage, kale and kohlrabi

The aroma of cabbage (*Brassica oleracea* var. *capitata*), kale (*B. o.* var. *sabauda*), kohlrabi (*B. o* var. gongylodes) and other vegetables of the genus *Brassica* (Brassicaceae) is characterised by the presence of isothiocyanates, which result from the enzymatic and non-enzymatic decomposition of glucosinolates. For example, cooking cabbage produces, as the main products, allyl isothiocyanate (prop-2-en-1-yl isothiocyanate) arising from sinigrin, but-3-en-1-yl isothiocyanate (from gluconapin) and 2-phenylethyl isothiokyanate (from gluconasturtiin). Especially important is the latter compound, as it has a low odour threshold concentration. The resulting aroma, in addition to isothiocyanates, is also influenced by a large number of other sulfur compounds, such as dimethylsulfide and dimethyltrisulfide that are formed by decomposition of *S*-methylcysteine sulfoxide, cysteine and methionine (via methional). Nitriles produced as byproducts of degradation of glucosinolates also have some relevance, and to some extent recall the aroma of garlic. The main component is allyl cyanide (but-3-ene nitrile).

8.2.12.6.2 Cauliflower and broccoli

The components of cooked cauliflower (*Brassica oleracea* var. botrytis) and broccoli (*B. o* var. *italica*) aroma are similar to the aroma components of cabbage. Another important compound is the aldehyde nonanal. The typical odour of cauliflower comes from 3-(methylthio)propyl isothiocyanate (**8-192**), which is produced from glucosinolate glucoibervirin. The typical odour of broccoli is also due to the presence of 3-(methylsulfinyl)propyl isothiocyanate (**8-193**), which develops from glucosinolate glucoiberin.

8-192, 3-(methylthio)propyl isothiocyanate



8-193, 3-(methylsulfinyl)propyl isothiocyanate

8.2.12.6.3 Radish and horseradish

The aroma of radishes and horseradish of the Brassicaceae family, as well as the aroma of *Brassica* vegetables, is influenced by the presence of sulfur compounds resulting from the decomposition of glucosinolates. The main component of numerous varieties of radishes (*Raphanus sativus*) is (*E*)-4-(methylthio)but-3-ene-1-yl isothiocyanate (**8-194**), which is produced from glucosinolate glucoraphasatin and is responsible for pungent taste of many radishes. The odour and pungent taste of horseradish (*Armoracia rusticana*) is caused by the presence of allyl isothiocyanate, which is a degradation product of sinigrin.

8-194, (*E*)-4-(methylthio)but-3-ene-1-yl isothiocyanate

8.2.12.6.4 Carrots

The aroma of carrots root (*Daucus carota*, Apiaceae) is very complex. It consists of various aldehydes, ketones, mono- and sesquiterpenic hydrocarbons and other compounds. The important hydrocarbons are myrcene, sabinene, terpinolene, β-caryophyllene, γ-bisabolene and α-pinene, which are present in the largest quantities. The significant carbonyl compounds are acetaldehyde and (2*E*,6*Z*)-nona-2,6-dienal. One of the typical aromatic substances determining the basic odour of carrots is 2-*sec*-butyl-3-methoxypyrazine. During the cooking of carrots, the contents of methanal, ethanal, propanal, octanal, (*Z*)-dec-2-enal and some sulfur compounds, such as dimethylsulfide and ethanethiol, increase. At the same time, the contents of monoterpenes and β-caryophyllene decrease.

8.2.12.6.5 Parsley

The cause of the typical smell of fresh parsley (*Petroselinum hortense*) is *p*-mentha-1,3,8-triene (Figure 8.9). As in other vegetables of the Apiaceae family, important substances of root parsley and leaf parsley are phthalides. The main phthalides are sedanenolide, (*E*)-ligustilide and butylphthalide, while (*Z*)- and (*E*)-butylidene-phthalide, (*Z*)-ligustilide, (*Z*)-sedanolide and 3-butyl-5,6-dihydrophthalide are present in smaller amounts. Other important components of leaf parsley are linalool, β-citronellol, methyl 2-methylbutanoate, oct-1-en-3-one, (*Z*)-octa-1,5-dien-3-one, 2-isopropyl-3-methoxypyrazine, 2-*sec*-butyl-3-methoxypyrazine, (*Z*)-hex-3-enal, (*E*)-dec-6-enal, (2*E*,4*E*)-deca-2,4-dienal and β-ionone resulting from the degradation of carotenoids. Other components are the monoterpenes myrcene, α-pinene, β-pinene, α-thujene, camphene, sabinene, car-3-ene (Δ^3-carene), α- and β-phellandrene, (*S*)-limonene, γ-terpinene, *p*-cymene and terpinolene. *p*-Mentha-1,3,8-triene is the main aroma constituent of parsley leaf oil.

8.2.12.6.6 Celery and celeriac

The typical components of the aroma of celery (*Apium graveolens* var. *rapaceum*, Apiaceae) and celeriac (*A. g.* var. *dulce*) are numerous dihydrophthalides, tetrahydrophthalides, hexahydrophthalides and phthalides. The main odour-active compound is 3-butyl-4,5-dihydrophthalide (sedanenolide) and 3-butyl-3,4,5,6-tetrahydrophthalide (sedanolide, neoknidilide), 3-butylphthalide and 3-butylidene-4,5-dihydrophthalide, known as (*Z*)-ligustilide, are likewise present in significant quantities. Also present in smaller amounts are other dihydrophthalides, tetrahydrophthalides and hexahydrophthalides.

8.2.12.6.7 Beetroot

The odour of raw and cooked beetroot, also known as table beet, red beet or simply as beet (*Beta vulgaris* var. *conditiva*, Amaranthaceae, formerly Chenopodiaceae), is strongly influenced by the presence of tertiary sesquiterpenic alcohol (−)-geosmin (**8-23**), which is responsible the earthy smell of this vegetable. It is produced in the soil by some microorganisms. Other important compounds include pyridine, 4-methylpyridine, 2-*sec*-butyl-3-methoxypyrazine, some carbonyl compounds, such as 3-methylbutanal, biacetyl, hexanal, furan-2-carbaldehyde, benzaldehyde and phenylacetaldehyde, and alcohols, for example 2-methylpropan-1-ol and 3-methylbutan-1-ol.

8.2.12.6.8 Tomatoes

The aroma of tomatoes (*Solanum lycopersicum*, syn. *Lycopersicum esculentum*, Solanaceae) represents about 400 different compounds. Important components of the aroma of fresh ripe tomatoes are 2-isobutylthiazole, which is also the bearer of the typical aroma of the whole plant. The precursors of 2-isobutylthiazole are 3-methylbutanal, which arise by deamination and decarboxylation of leucine, and cysteamine (2-mercaptoethylamine) are formed by decarboxylation of cysteine (Figure 8.85). Important components of tomato aroma are also C_6 aldehydes (*E*)-hex-2-enal, hexanal and (*Z*)-hex-3-enal that are products of enzymatic oxidation of fatty acids, 3-methylbutanal, 2-methylbutanal and the corresponding alcohols are formed from amino acids. Oxidation products of carotenoids also play a key role, such as unsaturated methylketones (*E*)-6-methylhept-5-en-2-one and (*E*)-6-methylhepta-3,5-dien-2-one and other products, such as β-ionone, β-cyclocitral, 5,6-epoxy-β-ionone and (*E*)-β-damascenone. A significant odorous substance is 2,5-dimethyl-4-hydroxy-2*H*-furan-3-one (furaneol), which occurs in the intact form of β-D-glucoside.

The aroma of thermally processed tomatoes, such as tomato paste, is mainly determined by the presence of acetic and isovaleric (3-methylbutanoic) acids, 3-methylbutanal, methional, eugenol, 4-vinylguaiacol, dimethylsulfide, β-ionone and (*E*)-β-damascenone. There are other less active components, such as linalool, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) and its lower homologue 4-hydroxy-5-methyl-2*H*-furan-3-one (norfuraneol). The aroma of tomato concentrates is influenced by the presence of some Maillard reaction products, such as 2-acetylpyrrole, 2-formylpyrrole and some pyrazines.

8.2.12.6.9 Bell peppers

Bell pepper (*Capsicum annuum*, Solanaceae), also known as sweet pepper, pepper or capsicum, and chilli pepper (*C. frutescens*), contains as the key compound 2-isobutyl-3-methoxypyrazine (**8-175**), which carries the typical sharp spice-like odour of fresh vegetables and has an extremely potent odour. Other major components identified include terpenic hydrocarbons and alcohols, such as (*E*)-β-ocimene, limonene and linalool, methyl salicylate, aldehydes (2*E*,6*Z*)-nona-2,4-dienal (as in cucumbers) and (2*E*,4*E*)-deca-2,4-dienal and (*Z*)-hex-3-en-1-ol produced from unsaturated fatty acids.

8.2.12.6.10 Cucumbers

The key odour-active components of fresh cucumbers (*Cucumis sativus*, Cucurbitaceae) are aldehydes generated by enzymatic oxidation of unsaturated fatty acids. The most important compounds are (3*Z*,6*Z*)-nona-3,6-dienal, (2*E*,6*Z*)-nona-2,6-dienal and (*Z*)-non-3-enal, which recall the smell of fresh cucumbers. Additional important components are some other aldehydes, such as (*Z*)-hex-3-enal, (*E*)-hex-2-enal, (*E*)-non-2-enal, nonanal, (*Z*)-hex-6-enal, certain alcohols and 2-alkyl-3-methoxypyrazines.

The odour of fermented cucumbers and cucumbers pickled in sour brine is almost exclusively influenced by the odours of the fermentation products used, such as vinegar and spices.

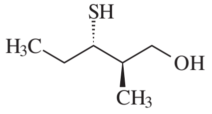
8.2.12.6.11 Garlic

The characteristic aroma of fresh garlic (*Allium sativum*, Amaryllidaceae) is almost exclusively represented by diallyl thiosulfinate (allicin) and to a lesser extent by allylmethyl thiosulfinate. The aroma of heat-treated garlic is associated with degradation products of thiosulfinates, especially diallyl sulfide, diallyl disulfide, diallyl

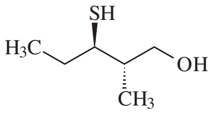
thiosulfonate, allylthiol, allylmethyl disulfide and vinyldithiines. At higher temperatures (during frying or baking) a number of dithiolanes and trithiolanes, dithianes, trithiepanes and tetrathiepanes are produced.

8.2.12.6.12 Onions, leeks and chives

The most important aromatic compounds of freshly sliced onions (*Allium cepa*, Amaryllidaceae), leeks (*A. ampeloprasum*) and chives (*A. schoenoprasum*) are dialk(en)yl thiosulfinates (prop-1-en-1-yl-, methyl and propyl derivatives) that give rise to a diverse mixture of odour-active degradation products. The tear factor of onion is (*Z*)-thiopropanal-*S*-oxide (Figure 8.63). The odorous constituent of raw and heat-treated onion is the intensively smelling 3-mercapto-2-methylpentan-1-ol (Figure 8.86). Its content in freshly cut raw onion ranges from 8 to 32 μg/kg, while in raw stored and then cooked onion its content rises to 34–246 μg/kg. The odour perception thresholds of (2*R*,3*S*)- (**8-195**) and (2*S*,3*R*)-isomers (**8-196**) are 0.04 and 0.03 μg/l in water, while the odour thresholds of the other two isomers are more than 100 times higher. Spontaneous degradation of dialk(en)yl thiosulfinates yields the corresponding disulfides and trisulfides that, together with 2-methylbut-2-enal and 2-methylpent-2-enal, represent the main aromatic components of cooked onions. The characteristic aroma components of fried onions are dimethylthiophenes, especially 2,4-dimethylthiophene and 3,4-dimethylthiophene (Figure 8.74).



8-195, (2*R*,3*S*)-3-mercapto-2-methylpentan-1-ol



8-196, (2*S*,3*R*)-3-mercapto-2-methylpentan-1-ol

8.2.12.6.13 Peas

Essentially important for the odour of green peas (*Pisum sativum*, Viciaceae) are aldehydes and some pyrazines. The typical smell is of 2-isopropyl-3-methoxypyrazine, an important component is also 2-*sec*-butyl-3-methoxypyrazine, which resembles the odour of bell peppers.

8.2.12.6.14 Asparagus

The characteristic aroma component of asparagus (*Asparagus officinalis*, Asparagaceae) is 3*H*-1,2-dithiol, which is produced during cooking from asparagusic (1,2-dithiolane-4-carboxylic) acid (Figure 8.89), which forms a redox system together with dihydroasparagusic acid. Asparagusic acid is present as free acid and as methyl and ethyl esters together with the methyl esters of

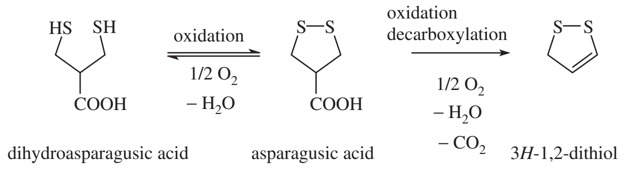


Figure 8.89 Decomposition of asparagusic acid during boiling of asparagus.

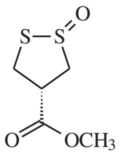
the epimeric sulfoxides of asparagusic acid, in which the *S*-oxide takes up either a *syn* or *anti* configuration relative to the methyl ester (**8-197**). A minor constituent of asparagus is 1,2,3-trithiane-4-carboxylic acid, which is a contact allergen from asparagus. Other aromatic compounds of cooked asparagus are dimethyl sulfide, various thiophenes, thiazoles (e.g. 2-acetylthiazole), pyrroles, pyrazines, aldehydes, ketones and phenols (e.g. vanillin).

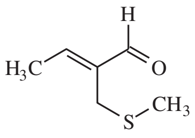


8-197, asparagusic acid *anti*-*S*-oxide methyl ester

8.2.12.7 Potatoes

2-Isopropyl-3-methoxypyrazine and 2,5-dimethylpyrazine, with their typical earthy flavour, have great importance for the aroma of raw potatoes (*Solanum tuberosum*, Solanaceae). In addition to these compounds, raw potatoes contain a range of carbonyl compounds and alcohols. A very important component of the aroma of cooked potatoes is methional.

The aroma of potato chips (French fries) is a mixture of more than 500 compounds. The important components are 2,3-diethyl-5-methylpyrazine, 2-ethenyl-3-ethyl-5-methylpyrazine, (2*E*,4*Z*)-deca-2,4-dienal, (*E*)-4,5-epoxydec-2-enal (8-183), 1-octen-3-one, (*Z*)- and (*E*)-non-2-enal, 2-methylpropanal, 2-methylbutanal and 3-methylbutanal, biacetyl and 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol). Another principal component is (*Z*)-2-(methylthiomethyl)but-2-enal (also known as 2-ethylidene methional, **8-198**), which arises in the reaction of methional with acetaldehyde. Both isomers of 2-(methylthiomethyl)but-2-enal are used as flavour enhancers. Less significant compounds are methanethiol and methional.



8-198, (*Z*)-2-(methylthiomethyl)but-2-enal

8.2.12.8 Alcoholic beverages

The characteristic aroma of beer, wine, spirits and other alcoholic beverages is formed by a large number of volatile compounds that are formed due to activities of yeasts or come from the raw materials used. In addition to fermentable sugars, higher fatty acids, organic nitrogen and sulfur compounds and many other substances pass into yeast cells from the media, and these substances participate in biochemical reactions in which aromatic components are formed as byproducts. Their number depends on the conditions during fermentation, and also, in spirits, on the method of distillation. A number of components arise by chemical reactions during ripening and storage of beverages.

8.2.12.8.1 Hops and beer

Worldwide, several hundred brands of beer are produced. Types of beer vary, being based on the basic classification into ales and lagers, which roughly corresponds to the division between bottom-fermented and top-fermented beers. Beers contain about 1000 different compounds, many of which can affect the organoleptic properties, which depend on the raw materials used and their quantity, brewing technology, the yeast used, possible contamination by other microorganisms and also on other factors. According to the current taxonomy, the yeasts used to produce alcoholic beverages are classified under one common species named *Saccharomyces cerevisiae*. Previously used names for bottom-fermented yeast were *S. carlsbergensis* and later *S. uvarum*, and *S. cerevisiae* was the name for top-fermenting yeast. The bottom-fermented yeast was also classified as a subspecies of *S. cerevisiae* yeast.

The primary aromatic substances in beer are derived from raw materials (barley or hops) that confer the beer's typical odour and taste. Bitter acids of hops have a bitter taste (see Section 8.3.5.1.3), but hop cones also contain 0.3–1% m/m of terpenoids (60–80% of hop essential oil), which have a considerable influence on the smell of beer. The main components of aromatic hop oils are sesquiterpenic hydrocarbons in which α-humulene, β-caryophyllene and farnesene dominate. The major monoterpenic hydrocarbon is myrcene. For example, the essential oil content of fine aromatic varieties, such as Saaz, is 0.8% m/m, of which 23% is myrcene, 20.5% α-humulene, 14% farnesene 6% and β-caryophyllene. Significant components of the hop aroma in beer are mainly isomeric terpenoid monoepoxides resulting from autoxidation and diepoxides of α-humulene and β-caryophyllene, but also other terpenoids. Important components of hops odour are also various alcohols (such as geraniol and linalool), esters (ethyl 2-methylpropanoate, methyl 2-methylbutanoate, propyl 2-methylbutanoate and esters of terpenic alcohols, such as geranyl isobutanoate), hydrocarbons, aldehydes and ketones formed by oxidation of fatty acids, such as (3*E*,5*Z*)-undeca-1,3,5-triene, (*Z*)-hex-3-enal, nonanal, (*Z*)-octa-1,5-dien-3-one, their epoxides, such as (*E*)-4,5-epoxydec-2-enal and sulfur compounds. Other important components of hops are so-called polyphenols (condensed tannins) that influence the beer's taste and have antioxidant effects. Less important compounds are waxes and other lipids. Hop products, such as powder, pellets and extracts (by extraction with carbon dioxide or organic solvents, such as dichloromethane, hexane or ethanol), are thus derived from hops.

Other aromatic substances are formed by enzymatic and chemical reactions during malting, and many compounds arise during the technological processes, such as mashing and fermentation. Fermentation changes the smell and taste of a young beer by reactions related to the metabolism of yeast. Top-fermented beers are sometimes very aromatic. Some beers, especially wheat beers, may contain a higher amount of 4-vinylguaiacol, which grants them a typical flavour. Other flavours can come from the addition of various spices, such as coriander, which is added to some Belgian beers.

Generally, some of the odour-active components of beer are considered desirable or desirable in small quantities, while others are indifferent or undesirable. For example, for the Pilsner type of beer, important odourous components include some alcohols (ethanol and linalool), aldehydes (acetaldehyde), acids (2- and 3-methylbutanoic acids), ethyl esters (butanoate, 2-methylpropanoate, 4-methylpentanoate and caprylate), sugar degradation products, such as of 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) and degradation products of carotenoids, such as (*E*)-β-damascenone. Interestingly, the feeling of an empty taste is associated with lower ethanol content. The bearers of caramel aroma in dark beers are maltol and isomaltol, which can come from caramel malts used in the production of dark beers, or from caramel used for colouring. Various esters of organic acids, such as 3-methylbutyl acetate and ethyl esters of fatty acids, have a flowery and ester aroma. An important descriptor of the taste of beer is called fullness, which may be caused by increased extract in unfermented beer, higher protein and carbohydrate content, and by the composition of the brewing water, which may for example have increased chloride content. Carbon dioxide content also significantly affects the physiological and sensory perception and beer foaming.

A range of different reasons may lead to the formation of undesirable sensory active substances, such as microbial contamination, pasteurisation and long-term storage. Various secondary substances, formed during the fermentation, pasteurisation and during long-term storage, may affect the smell/taste profile of beer – usually negatively. The carriers of sulfur odour are sulfane and various thiols, dimethyl sulfide and dimethyltrisulfide (arising either from hop *S*-methylcysteine sulfoxide or methional). Their smell resembles cooked vegetables, biacetyl smell resembles butter, acetic acid has a smell resembling vinegar, volatile phenols cause a phenolic aroma, and some lactones (especially δ-decalactone) give rise to a fruity odour. The development of a solvent-like stale flavour is associated with the formation of furfuryl ethyl ether, which is formed in an acid-catalysed substitution reaction of ethanol and furfuryl alcohol formed in the Maillard reaction. Various physical factors accelerate the aging of beer, particularly temperature and light radiation. During transport and storage, beer may be exposed to the effects of visible light (in the presence of photosensitisers, such as riboflavin), leading to an old, cardboard-like flavour caused by the formation of alkenals represented by 3-methylbut-2-en-1-thiol. The oxidation of unsaturated fatty acids to (*E*)-non-2-enal (and other products) leads to an off-flavour known as light-struck (cardboard) flavour (see Section 8.2.9.1.2) in

aged beers when present at levels as low as 0.035 μg/l). Concentrations of (*E*)-non-2-enal ranging from 0.2 to 0.5 g/l are usually found after 3–5 months at 20 °C, but then decrease below the threshold concentration after one year of aging, which is probably due to hydration to 3-hydroxynonanal or oxidation to non-2-enoic acid.

8.2.12.8.2 Grapes and wine

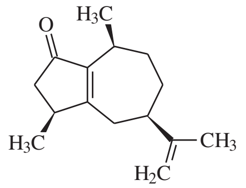
The organoleptic properties and quality of wine are influenced by many different factors. The quality of odour and taste depends on the balance of individual constituents. Specific wines are different depending on the vine variety, the ripeness of the grapes, the eventual attack by microorganisms (especially by *Botrytis cinerea* fungi), conditions during must fermentation (a dominant species of microorganisms are yeast *Saccharomyces cerevisiae*), such as temperature, and other factors.

Compared with other beverages prepared by fermentation, wines are very acidic (their pH value is within 2.8 to 3.8, and tartaric acid is a major carrier of sour taste) and they have a relatively high ethanol content. Ethanol has a significant influence on the nature of the taste. Its content is related to sugar content in the must, and therefore it is related to the degree of grape ripeness and the extent of the fermentation. For the red wine taste, tannins, condensation products of catechins and other flavonoid molecules are important compounds. Ethanol corrects their bitter and astringent taste.

It is estimated that wines contain 400–600 flavour-active compounds in a total amount of 0.8–1.2 g/l. In wine terminology, 'aroma' is the term used for the smell of young wines. The transformation of aroma during aging by chemical reactions leads to a wine's bouquet. Wine flavour is classified into primary – the bearer of which are substances present in grapes and musts – and secondary, the bearer of which are substances produced during fermentation.

According to the grape varieties, wines can have neutral (such as Müller Thurgau) and strong aroma (such as Muscat, Sauvignon, Gewürztraminer and Scheurebe). The primary aroma of muscat grapes is determined by the presence of ten terpenic alcohols, especially linalool (the content is about 0.4 mg/l, odour threshold concentrations in wine is 0.1 mg/l), geraniol (0.3 mg/l, odour threshold concentration of 0.1 mg/l), nerol (0.1 mg/l, odour threshold concentration of 0.4 mg/l), α-terpineol (0.1 mg/l, odour threshold concentration of 0.5 mg/l) and linalooloxides (0.1 mg/l, odour threshold concentrations of 3–7 mg/l). The characteristic impact components of Gewürztraminer and Scheurebe wines are *cis*-rose oxide and 4-mercapto-4-methylpentan-2-one (**8-125**). Some of the above terpenes are also involved in the odour of other grape varieties (such as Riesling), where their concentration is lower and only reaches 0.1–0.3 mg/l. In varieties lacking the characteristic aroma, these terpenoids are present only in traces, or not at all.

The peppery character of grapes and wines is attributed to the presence of the sesquiterpenoid (–)-rotundone, (3*S*, 5*R*,8*S*)-5-(isoprop-2-en-1-yl)-3,8-dimethyl-3,4,5,6,7,8-hexahydro-2*H*-azulen-1-one (**8-199**). Rotundone has a very distinctive aroma and low sensory threshold concentrations (16 ng/l in red wine and 8 ng/l in water). This guaiane-like compound was first found in Syrah (Siraz), Mourvèdre and Durif wines produced in Australia, at concentrations of up to 145 ng/l and later in higher amounts (up to 561 ng/l) in Schioppettino and Vespolina red wines and in Gruener Veltliner white wines produced in Europe. Rotundone was also found in much higher amounts in some common herbs and spices, such as black pepper, marjoram, oregano, rosemary, basil and thyme. In black and white peppercorns it is present at about 10 000 times higher levels than found in very peppery wine.



8-199, (–)-rotundone

The secondary aromatic compounds are mainly higher alcohols (Table 8.5) and esters (Table 8.25). Higher alcohols are present in somewhat larger quantities than those that correspond to their odour thresholds. At low concentrations they have a positive effect on the wine aroma, but in concentrations higher than about 400 mg/l they have a negative effect on wine aroma. An important role is played by ethyl acetate. In sub-threshold concentrations of 50–80 mg/l (the odour threshold concentration in wine is 160 mg/l), together with other substances, ethyl acetate is a desired aroma component, but in concentrations higher than 160 mg/l it has a harsh taste and smell. For the particular aroma of white wines, ethyl esters of fatty acids are also important (such as caproic, caprylic, capric and lauric acids), and occur in relatively low concentrations (5–10 mg/l), which are nevertheless about ten times higher than the threshold concentrations. The smell of ethyl caproate is fruity, but the smell of ethyl laurate is soap-like.

Thiol-containing compounds released from non-volatile precursors during alcoholic fermentation, in particular enantiomers of 4-mercapto-4-methylpentan-2-one, 4-mercapto-4-methylpentan-2-ol and 3-mercaptohexan-1-ol (**8-125**, **8-126**), are responsible for citrus and grapefruit scents of Sauvignon Blanc white wines and some other grape varieties (e.g. Gewurztraminer, Riesling, Muscat, Sylvaner, Cabernet Sauvignon and Merlot). For example, the aroma of 3-mercaptohexan-1-ol (0.03–13 μg/l) resembles grapefruits and passionfruit. Various other thiols have likewise been identified in wines, such as 2-furanmethanethiol and benzylmercaptan.

Certain heterocyclic compounds are also important aromatic substances in wines, such as pyrazines in Cabernet Sauvignon and Sauvignon Blanc wines (see Section 8.2.11.1.7) and both enantiomers of 3-hydroxy-4,5-dimethyl-5*H*-furan-2-one (sotolon), which occur in white wines, sherries and are a key component of the typical aroma of aged Port wines. The precise chemical reactions leading to the formation of bouquet substances are not yet widely known. There are two types of reactions that produce bouquet constituents: oxidation, which is characterised by the presence of aldehydes and acetals (e.g. in Madeira-type wines) and reduction (such as in quality table wines after a period of bottle maturation; the flavour of low-quality wines does not improve under the same conditions, but instead maturation often leads to a loss of freshness). During wine aging, glycosides of terpenic alcohols and

some esters of carboxylic acids hydrolyse. Aldehydes are oxidised to carboxylic acids and these are partially esterified, the content of degradation products of carotenoids called norisoprenoids (such as vitispirane and others) increases and tannins polymerise.

Wines infected with either lactic acid bacteria (particularly heterofermentative strains) or *Dekkera*/*Brettanomyces* yeast can potentially produce mousy off-flavor for which 2-ethyltetrahydropyridine, 2-acetyltetrahydopyridine and 2-acetylpyrroline are responsible. The impact odorants contributing to mushroom off-flavour in wines are oct-1-en-3-one and non-1-en-3-one.

8.2.12.8.3 Spirits

In addition to ethanol, distillates contain a large number of volatile compounds, which either come from raw materials or are produced during fermentation. Other flavour-active components are formed during storage and maturation by reactions of the individual components of the distillates. Their content varies according to the quality of raw material, technology and depends on a number of other factors. Many aromatic compounds are fundamental to the final product; additional components have little importance or may have no importance at all. The main components are ethanol, methanol and higher alcohols. The total content of methanol and higher alcohols in whisky is usually about 1 g/l, and in brandy 1.5 g/l. Other compounds include carbonyl compounds and acetals, of which acetaldehyde and 1,1-diethoxyethane are the major components. The total content of carboxylic acids in whisky ranges from 100 (in Scotch whisky) to 400 (in Bourbon whisky) mg/l, of which the main component (amounting 40–95% of the total acidity) is acetic acid. The characteristic component of rum is 2-ethyl-3-methylbutanoic acid. Fatty acid esters of lower aliphatic alcohols are particularly important, as they carry a fruity flavour (especially in apricot fruit spirits and rum). The main ester is always ethyl acetate. Ethyl esters of higher fatty acids (up to ethyl palmitate) carry the soapy flavour of some spirits, such as whisky and brandy. Lactones, phenols (e.g. in whisky), terpenoids, nitrogen heterocycles and many other compounds also play important roles.

For example, the main odour-active components of Bourbon whisky are aldehydes, the most important of which are 3-methylbutanal, 2-methylbutanal, 2-methylpropanal and (2*E*,4*E*)-deca-2,4-dienal. Important components are also ethyl esters, such as butanoate, 2-methylpropanoate, (*S*)-2-methylbutanoate, 3-methylbutanoate, hexanoate and octanoate, and lactones, especially (3*S*,4*S*)-whisky lactone, δ-nonalactone and γ-decalactone, some phenols (vanillin and eugenol) and (*E*)-β-damascenone, which is a degradation product of carotenoids.

8.2.12.9 Additional commodities

8.2.12.9.1 Tea

The amount of black tea (*Camellia sinensis*, Theaceae) volatiles is about 0.01 to 0.02% of dry matter. Black tea contains about 4–5 times the number of aromatic compounds of green tea. Of the more than 300 known substances in tea, only certain compounds are important for the aroma. The basic aroma consists mainly of regular compounds having green odour, such as (*Z*)-hex-3-en-1-ol, (*E*)-hex-2-enal and hexanal, usually present are 3-methylbutan-1-ol, 2-phenylethanol, methyl salicylate, phenol and guaiacol. In Darjeeling tea, an important component is also (2*E*,4*E*,6*Z*)-nona-2,4,6-trienal, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) and vanillin. Critical terpenoids and sensory active degradation products of carotenoids include α-terpineol, linalool, nerol, linalooloxides, β-damascone, (*E*)-β-damascenone, β-ionone, dihydroactindiolide and theaspiran and its derivatives, such as theaspiron and hydroxytheaspiran. The last compound is a very important component of the aroma of tea (its odour threshold concentration is about 0.2 μg/l in water). It constitutes about 1% of volatile substances. Compared with black tea, green tea contains lower amounts of linalool, linalool oxides and some other compounds, but higher amounts of nerolidol and β-ionone. A significant compound is 3-methylnonan-2,4-dione.

8.2.12.9.2 Coffee

Volatile components constitute about 0.1% of roasted coffee by weight (*Coffea* species, Rubiaceae), and more than 200 substances have been shown in green coffee. More than 800 compounds are known to make up the aroma of roasted coffee. Of these, only about 60 compounds have a significant role in the coffee aroma. Especially typical are a large number of heterocyclic compounds, mainly furans, pyrroles, indoles, pyridines, quinolines, pyrazines, quinoxalines, thiophenes, thiazoles and oxazoles, which arise in caramelisation and the Maillard reaction during coffee roasting. In addition to heterocyclic products, other important volatiles are also some aliphatic compounds (hydrocarbons, alcohols, carbonyl compounds, carboxylic acids, esters, aliphatic sulfur and nitrogen compounds), alicyclic compounds (especially ketones) and aromatic compounds (hydrocarbons, alcohols, phenols, carbonyl compounds and esters).

The aroma of coffee is very complex and virtually none of the above mentioned constituents provides the typical aroma by itself. Exceptions are 2-furanmethanethiol and 5-methyl-2-furanmethanethiol that have odours reminiscent of coffee. In freshly roasted coffee, 2-furanmethanethiol is present in an amount ranging from 0.01 to 0.5 μg/kg. A highly efficient sulfur-containing substance is also 2-methyl-3-furanthiol arising from thiamine. An important heterocyclic compound is 2-acetyl-4-methylthiazole and diterpene kahweofuran.

Significant aliphatic sulfur compounds are methional, 3-methylbut-2-ene-1-thiol, 3-mercapto-3-methylbutan-1-ol (**8-124**), its ester 3-mercapto-3-methylbutyl formate, methanethiol and dimethyltrisulfide. 3-Mercapto-3-methyl-1-ol also occurs in passion fruit and blackcurrant, and as a putative cat pheromone in cat urine, where it is formed as a degradation product of amino acid L-felinine (see Section 2.2.1.2.2). Of more than 70 known pyrazines, the most important compounds in roasted coffee are isopropylpyrazine, 2-isobutyl-3-methoxypyrazine, 2-ethyl-3,5-dimethylpyrazine, 2,3-diethyl-5-methylpyrazine, 2,6-dimethyl-3-vinylpyrazine and 2-ethyl-6-methyl-3-vinylpyrazine. Pyridine and its alkyl derivatives and bicyclic pyridines have a negative impact on the quality of coffee aroma. Important aromatic

compounds include some furans and pyrans, especially γ-lactones, such as 3-hydroxy-4,5-dimethyl-(5*H*)-furan-2-one (sotolon), 5-ethyl-3-hydroxy-4-methyl-(5*H*)-furan-2-one (abhexon), as well as furan-2-carbaldehyde and maltol. Important phenols are vanillin, 4-vinylguaiacol and 4-ethylguaiacol, important carbonyl compounds include (*E*)-β-damascenone, biacetyl and pentane-2,3-dione, some Strecker aldehydes, such as acetaldehyde, 2-methylbutanal, 3-methylbutanal, propanal, (*E*)-non-2-enal and 2-hydroxy-3-methylcyclopent-2-en-1-one, known as cyclotene.

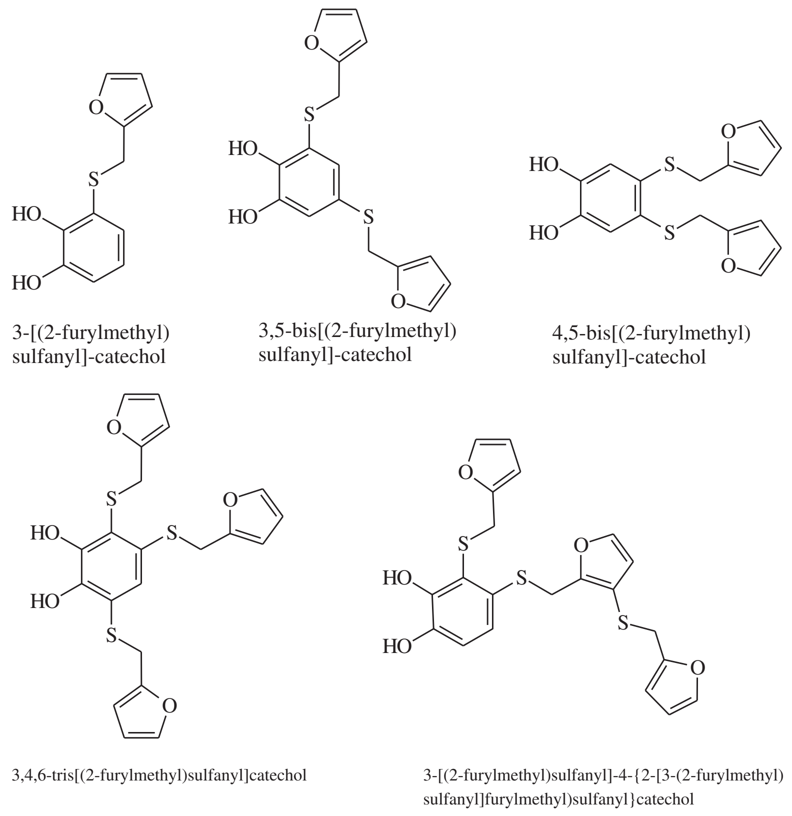
During storage of raw coffee beans atypical odours may develop, which are suggested to influence the aroma of coffee beverages. The compounds responsible for the atypical odour include (*E*)-β-damascenone with cooked apple-like odour, 2-methoxy-4-vinylphenol with clove-like odour and methyl 2-methyl and methyl 3-methylbutanoates showing fruity odour. The reduction of the water content in combination with lower temperatures are suggested to avoid aroma changes in raw coffee beans during storage.

Components of roasted coffee aroma, especially sulfur compounds, are easily oxidised, and ground roasted coffee kept in storage soon loses its typical aroma due to exposure to air. In order to retain the aroma, it is necessary to store it in impermeable containers under an inert atmosphere. Reactions of the odour-active thiols, such as 2-furanmethanethiol, with phenols generated from chlorogenic acid degradation products are responsible for the rapid aroma staling of coffee beverages. Examples of such reaction products are conjugates of catechol (pyrocatechol) with one, two and three molecule of 2-furanmethanethiol (**8-200**). Thiols also react with cysteine bound in proteins through thioether bond formation.

8.2.12.9.3 Cocoa and chocolate

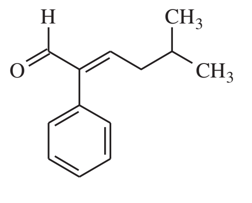
Fresh cocoa beans, the seeds of cacao tree (*Theobroma cacao*, Sterculiaceae), have a sour odour and a sour, bitter and astringent taste. The main contributors to the bitter taste are purine alkaloids. The astringent taste of cocoa products is mainly influenced by oligomeric procyanidins, flavan-3-ol-*C*-glycopyranosides (see Section 8.3.6.2.2) and *N*-phenylpropenoyl amino acids (see Section 2.2.1.2.1).

The formation of the characteristic aroma of cocoa depends on a number of factors, such as good harvest, fermentation, drying and roasting of cocoa beans. Precursors of aromatic compounds are produced mainly by anaerobic fermentation of cocoa beans. The aroma of roasted beans is created largely by the Maillard reaction and caramelisation, and is represented by more than 400 compounds. The major components are aldehydes, sulfides, heterocyclic compounds, carboxylic acids and terpenoids. Important aldehydes are 2-methylpropanal and 2-methylbutanal, which recalls the smell of cocoa and malt, and (*E*)-2-phenyl-5-methylhex-2-enal (**8-201**), which resembles chocolate. The latter aldehyde is formed by aldol condensation of another important aroma component, 3-methylbutanal with phenylacetaldehyde, and dehydration of the aldolisation product. Linalool and 2-phenylethanol

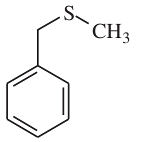


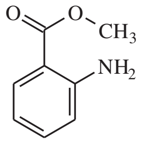
8-200, conjugates of catechol and 2-furylmethanethiol

carry sweet and floral scents, and 2-acetylpyridine has a roasted smell. Also important as aroma constituents are sulfides, especially dimethylsulfide, dimethyltrisulfide and benzyl methyl sulfide (**8-202**); among the other compounds, 2- and 3-methylbutyric acids, methyl anthranilate have a greater significance (**8-203**), and some Maillard reaction products, such as 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) and maltol, the smell of which resembles caramel, trimethylpyrazine, 2-ethyl-3,5-dimethylpyrazine resembling aroma of fried potato chips, 2,4,5-trimethyloxazole and 4-methyl-5-vinylthiazole. A mixture of 24 compounds are reportedly necessary to simulate cocoa aroma, as with coffee aroma.



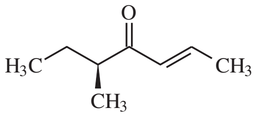
8-201, (*E*)-2-phenyl-5-methylhex-2-enal





8-202, benzyl methyl sulfide **8-203** methyl anthranilate

The main (key) components of chocolate aroma are C_5 carboxylic acids with a sweet smell (2-methylbutyric), lactones (γ-lactone with a sweet, peachy aroma), aldehydes (such as isovaleraldehyde with a sharp odour resembling malt), (*E*)-non-2-enal (with green and tallowy smell), (2*E*,4*E*)-nona-2,4-dienal and (2*E*,4*E*)-deca-2,4-dienal (with oily smell resembling fried foods), ketones, such as oct-1-en-3-one (with the mushroom-like smell), (2*E*,5*S*)- and (2*E*,5*R*)-5-methyl-hept-2-en-4-one (known as filbertone, which has the odour of hazelnuts, **8-204**), 2-ethyl-3,5-dimethylpyrazine (with a smell reminiscent of fried potato chips), 2-ethyl-3,6-dimethylpyrazine (with the smell of nuts with earthy tones) and methyl 2-methyl-3-furyl disulfide with meaty and sulfur smell.



8-204, (2*E*,5*S*)-5-methyl-hept-2-en-4-one

8.2.12.9.4 Peanuts

Unroasted peanut seeds (*Arachis hypogaea*, Fabaceae) contain about 75 volatiles, and in roasted seeds around 320 volatiles have been identified. The compounds of the greatest importance for the aroma of raw seeds are 2-isopropyl-3-methoxypyrazine (earthy and pea-like), 2-isobutyl-3-methoxypyrazine (bell pepper-like and earthy), and (*E*)-4,5-epoxy-dec-2-enal (metallic). Aroma components of roasted seeds include 2-acetyl-1-pyrroline, 2-propionyl-1-pyrroline, 6-acetyl-1,2,3,4-tetrahydropyridine, its tautomer 6-acetyl-2,3,4,5-tetrahydropyridine and 2-acetylpyridine (roasted aroma), 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol) with a somewhat caramel odour, oct-1-en-3-one with a mushroom-like odour, 2-isopropyl-3-methoxypyrazine (pea-like odour), 2-isobutyl-3-methoxypyrazine (resembling a bell pepper flavour), methional (resembling cooked potato) and phenylacetaldehyde and phenylacetic acid with a sweet odour resembling honey). Important aldehydes formed by oxidation of fatty acids include (2*E*,4*E*)-deca-2,4-dienal (fried foods odour), (*E*)-4,5-epoxydec-2-enal (metallic odour), (*E*)-non-2-enal and (2*E*,4*E*)-nona-2,4-dienal (oily odour).

8.2.12.9.5 Honey

From more than 100 aroma components identified in different types of honey, the most important compounds are esters of aliphatic and aromatic acids, aldehydes, ketones and alcohols. Significant compounds are esters of phenylacetic acid and phenylacetaldehyde with strong honey-like odour. The origin of the honey also has a big influence.

8.2.12.9.6 Vinegar

The flavour of wine vinegar depends on the constituents formed during the fermentation of the wine and during the storage or the aging. Vinegar made from ethanol contains almost exclusively acetic acid, ethanol and ethyl acetate, which are the result of non-enzymatic esterification of acetic acid with ethanol during storage. In addition to the characteristic substances of the plant material, wine vinegars and vinegars made from fruit wines contain fermentation products, such as acetic, 3-methylbutyric, 2-methylbutyric and butyric acids, 2-phenylethanol, acetoin, biacetyl and fusel oil alcohols (mixture of 2- and 3-methylbutan-1-ol).

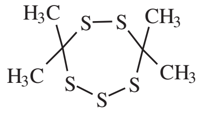
8.2.12.9.7 Mushrooms

Most types of wild and cultivated edible mushrooms of the phyla Basidiomycota (club fungi) and Ascomycota (sac fungi), which cover most of the so-called higher fungi, contain as the key compound alcohol (*R*)-oct-1-en-3-ol, which is produced by enzymatic oxidation of linoleic acid. Oct-1-en-3-ol is accompanied by a number of other compounds. For example, the components of common mushroom (*Agaricus bisporus*) aroma are the following alcohols and carbonyl compounds: 3-methylbutan-1-ol, (*R*)-octan-3-ol, (3*R*,5*Z*)-octa-1,5-dien-3-ol, (*Z*)-oct-2-en-l-ol (having a weak mushroom odour), octan-3-one, benzyl alcohol, benzaldehyde and furan-2-carbaldehyde. Certain non-volatile compounds are important for the mushroom taste, especially free nucleotides.

Some other sensory active substances are formed during cooking. A particularly significant compound is oct-1-en-3-one, which has a metallic and faintly mushroom odour that is important in the transformation of raw mushroom smell to the smell of cooked mushrooms. The aromatic components of dried mushrooms are numerous carboxylic acids, their lactones, aliphatic sulfur

compounds and heterocyclic compounds (especially pyrazines and pyrroles) formed as products of the Maillard reaction.

For the typical aroma of some species of fungi, other substances are significant. Aliphatic sulfur compounds methyl (methylthio)methyl disulfide (**8-186**), bis(methylthio)methane, tris(methylthio)methane and dimethyl sulfide contribute significantly to the typical aroma of truffles (*Tuber brumale*, *T. melanosporum* and *T. magnatum*). The musky odour of these mushrooms is derived from (3α,5α)-androst-16-en-3-ol, which is present in mushrooms at concentration of about 50 mg/kg. In China and Japan (and also in Europe) the widely used shiitake mushroom (*Lentinula edodes*), with a distinctive sulfurous aroma, has as a characteristic component 4,4,7,7-tetramethyl-1,2,3,5,6-pentathiepane, known as lenthionine (**8-205**). Lenthionine arises from lentinic acid by enzymatic reaction along with other sulfur compounds. The odour threshold concentration ranges from 0.3 to 0.5 mg/kg in water. The major constituents of the unpleasant smell of common stinkhorn (*Phallus impudicus*) are dimethyl disulfide and dimethyl trisulfide. Minor components are linalool, *trans*-β-ocimene and phenylacetaldehyde.



8-205, lenthionine

8.2.12.9.8 Spices

Fresh, dried or otherwise prepared parts of some plants have an intense, pleasant and characteristic odour and taste, and are therefore used as spices for food flavouring. The main constituents of the aroma of spices are various volatile mono- and sesquiterpenoids, in particular hydrocarbons, alcohols, aldehydes, ketones, esters and ethers (Table 8.32). The total content of essential oils is in the tenths to units of percent. Some spices also contain components with characteristic spicy, sharp and burning taste and important pigments.

8.2.13 Physiology and nutrition

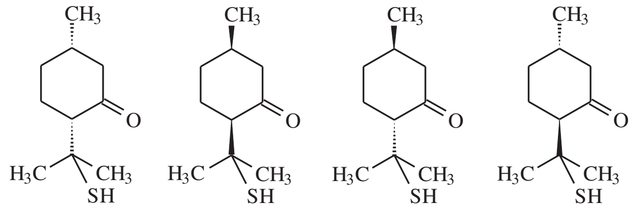
8.2.13.1 Organoleptic properties

8.2.13.1.1 Structure of odour-active compounds

Characteristic organoleptic properties of odoriferous substances are related to their structure and their stereochemistry. Small changes in the structure of molecules often lead to drastic changes in the quality and quantity of sensory perception. Structural analogues of compounds or structural isomers (positional isomers as well as functional isomers) therefore often exhibit different organoleptic properties. Odour-active substances are mostly chiral molecules, and the individual enantiomers or diastereoisomers have different organoleptic properties. Smell is a phenomenon associated with the elementary composition of substances, their spatial arrangement and, in unsaturated compounds, with molecular geometry. Reactions in which these compounds arise are enantioselective and diastereoselective.

For example, the pleasant smell of α-terpineol (**8-19**) resembles lilac flowers, but the substitution of oxygen for sulfur turns this into a very aggressive smell of *p*-menthene-8-thiol (**8-188**), which only at very low concentrations (below 1 μg/kg) recalls the scent of grapefruits for which (*R*)-*p*-mentha-1-en-8-thiol is a key component. The individual enantiomers of α-terpineol and 1-*p*-menthene-8-thiol also have different odours. (+)-(*R*)-α-terpineol (**8-19**) has a typical heavy smell of lilac flowers, (−)-(*S*)-α-terpineol (**8-19**) has smell of coniferous trees and tar, the natural isomer (+)-(*R*)-1-*p*-menthene-8-thiol (**8-188**) has the aroma of grapefruit, but the (*S*)-enantiomer (**8-188**) has a weak and non-specific flavour.

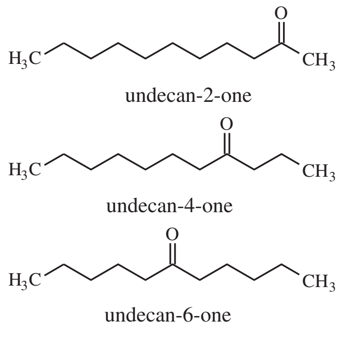
Blackcurrant aroma is reminiscent of only one diastereoisomer of *p*-menthan-8-ol-3-one, that is (1*S*,4*R*)-*p*-menthan-8-ol-3-one (**8-206**). This compound is also a characteristic component of blackcurrant leaves and fruits. In contrast, (1*R*,4*S*)-*p*-menthan-8-ol-3-one (**8-206**) has an unpleasant smell resembling burnt rubber and mercaptans, (1*R*,4*R*)-*p*-menthan-8-ol-3-one (**8-206**) smells like onion and has a weak fruity odour, and (1*S*,4*S*)-*p*-menthan-8-ol-3-one (**8-206**) has a similar but stronger smell of tropical fruits and a faint sulfur smell.



(1*S*,4*R*)-isomer (1*R*,4*S*)-isomer (1*R*,4*R*)-isomer (1*S*,4*S*)-isomer

8-206, *p*-menthan-8-ol-3-one isomers

The long-chain ketone undecan-6-one (**8-207**) has a strong fruity smell, but its positional isomer undecan-2-one (**8-207**) smell is reminiscent of rue (*Ruta graveolens*, Rutaceae). The smell of undecan-4-one (**8-207**) lies between these two extremes.



8-207, undecanone isomers

Table 8.32 Basic composition of common spices.

Latin name	Main components of essential oil[a]
Apiaceae	
Anethum graveolens Dill	**(+)-Carvone, limonene, (+)-dihydrocarvone**, (−)-carveol (seeds); **α-phellandrene, (+)-dill ether** (haulm)
Carum carvi Caraway	**(+)-Carvone, (+)-limonene**, α-pinene, α-phellandrene, dihydrocarvyl acetate, 1,8-cineole, linalool
Coriandrum sativum Coriander	**(+)-Linalool**, linalyl acetate, citral, α-pinene, β-pinen, α-phellandrene, α-terpinene, *p*-cymene, decan-1-ol, geraniol, borneol
Cuminum cyminum Cumin	**Cuminaldehyde**, **α-pinene**, **β-pinene**, *p*-cymene, 2-ethoxy-3-isopropyl-, 2-methoxy-3-*sec*-butylpyrazine, 2-methoxy-3-methylpyrazine
Foeniculum vulgare Fennel	(*E*)-**Anethole**, **fenchol**, α-phellandrene, (+)-limonene, estragol, camphene
Levisticum officinale Lovage	3-Butylidene-4,5-dihydrophthalide (ligustilide), other phthalides, α-terpinyl acetate, α-terpineol, carveol, carvacrol, coumarin
Pimpinella anisum Anise	**(*E*)-Anethole**, estragol, 4-methoxyacetofenone, acetaldehyde, 4-isopropylbenzaldehyde, 1,8-cineole
Asteraceae	
Artemisia dracunculus Tarragon	**Estragol**, 4-methoxycinnamaldehyde, 5,7-dimethoxycoumarin, anethole, α-pinene, myrcene
Cupressaceae	
Juniperus communis Common juniper	**α-Pinene**, **myrcene**, **β-pinene**, (+)-limonene, *p*-cymene, camphene, terpin-1-en-4-ol, α-terpineol, borneol, β-cadinene, sabinene
Illiciaceae	
Illicium verum Star anise	**(*E*)-Anethole**, α-phellandrene, α-pinene, β-cadinene, Δ^3-carene, *p*-cymene, dipentene, α-terpineol, estragol
Lamiaceae	
Mentha piperita Peppermint	**(−)-Menthol, (−)-menthone, (−)-menthyl acetate**, (+)-menthofuran, α-pinene, α-phellandrene, β-caryophyllene
Mentha spicata Spearmint	**(−)-Carvone, limonene**, dihydrocarvone, sabinene hydrate, (−)-menthone
Ocimum basilicum Basil	**Estragol**, **linalool**, 1,8-cineole, eugenol, methyl cinnamate, nerol, linalyl acetate
Origanum majorana Marjoran	**Terpin-1-en-4-ol**, **(*Z*)-sabinene hydrate**, (*E*)-sabinene hydrate, **1,8-cineole**, **estragol**, **α-terpineol**, **eugenol**
Origanum vulgare Oregano	Carvacrol, thymol, *p*-cymene, carvacryl methyl ether, linalool, α-pinene, bornyl acetate, camphor
Rosmarinus officinalis Rosemary	**1,8-Cineole**, **α-pinene**, **camphor**, camphene, borneol, bornyl acetate
Salvia officinalis Common sage	α-Thujone, β-thujone, camphor, 1,8-cineole, α-pinene, β-pinene, bornyl acetate, myrcene, borneol, linalyl acetate, β-ocimene
Thymus vulgaris Common thyme	**Thymol**, **carvacrol**, *p*-cymene, linalool, limonene, α-pinene, camphene, terpinene, β-caryophyllene, geraniol, carvacrol,
Lauraceae	
Cinnamomum verum True cinnamon	**Cinnamaldehyde**, **eugenol**, **safrol**, **linalool**, camphor

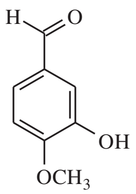
(*continued overleaf*)

Table 8.32 (*continued*)

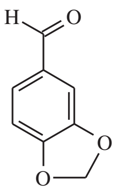
Latin name	Main components of essential oil[a]
Laurus nobilis Bay laurel	**1,8-Cineole, linalool**, eugenol, α-pinene, α-phellandrene, geraniol, γ-terpinene, *p*-cymene, β-caryophyllene, eugenyl acetate, camphene
Myristicaceae	
Myristica fragrans Nutmeg	**α-Pinene, β-pinene, sabinene, limonene**, 1,8-cineole, safrol, myristicin, γ-terpinene, terpinen-4-ol, eugenol, isoeugenol
Myrtaceae	
Syzygium aromaticum Clove	**Eugenol, β-caryophyllene**, eugenyl acetate, α-pinene, methyl benzoate, methyl salicylate, heptanol, nonanol, furfuryl alcohol
Pimenta dioica Allspice	**Eugenol**, 1,8-cineole, β-caryophyllene, methyleugenol, α-phellandrene
Piperaceae	
Piper nigrum Black pepper	**α-Pinene, β-pinene, sabinene, β-caryophyllene, Δ^3-carene, limonene**
Zingiberaceae	
Curcuma longa Turmeric	**(+)-*ar*-Turmerone, zingiberene**, 1,8-cineole, borneol, α-phellandrene
Elettaria cardamomum Cardamom	**1,8-Cineole, α-terpinyl acetate, (+)-limonene**, sabinene, borneol
Zingiber officinale Ginger	**(−)-Zingiberene, β-sesquiphellandrene, β-bisabolene**, citral, citronellyl acetate

[a]Components occurring in quantities higher than 10% are highlighted in bold.

Vanillin (**8-43**) has a typical smell of vanilla, isovanillin (**8-208**) does not resemble vanilla at all, and heliotropin (**8-209**) has a floral and spicy smell reminiscent of both vanillin and isovanillin.



8-208, isovanillin



8-209, heliotropin

Similarly, different organoleptic properties are also found in *cis/trans*, respectively (*E*,*Z*)-isomeric substances. For example, hydrocarbon galbanolene, which is (3*E*,5*Z*)-undeca-1,3,5-triene (**8-210**) occurring in galbanum (aromatic resin of *Ferula gumosa*, Apiaceae), celery and parsley leaves, celery root and mandarin oil, has a green smell, but its *all-trans* isomer (3*E*,5*E*)-undeca-1,3,5-triene has an oily smell (**8-210**). (*Z*)-Isomers are generally considered natural and are therefore more acceptable, (*E*)-isomers are often associated with synthetic compounds and various off-flavours.

(3*E*,5*Z*)-undeca-1,3,5-triene

(3*E*,5*E*)-undeca-1,3,5-triene

8-210, undeca-1,3,5-triene isomers

Enantioselectivity and diastereoselectivity of substances is of clear importance for the biological activity of compounds, and plays a role in chemical communication systems in bacteria, algae, insects, fish and higher animals. It is not surprising, therefore, that the enantiomeric forms of compounds often show differences in smell (and taste).

Analysis of individual forms is also important to determine the authenticity of foods or essential oils. The presence of certain forms, such as the geometrical (*E*)-isomers, is often evaluated as an off-flavour. For example, (+)-(*R*)-limonene (**8-5**) is a natural component of citrus essential oils and has a citrus smell like oranges. The isomer (−)-(*S*)-limonene (**8-5**), which is the main component of essential oils of silver fir (*Abies alba*, Pinaceae), other conifers and various types of mints (*Mentha* spp.), has a smell reminiscent of turpentine. The alcohol (−)-(*R*)-linalool, also known as licareol (**8-18**) has a strong woody smell like lavender, but (+)-(*S*)-isomer, also known as coriandrol (**8-18**) has a sweet smell with lavender tones. Another alcohol (−)-(*R*)-oct-1-en-3-ol (**8-16**), has an intense smell of fresh mushrooms, but (+)-(*S*)-isomer (**8-16**) has a smell resembling vegetables with faint mushroom notes. The ketone (−)-(*R*)-carvone (**8-50**) has a mint-like smell (and is the main component of spearmint essential oil), while its isomer (+)-(*S*)-

carvone (**8-50**) smells like caraway and is a major component of caraway essential oil.

Menthol has three asymmetric carbon atoms in the molecule, so there exist four pairs of optical isomers, but only (−)-(1*R*,3*R*,4*S*)-menthol (**8-19**) has any practical significance. It has a sweet, fresh, minty smell and a cool, refreshing taste. In the other isomers the mint smell and cool taste are weaker, and the dominating characteristic is vegetable-like. The other three menthol isomers, (+)-neomenthol, (+)-isomenthol and (+)-neoisomenthol have certain significance, but further isomers have little importance.

The only isomer of nootkatone that resembles the odour of grapefruits is (+)-nootkatone (**8-52**), while the remaining isomers have a more woody and spicy smell.

8.2.13.1.2 Sensitivity to perception of odours

Sensitivity to odour perception is different for each person, and also depends on the physiological state of the organism, psychological conditions, pathological changes and other factors. Generally, women are more sensitive to odours than men. Both sexes show a maximum sensitivity at puberty, and sensitivity to the perception of odours is reduced after the 70th year of life, and drastically after the 80th year of life. The sensitivity is also lower during pregnancy, colds and some diseases. Smokers perceive some odours as less intense (e.g. odour of cloves and smell of thiols), but other odours more intensely (such as banana aroma).

Part of the population suffers from so-called specific **anosmia** (specific olfactory blindness), which is manifested by an inability to perceive certain odours. About 100 substances are known that are not perceived by a limited number of human beings. For example, 70.5% of women and 62.8% of men reportedly perceive (5α)-androst-16-en-3-one, while the scents of cloves and bananas are perceived by nearly 100% of the population. About 1.2% of the total population suffer from total anosmia, which is a condition in which people have no sense of smell. People with anosmia often also experience **ageusia**, the inability to taste, because smell also plays an important role in taste perception. Hyperosmia is an extremely sensitive sense of smell, while parosmia causes people to misinterpret smells, detecting something unpleasant when the odour is neutral or pleasant. In phantosmia (a sort of olfactory hallucination), people detect smells where there are none. Anosmia differs from temporary olfactory adaptation (fatigue), which is adaptation to the smell of an odoriferous substance after a very short time when the smell ceases.

The ability to perceive the odour of a particular substance also depends on its **odour threshold** (aroma, flavour) **value**, which is the concentration of a substance detectable by the sense of smell. The **odour detection threshold value** is the lowest concentration of a stimulus (odoriferous substance), which can be detected in comparison with an environment that does not contain this substance. The **odour recognition threshold value** is the concentration at which a substance can not only be detected, but also recognised. It corresponds to a concentration that allows identification of the odour quality of a substance, which is usually higher than the odour detection threshold. Both values are measures of the odour intensity, but depend considerably on the environment, solubility, partition coefficients between air and water (oil) and some other factors. For example, values measured in air are typically several orders of magnitude lower than the values measured above aqueous solutions. The substance with a high odour threshold value must be present in foods in higher concentrations than substance with a low odour threshold value, otherwise its smell is imperceptible. The measure of whether the substance acts as an odour-active substance is its **odour unit**, its actual concentration divided by odour threshold concentration.

The presence of lipids, proteins, carbohydrates and other substances significantly influences the retention of aromatic compounds in foods and has an effect on their odour intensity and quality (e.g. the odour threshold values of non-polar substances measured in water are usually lower than the values measured in

Table 8.33 Odour detection threshold values of most powerful odoriferous substances (in μg/l in water at 20 °C).

Compound	Occurrence	Odour detection threshold
5-Ethyl-3-hydroxy-4-methyl-5*H*-furan-2-one (abhexon)	Acid protein hydrolysates	0.000 000 01
(*S*)-Butylphthalide	Celery, celeriac	0.000 000 01

β-Damascenone	Apples, alcoholic beverages	0.009

emulsions or fats). The effects known as **synergism** and **antagonism** play important roles in mixtures of odoriferous substances, causing higher (in synergism) or lower (in antagonism) response to the mixture of compounds than that expected from simple additivity among the components. For example, the odour of butyric acid is more intense in the presence of isovaleric acid and less intense in the presence of acetic acid. Antagonistic odorants are, for example, eugenol and methyl isoeugenol.

Table 8.33 displays the odour threshold values of some intensely odoriferous substances. The odour threshold values of selected common odoriferous substances are listed in Table 8.34 and Table 8.35.

8.2.13.2 Physiological effects

Odoriferous substances and their mixtures (e.g. essential oils) show a number of beneficial effects for which they have found use as pharmaceuticals, pharmaceutical ingredients and food additives. Bactericidal and anti-inflammatory effects are seen in borneol, eugenol, pinenes, camphor, thymol and menthol, cholinolytic (spasmolytic) effects preventing a drop in blood pressure and suppressing the secretory activity of various organs are found in camphor, pinenes and camphene, and analeptic effects (stimulating activity of circulation and respiratory system) are seen in camphene. The essential oils of many spices (such as marjoram, sage, thyme and many others) exhibit antioxidant effects, and therefore find use as natural antioxidants of fats.

Some terpenoids and other aromatic substances also show a variety of toxic effects, and their content in foods is therefore restricted by legislation in many countries.[5]

The monoterpenes α-thujone, known as (−)-thujone, and β-thujone, known as (+)-isothujone (**8-50**), are the dominant components of various essential oils of plants of the genus *Artemisia* (Asteraceae) that are referred to under various names, such as mugwort, sagebrush, sagewort, wormwood, tarragon and others. The content of essential oils ranges from 0.25 to 1.32%, in which thujones are present in amounts of 3–12%. Thujones also occur in the essential oil of sage (*Salvia officinalis*, Lamiaceae) and tansy (*Tanacetum vulgare*, Asteraceae), while in lower levels thujones are found in yarrow (*Achillea millefolium*, Asteraceae) and other plants. All these plants are used as medicinal herbs or find use as bittering agents in alcoholic beverages. For example, tansy is used for bittering Chartreuse liquor and wormwood for absinthe. α-Thujone is perhaps best known as the active ingredient of the green liquor absinthe, which was a very popular French drink in the 1800s and gained considerable notoriety as a preferred liqueur of artists and writers. For example, by 1910, the French were drinking 36 million litres of absinthe per year. Although absinthe became an epidemic health problem, leading to a ban in France in 1915, its use continues on a small scale, either legally or illicitly. The acute toxicity of α-thujone can be attributed to blocking the γ-aminobutyric acid (GABA)-gated chloride channel. Both thujones show chronic neurotoxicity manifested by hallucinations, hyperexcitability, sleeplessness, tremors, convulsions and later damage of the cerebral cortex. Manifestations of chronic toxicity are called absinthism, the disorder associated with the habitual abuse of absinthe. The thujones content is therefore restricted. For example, the preban absinthes produced in the period 1895–1914 contained 0.8–7.7 mg/l α-thujone and 0.6–39.5 mg/l β-thujone, while the concentrations of these two substances in modern legal absinthes (produced in Europe in 2003–2006) were 1.4–5.6 and 0.7–67.6 mg/l, respectively.

Toxic effects have are also been found for (+)-(*R*)-*p*-mentha-4(8)-en-3-one, known as (+)-pulegone (**8-50**), which is found in essential oils of different mint species, especially in squaw mint, also know as pennyroyal (*Mentha pulegium*, Lamiaceae), but also in other mint species. Mints are mostly used as carminative agents (anti-flatulence agents), spasmolytic agents (release spasms), stimulants of bile and gastric juices production and food flavouring. Pulegone occurring, for example, in peppermint oil exhibits neurotoxicity and relatively high hepatotoxicity leading to necrosis of liver cells. Its content in food is therefore restricted. The bitter sesquiterpene santonin (see Section 8.3.5.1.3) occurs mainly in the flowering tops of plants of the genus *Artemisia* and in their essential oils. Previously, these drugs were used as intestinal anthelmintic drugs. Santonin promotes chromatopsia (an abnormal condition, in which all objects appear in purple colour). Its level in food is therefore legally restricted. Carcinogenic effects are shown by some substituted alkenylbenzenes (e.g. prop-1-en-1-ylbenzenes and prop-2-en-1-ylbenzenes), such as safrole (**8-34**) and methyleugenol (**8-33**) that occur in several essential oils. Myristicin, found in seed essential oils of some root vegetables (such as carrots), is a psychomimetic substance having narcotic and hallucinogenic effects similar to the effects of ethanol. It also displays antimicrobial effects. β-Asarone (**8-33**), occurring mainly in wild ginger (*Asarum europaeum*), has chemosterilation effects. Another aromatic substance, the use of which is restricted, is coumarin (**8-99**), which occurs, for example in tonka beans (*Dipteryx odorata*, Fabaceae) and many other plants. Coumarin has hepatotoxic effects, but certain anti-carcinogenic properties and some positive effects in the treatment of varicose vein syndrome (such as rutin and hypericin) have also been demonstrated.

8.2.14 Production and use

Flavourings are products that are intended to be added to food in order to impart or modify odour and/or taste. They are made or consist of the following categories: flavouring substances, flavouring preparations, thermal process flavourings, smoke flavourings, flavour precursors or other flavourings or mixtures thereof. Food flavourings are derived from natural materials or produced synthetically. It is estimated that of the food flavourings used in developed countries, about 75% of substances are natural compounds and the rest are synthetic compounds. About 99% of synthetic substances

[5] Influence of odoriferous substances on human health is concerned with the organisation IFRA (International Fragrance Association) and other organisations. In the Code GRAS (Generally Regarded as Safe) published by FEMA (Flavour and Extract Manufacturer's Association) and in the Code published by CoE (Council of Europe), non-toxic flavour-active substances are allocated numbers (FEMA numbers or CoE numbers), as well as Chemical Abstracts Service (CAS numbers).

Trimethylamine	Fish, eggs (off-flavour)	2

[a] The odour detection threshold value of non-polar substances in oil is different. For example, for hexanal 0.12 mg/kg, for (*E*)-non-2-enal 0.15 mg/kg, for (2*E*,4*E*)-deca-2,4-dienal 0.135 mg/kg and for phenylacetaldehyde 0.022 mg/kg.

are substances occurring in nature (nature identical substances) and 1% of substances are artificial, synthetic flavourings.

The most important materials for the production of natural food flavourings (but also perfume compositions for cosmetic purposes) are **essential oils**, **oleoresins**, extracts, juices, pulps and distillates. They are obtained almost exclusively from plant materials, fresh or dried plants or parts of plants otherwise prepared for drugs. Materials called **resinoids** are primarily used for the fixation of fragrance compositions in cosmetics and only occasionally in foods. Drugs of animal origin are not used for the production of food flavourings, in contrast to cosmetic products.

8.2.14.1 Essential oils

Essential oils are complex mixtures of volatile substances contained in natural plant materials. They are obtained from different parts of plants, their flowers (such as jasmine oil), flowering stalks or straw (such as mint and thyme oils), fruits or seeds (such as cumin, pepper and juniper oils), fruit pericarp (such as citrus oils), wood (sandal oil) leaves (bay oil), bulbs (such as garlic oil), rhizomes (such as sweet flag and turmeric oils) and roots (such as gentian oil). Essential oils are obtained by three basic procedures or their combinations:

- mostly by distillation with water vapour and separation of the oil layer in the distillate (mainly oils from the seeds, stems, leaves, wood and roots); on extraction of the distillation waters an additional portion of oil, usually of lower quality is obtained;
- by extraction with non-polar solvents, such as petrol and petroleum ether (mainly oils of flowers), the extract obtained is called **miscella**; Freons are used as solvents (the trade name refers to several chlorofluorocarbons) and carbon dioxide at supercritical pressures, extraction with animal fats (such as pork lard) is now used less frequently, the procedure is called **enfleurage** (mostly for volatile oils of flowers)
- by pressing and separation of the oil layer (mainly oils of citrus fruit peels).

Steam distillation, extraction with non-polar solvents, pressing and evaporation of solvent produce an essential oil known as a **concrete**, which is a mixture of essential oil, various lipophilic substances and mainly waxes. The accompanying substances are separated by dissolution in hot ethanol, freezing and filtration and the essential oil thus obtained is **absolute**.

Most essential oils contain a significant proportion of terpenes (monoterpenic and sesquiterpenic hydrocarbons). For example, their level in some citrus essential oils is 95% or more. These substances are not usually essential to the smell and aroma character of essential oils, as the most important odoriferous compounds are alcohols, aldehydes, ketones, esters and other compounds. Furthermore, terpenic hydrocarbons are a reason for the limited solubility of essential oils in diluted ethanol and are often the cause of deterioration of essential oils that easily oxidise or polymerise. By removing hydrocarbons from essential oils, concentrates are obtained. Monoterpene-free or sesquiterpene-free essential

Table 8.35 Odour detection threshold values of heterocyclic substances in mg/l in water at 20 °C.

Compound	Occurrence	Odour detection threshold
Oxygen heterocycles		
Furan-2-carbaldehyde	Widespread, degradation of pentoses	3
4-Hydroxy-2,5-dimethyl-2*H*-furan-3-one (furaneol)	Widespread (meat, milk, cheeses, bread, fruits, vegetables)	0.03

3,4-Dimethylthiophene	Roasted onion	0.001
2-Isobutylthiazole	Fresh tomatoes	0.002–0.03
2-Furanmethanethiol	Coffee, meat	0.000 005
2-Methyl-3-furanthiol	Coffee, meat	0.000 01
2-Methyl-3-thiophenethiol	Coffee, meat	0.000 02
Nitrogen heterocycles		
Acetylpyrazine	Widespread in cooked foods	0.1
2-Acetylpyridine	Widespread in cooked foods	0.02
2-Acetyl-1-pyrroline	Bread, cereal products	0.0001
2-Acetyl-1,2,3,4-tetrahydropyridine	Bread, cereal products	0.001
2,5-Dimethylpyrazine	Widespread in cooked foods	0.8
2,6-Dimethylpyrazine	Widespread in cooked foods	0.2
2-Methyl-3-ethylpyrazine	Widespread in cooked foods	0.000 4

oils (that do not even contain monoterpenic hydrocarbons) are collectively called **deterpenic essential oils**. They are more concentrated than the starting oils, have a sensory character of the original oils and are more stable against autoxidation and suitable for products with a lower ethanol content. Deterpenation of essential oils is carried out by distillation, extraction, adsorption on suitable sorbents or by a combination of these procedures.

Essential oils obtained by cold pressing or extraction contain, in addition to volatile substances, low volatile and non-volatile substances, such as oleoresins. For example, the dry matter content in citrus essential oils is about 4%. The main components are flavonoids, such as naringin, or metabolites of bitter triterpenes of limonin type. Coumarins such as scopolaron are present at a level of 1.5%, along with furanocoumarins (psoralens), such as bergaptene and bergamottin.

8.2.14.2 Oleoresins

Oleoresins are the flavour extracts obtained by the solvent extraction of the ground spices or vegetables and solvent evaporation from the miscella. They are mixtures of essential oils, resins and other components that are extracted with organic polar (methanol, ethanol and isopropyl alcohol), non-polar solvents (hexane, petroleum ether and gasoline) or by supercritical carbon dioxide extraction. Oleoresins have the aroma of the original spices or vegetables as they contain essential oils in varying proportions, and possess attributes which contribute to the taste, such as pungency of black pepper and ginger oleoresins, and colour of turmeric and hot bell pepper oleoresins. For example, the essential oils of black pepper (Table 8.32) obtained by steam distillation contain as major components (about 20%) the terpenes α-pinene, sabinene and β-caryophyllene and in smaller amounts car-3-ene, limonene, β-pinene and other compounds. Oleoresin of black pepper obtained by extraction contains about 13–14% essentials oil and 50% of hot piperine and related non-volatile substances.

The oleoresins have some advantages over natural spices (Table 8.36), because of their low microbial contamination, uniformity in flavour, colour and pungency, easy storage and transport. Oleoresins as such or deposited on suitable media (such as starch or flour) have several applications such as in preparation of beverages, soup powders, confectionary, curries, noodles, sauces, canned meat and meat products.

Table 8.36 Characteristics of some common oleoresins.

Oleoresin	Essential oil (ml/kg)	Spice equivalent[a]	Oleoresin	Essential oil (ml/kg)	Spice equivalent[a]
Bay leaf	300	3.5	Allspice	600	4.5
Loves	700	6	Bell pepper	Traces[b, c]	10
Cumin	600	5	Black pepper	150[c, d]	4.5
Coriander	330	10	Cinnamon	160	5.5
Turmeric	Traces[b, e]	15	Sage	250	2
Marjoram	400	3	Vanilla	50[f]	5
Mace	500	7.5	Thyme	500	4
Nutmeg	800	6	Ginger	250[c, g]	4

[a]Spice equivalent is given by the number of weight units that have the same flavour as 100 units of natural spices.
[b]A minimum content of dyes is required.
[c]By sensory analysis is measured the sharpness (heat) of hot oleoresins, which is expressed in Scoville Heat Units.
[d]50% of piperine.
[e]At least 12.5% of curcumine.
[f]10% of vanillin.
[g]12% of hot ketones.

8.2.14.3 Resinoids

Resinoids are products obtained by the extraction of natural materials, mostly resins, gum resins and balsams, by solvents other than petroleum ether or petrol. Chlorinated hydrocarbons (dichloromethane and chloroform), acetone, methanol or ethanol are typically used for this. Resinoids have a characteristic smell, which due to the volatile substances (essential oils) present.

Resins are the products of various shrubs and trees, especially conifers. In addition to essential oils, resins contain resin acids, such as tricyclic diterpene abietic acid, resin alcohols (resinols), resin esters and other substances. Particularly well known is Chios mastic gum. Real mastic is only produced in the south part of Chios Island, and comes from the mastic tree (*Pistacia lentiscus* var. *chia*, Anacardiaceae). It is used to flavour alcoholic beverages (especially liqueurs and ouzo), wine, baked goods, chewing gum and some cosmetic products. The essential oil with a balsam-like odour has antiseptic properties as it contains α- and β-pinene as essential ingredients.

Gum resins are secreted by some plants. They contain essential oils, resins and gums that form gels in water. A well-known gum resin is myrrh, an extract from gum myrrh plants of the family Burseraceae, such as *Commiphora habessinica* (syn. *C. abyssinica*).

Balsams are physiological or pathological substances secreted by some plant species. They contain essential oils and resins and esters of organic acids (mainly benzoic and cinnamic acids). The well-known Peruvian balsam flows from injured trees of the genus *Myroxylon* (Fabaceae), such as *M. balsamum* var. *genuinum* and *M. b.* var. *pereirae*, which are native to Central and South America.

8.2.14.4 Other materials

Extraction is not only used for obtaining essential oils and oleoresins, but also other materials for flavouring foods, such as **extracts** and **tinctures** that are also acquired by extraction. Extraction with a solvent (mostly ethanol) by standing at room temperature is called maceration, and the product is the **macerate**. Extraction with the flow of a solvent that passes through a material is percolation, and the product thus obtained is the **percolate**. Products obtained by cold **maceration** or **percolation** usually have better organoleptic properties. Extraction at higher temperatures is often called **digestion**. An alcoholic (or aqueous) extract (or extract obtained using other solvents) is usually called a **tincture**. In practice, the basic extraction procedures are variously combined and modified. For example, hop extract is produced by two-stage extraction. The first stage is percolation of a volatile solvent (such as dichloromethane) to obtain the oil, which is followed by hot water extraction (extraction of tannins and so-called soft resins). Both extracts, after evaporation of solvents, are combined and homogenised. The name **essence** is used for alcoholic extracts of materials, but today it is used more for special composed products used for food flavouring that are mainly known as **aroma compositions**.

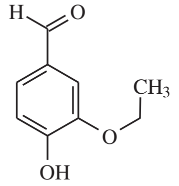
Other raw materials for producing food flavourings include **musts** or **juices** and **pulps** from fruits and vegetables. Citrus fruit juices, apple, grape, currant, cherry juices and other ingredients are all commonly used as the starting material. Concentrated apple juice is used as the basis for the production of other flavours (such as apricot); intensely coloured juices (e.g. juices from elderberries and blackcurrants) are used to dye various products. Vegetable juices that are usually used as basic raw materials for food flavourings include carrot, cabbage, tomato and onion and garlic juices. Fruit

and vegetable pulps are also used as a supporting medium for the production of paste-like flavours. The raw materials for flavour production also include various **distillates** (fruit and herbal), which usually contain ethanol.

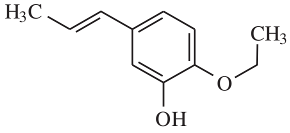
8.2.14.5 Synthetic compounds

Hundreds of different essential oils are used in current industrial practice. Their scarcity, higher price and differences in their quality have led to the production of cheaper **reconstituted essential oils**, which contain the same fragrances as natural essential oils, but are synthetic. These essential oil reconstitutions usually lack the subtle characteristics of natural essential oils.

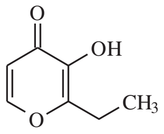
Examples of synthetic substances that do not occur in nature and yet find a use in food flavouring are ethyl vanillin, known as bourbonal (**8-211**), and (*E*)-2-ethoxy-5-(prop-1-en-1-yl)phenol (propenyl guethol, **8-212**) which has a vanilla-like smell. The advantage is that the smell of ethyl vanillin is between 2 and 4 times more intense than the smell of vanillin. Another commonly used compound is ethylmaltol (**8-213**), which has a caramel odour 4–6 times more intense than maltol. Allyl phenoxy acetate (**8-214**) has a sweet smell of honey and pineapple. One of the first synthetic substances with a strawberry flavour, used for confectionery, ice cream and other products, was (*E*)-isomer of ethyl 3-methyl-3-phenylglycidylic acid (ethyl 3-methyl-3-phenyloxiran-2-carboxylate, also known as fraseol or strawberry aldehyde, **8-215**). Only the (2*R*,3*R*)-isomer, however, has a desirable strawberry flavour. Ethyl 3-phenylglycidylic acid (ethyl 3-phenyloxiran-2-carboxylate, also known as raspberry aldehyde, **8-216**) found use as a flavouring agent in similar products that require the aroma of raspberries.



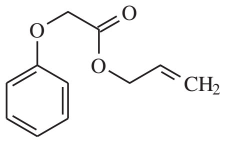
8-211, bourbonal



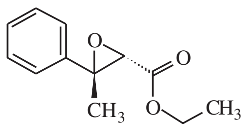
8-212, (*E*)-prop-2-en-1-ylguethol



8-213, ethylmaltol

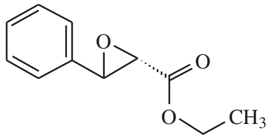


8-214, allyl phenoxyacetate



8-215, ethyl 3-methyl-3-phenyloxirane-2-carboxylate

Adulterating and diluting essential oils to increase profits can sometimes happen in the essential oil and aromatherapy industries.



8-216, ethyl 3-phenyloxirane-2-carboxylate

Adulterating an essential oil is relatively easy; forms of adulteration may include the addition of alcohol, synthetic products, substituting different and cheaper oils and passing them off as natural oils.

8.3 Taste-active substances

Oral ingestion of food and other substances in humans and higher animals are inseparable from the subjective taste sensations. The stimulae for irritation of taste receptors localised in the mouth, especially on the tongue, are **taste-active substances**. They are usually polar, water-soluble and non-volatile compounds. The resulting sensation is usually a combination of fundamental and other tastes:

- **sweet**
- **salty**
- **acid**
- **bitter**.

These basic taste sensations arise at relatively specialised receptors located in different places of the mouth. Sweet substances are perceived primarily at the tip of the tongue, salty substances in defined areas of the upper surface of the tongue, sour substances to the sides and bitter substances in the root of the tongue and soft palate. Taste receptors also respond to other stimuli (tastes) that are incorporated virtually in the whole oral cavity:

- **umami** (now considered to be a fifth basic taste)
- **astringent**
- **pungent** (burning or hot)
- **cooling** and others.

The interpretation of taste in terms of molecular interactions of taste-active compounds with biopolymers in taste receptors is probably analogous to the general scheme of pairs of interactions of the type of enzyme–substrate, hormone–receptor or antigen–antibody. These interactions and relationships between the chemical structure of a substance and its taste are best known (relatively) for sweet substances, but information on other substances is still largely incomplete.

The measure of taste intensity is the lowest detectable concentration of a substance in the solution causing the sensation, called the **threshold value**. As in the case of odour-active substances, **taste detection threshold values** and **taste recognition threshold values** are likewise recognised. Both values are measures of taste intensity.

8.3.1 Sweet substances

Sweet taste is commonly associated with sugars, especially sucrose (saccharose). Sweet substances are, with few exceptions, monosaccharides, oligosaccharides and sugar alcohols, but most of these are less sweet than sucrose. Many sugars are not even sweet at all and some, such as β-D-mannose and some oligosaccharides, are even bitter. In contrast, there are other compounds that have a completely different structure than sugars and yet are much sweeter than sucrose (e.g. synthetic sweeteners).

8.3.1.1 Sweet taste quality and intensity

Sugar and all sweet substances differ in their:

- sweet taste quality
- sweet taste intensity.

Sucrose has a particularly full taste, which is acceptable even at high concentrations. It is therefore used as a standard for sweet taste in the sensory evaluation of sweet substances. The threshold values of some sugars in aqueous solutions are listed in Table 8.37. For practical reasons, the sweetness of substances is expressed as a multiple of the sweetness of the sucrose solution (mainly 10% solution). The relative sweetness of certain sugars and sugar alcohols is given in Table 8.38. These values are only approximate, as they depend on sugar concentration, type and amount of anomers, temperature, presence of other substances and other factors.

For example, D-fructose solutions are sweeter than sucrose solutions, but in pastries and hot coffee both sugars show the same sweetness. The sweetest form is β-D-fructopyranose, which has about 180% of sucrose sweetness, but as a result of mutarotation, the sweetness of solutions decreases to about 150% of the sucrose sweetness because the individual anomers each have a different sweetness. The sweetness of fructose syrups depends on the fructose content. Syrups containing 42% fructose are about as sweet as sucrose solutions, syrups with 55% fructose show 100–110% of sucrose sweetness, and syrups with 90% fructose have 120–160% of sucrose sweetness.

Table 8.37 Taste threshold values of selected sugars.

	Detection threshold		Recognition threshold	
Sugar	Mol/l	%	Mole/l	%
D-Glucose	0.065	1.17	0.090	1.63
D-Fructose	0.020	0.24	0.052	0.94
Maltose	0.038	1.36	0.080	2.89
Saccharose	0.011	0.36	0.024	0.81
Lactose	0.072	2.60	0.116	4.19

Table 8.38 Relative sweetness of selected sugars and sugar alcohols (10% saccharose solution = 1).

Compound	Sweetness	Compound	Sweetness
Monosaccharides		***Trisaccharides***	
D-Xylose	0.70	Raffinose	0.15–0.20
D-Glucose	0.40–0.80	***Alditols***	
D-Mannose	0.30–0.60	L-Arabinitol	1.00
D-Galactose	0.30–0.60	Xylitol	0.90–1.20
D-Fruktose	0.90–1.80	D-Glucitol	0.40–0.60
Disaccharides		D-Mannitol	0.50–0.70
Invert sugar	0.95–1.80	Galactitol	0.40
L-Rhamnose	0.30	Maltitol	0.70–0.90
α,α-Trehalose	0.60	Isomaltitol	0.40–0.50
Maltose	0.30–0.60	Palatinitol	0.45
Lactose	0.20–0.60	Lactitol	0.30–0.40
Lactulose	0.60	***Various***	
Saccharose	1.00	Glycerol	0.50

In 10% solutions, the relative sweetness of D-glucose is about 50–60% of sucrose sweetness, while in solutions containing 50–60% glucose its sweetness is higher (90–100% of sucrose sweetness). β-D-Glucopyranose has about 66% of the sweetness of α-D-glucopyranose. The sweetness of glucose syrups depends on the glucose content and its lower oligomers. A syrup with a DE value of 30 has about 30–35%, syrup with a DE value of 36 has 35–40%, syrup with a DE value of 42 has 45–50%, syrup with a DE value of 54 has 50–55% and syrup with a DE value of 62 has 60–70% of sucrose sweetness.

Besides the sweet taste, some sweet substances show other side-tastes. For example, maltose and D-glucitol have the flavour of syrups and the taste of D-fructose solutions is fruity and slightly sour. Sucrose taste in threshold concentrations is even described as slightly bitter. Xylitol shows a cooling effect on dissolution.

Sweet substances are classified depending on various criteria:

- according to the origin as natural, synthetic identical to the natural or modified natural and synthetic substances (absent in nature);
- from the nutritional point of view to substances that are a source of energy and substances that have no nutritional value;
- medically contraindicated substances in diabetics (people with *diabetes mellitus*) and substances that do not increase blood

glucose levels; also recognised are cariogenic (causing tooth decay) and non-cariogenic sweet substances.

The relative sweetness of some non-sugar sweet natural, modified natural and synthetic compounds and other aspects of sweet substances, which include food additives (sweeteners), are described in Section 11.3.2.

8.3.1.2 Physiology, nutrition and use

Sucrose has major significance as a natural sweet substance, as do starch syrups (mixtures of D-glucose, maltose and maltooligosaccharides), D-glucose, invert sugar (equimolar mixture of D-glucose and D-fructose), D-fructose and lactose. Sugar alcohols, D-glucitol (also known as D-sorbitol), D-mannitol and xylitol, have found widespread use as sweeteners for diabetics. Other sugars, sugar alcohols and non-sugar natural sweeteners are, with a few exceptions, primarily the subject of academic rather than industrial interest. All these sweet substances have some nutritional value, while alcoholic sugars are non-cariogenic or slightly cariogenic substances. Modified natural and synthetic sweet substances used as sweeteners have, with some exceptions, no nutritional value, and are also non-cariogenic.

8.3.2 Salty substances

Salty tastes are exhibited almost exclusively by some inorganic salts (especially halides, sulfates, phosphates, nitrates and carbonates of alkali metals, alkaline earth metals and ammonium salts). Salty tastes combined with other tastes are also shown by some salts of carboxylic acids (salts of formic, acetic, succinic, adipic, fumaric, lactic, tartaric and citric acids), amino acids (such as salts of glutamic acid and choline) and some oligopeptides.

8.3.2.1 Salty taste quality and intensity

The quality of salty taste varies in different substances depending on the type of compound, its concentration and the presence of other ingredients. In the case of inorganic salts, both types of ions, cations and anions, are involved in the salty taste perception. For example, sodium chloride (NaCl) and sodium sulfate (Na_2SO_4) differ in the intensity of salty taste (effect of anion), while sodium chloride (NaCl) and potassium chloride (KCl) do not have the same salty taste quality (the effect of cation). The intensity of the bitter taste usually increases with increased relative molecular weight (apparent diameters of the two ions) of salt. Only sodium chloride has a pure salty taste (the sum of the apparent diameters of the two ions is 0.556 nm), corresponding to the hydrated sodium cation in combination with the hydrated chloride anion released from the crystal lattice of NaCl. Other salty substances also exhibit more or less intense bitter taste or salty taste when combined with some other tastes, such as the metallic taste. For example, potassium bromide (KBr, 0.658 nm) tastes salty and bitter and potassium iodide (KI, 0.706 nm) is bitter as is magnesium chloride ($MgCl_2$, 0.850 nm). The character of salinity in many cases varies with salt concentration. Sodium chloride, which is considered the standard of salty taste, has a sweet taste at very low concentrations. Potassium chloride at low concentrations has a sweet taste that is enhanced with increasing concentration, while the intensity of the bitter taste also increases. At higher concentrations it tastes bitter and salty with a slightly sour taste.

The quality of the salty taste of foods depends on the ratio of sodium cations (Na^+) and chloride anions (Cl^-). Foods with natural levels of these ions, however, do not always taste salty, because both ions may be not present in the required stoichiometric ratio. The quality of salty taste of a mixture of salty substances depends on their type and mutual ratio, which is employed to compose the salt substitutes used in various diets. The intensity of the salty taste depends on the concentration of salty substances and the presence of other components in the mixture. The salinity of various salts is an additive property, but some mixtures exhibit synergism, which means that the intensity of a mixture of salty compounds is higher than the sum of salty tastes of its components. The threshold concentrations of the most common salty substances are listed in Table 8.39.

In practice, the most important salty compound is sodium chloride, which occurs in lower or higher quantities in virtually all foods as a natural constituent or an intentionally added additive. The content of NaCl in selected foods is given in Table 8.40. According to the sodium content (salt contains 38.4% sodium), which roughly corresponds to the NaCl content, foods can be divided into four categories:

- foods with very low Na content (usually containing a thousandth of a gram, but less than 0.4 g of sodium per 1 kg food), such as fruits, fresh vegetables, most fats, sugar, confectionery and some dairy products;
- foods with low Na content (0.4–1.2 g/kg), such as fresh meat, fish, poultry, milk and dairy products (except hard and processed cheeses) and some edible fats;
- foods with high Na content (1.2–4.0 g/kg), examples are some types of bread and pickles;
- foods with very high Na content (more than 4.0 g/kg), such as smoked meat products, hard and processed cheeses, some bakery

Table 8.39 Detection threshold concentrations of selected salty inorganic salts.

Salt		Threshold concentration (mg/l)
Sodium chloride	NaCl	160–240, 584, 296–839,[a] 1750
Potassium chloride	KCl	1267, 345–1270[b]
Ammonium chloride	NH_4Cl	214
Magnesium chloride	$MgCl_2$	1430

[a] In men, higher by about 50% compared with women.
[b] In men, higher by about 40% compared with women.

Table 8.40 Sodium chloride content in edible portions of selected foods.

Food	NaCl (g/kg)	Food	NaCl (g/kg)
Meat (beef, pork, poultry)	1.82–2.02	Rice	0.15
Meat products	12–50	Lens	0.15
Fish	0.98–5.50	Fresh fruits	0.04–0.08
Milk	0.88–2.25	Fresh vegetables	0.05–1.55
Dairy products	0.83–80	Canned vegetables	5.0–24.5
Butter	1.30	Potato	0.48
Eggs	1.50	Beer	0.13
Flour	0.050	Wine	0.05–0.08
Bread and pastries	0.55–10.4	Nuts	0.05–0.75

products, dried soups, olives and vegetables in brine, salty snacks and similar products.

Poultry products usually have a lower NaCl content than pork meat products; the highest content of NaCl is found in uncooked and raw smoked meat, dry or hard salami, some cheeses and fish. For example, the dry pork salami NaCl content may be 58 g/kg and beef jerky contains 50 g/kg NaCl. Salted fish contain an extremely high salt content (dry and salted cod contains 180 g/kg Na) so before eating it is necessary to remove NaCl by digesting in water. With regard to dairy products, the highest content of NaCl is found in cheeses (parmesan 40 g/kg, blue cheese 36 g/kg, feta 28 g/kg, camembert 21 g/kg and cheddar 16 g/kg). Egg white and yolk contain NaCl as a natural component at levels of 0.25 and 12.5 g/kg, respectively. Examples of fruit products with extremely high salt content are olives pickled in salty brine. Fermented olives have an NaCl content of 60–90 g/kg, black unfermented olives only 10–30 g/kg. Various paste type soup products have even higher sodium chloride content, such as broths (about 650 g/kg), soy sauces (about 180 g/kg) and acid protein hydrolysates used as soup seasonings (200 g/kg).

Sodium added to food is not always in the form of NaCl. Common food additives, such as baking soda, some preservatives and monosodium glutamate also contribute to the total amount of sodium we consume (see Section 6.3.1).

8.3.2.2 Physiology and nutrition

Salty substances exhibit a variety of pharmacological effects, whose character depends on the type of cation and anion. Some substances are toxic at higher concentrations. The compound consumed in the largest amount is sodium chloride. The daily intake of salt in developed countries is estimated at 8–15 g. Sodium chloride supports the perception of taste of foods at the required intensity and fullness, stimulates not only receptors for salty taste, but significantly increases the perception of the sweet taste of sucrose and some other sweet substances, as well as sour taste perception, and suppresses the sensation of metallic taste and some other off-tastes, feel of diluted (watery) taste, optimises the resulting taste sensation and promotes balance between various basic tastes.

Sodium chloride is essential for the human body. Excessive intake of NaCl, however, causes fluid retention, swelling, burdens the kidneys, heart and blood circulation, and contributes to the emergence of hypertension. In industrialised countries, the consumption of NaCl in the majority of the population is excessive. It is recommended that it should be reduced below 10 g per person per day (see Section 6.3.1). Some diseases (hypertension, renal insufficiency and oedema) need a diet with a limited supply of salt or a completely salt-free diet. In these cases, the palatability of food is achieved by recipe modification, especially by the addition of spices or salt substitutes, in which the Na^+ cation is replaced by other cations, especially by the K^+ cation.

8.3.2.3 Use

Sodium chloride is added to food for the following reasons:

- to achieve the desired organoleptic properties of food products and dishes;
- to improve the processing conditions (e.g. salt in the manufacture of bread strengthens gluten in the dough and thus contributes to the stability of dough during mechanical processing, in the manufacture of processed cheeses NaCl, which is part of the cheese-melting salts, displaces calcium from milk proteins, in the meat industry NaCl increases the meat binding capacity, in sausages it increases protein solubility and emulsification of coagulated proteins with fat and water to the desired structure);
- to achieve conservation, which lies in the ability of NaCl to reduce water activity below the level required by the growth of undesirable microorganisms, which is known as the bacteriostatic effect;
- to control desirable fermentation processes by suppression of growth of undesirable microflora (e.g. during dough rising,

cheese ripening, lactic acid fermentation of olives, cucumbers and cabbage).

Other saline substances have found application almost exclusively in salt substitutes, which are used in diets with reduced salt content (low sodium diets) for patients who have to radically reduce sodium intake. A salt-free diet is suitable in cases of failure of the excretion of sodium ions and water retention in the body, which results in massive swelling, especially of the feet (occurring during certain heart and kidney diseases or during pregnancy). The main salt substitute is potassium chloride, the properties of which are similar to sodium chloride properties. This suits quite well in terms of technological and preservative properties, but less so in terms of taste, because it has a strong bitter taste in addition to its salty taste. Potassium chloride is therefore used in mixtures with other salty compounds to correct its taste. The cations Mg^{2+}, Ca^{2+} and $NH_4{}^+$ are also used in salt substitutes in various combinations with inorganic and organic anions (chlorides, sulfates, phosphates, citrates, succinates, lactates, acetates and formates). Some dipeptides also have a salty taste (see Section 2.3.3.2) and monosodium glutamate is often used as a salty taste enhancer. Compounds used as substitutes for table salt are often very complex and are subject to a number of patents.

8.3.3 Sour substances

The acidity of food is related to the amount of undissociated and dissociated forms of carboxylic acids and oxonium ions, respectively, that are present. The major substances that give a sour taste in foods are undissociated hydroxycarboxylic acids, citric and malic acids. Often, however, other carboxylic acids occur, such as ascorbic acid in most types of fruits, tartaric acid in grapes, isocitric acid in blackberries, oxalic acid in rhubarb, lactic acid in some dairy products (such as yoghurt), fermented cucumbers, cabbage, olives, vinegar and propionic acid in Emmental type cheeses (see Section 8.2.6). The acidity of cola drinks is provided by phosphoric acid, sometimes accompanied by citric or other acids. Carboxylic acids also act as bacteriostatic agents and affect a number of biochemical and chemical reactions.

8.3.3.1 Sour taste quality and intensity

Individual acids differ in the nature of their sour taste, and often in the quality. Threshold concentrations of sour taste perception of different acids also differ to a certain extent. They vary over a rather wide range depending on a number of subjective and objective factors, such as sensory analysis methodology, quality of respondents, quality of water and its pH (Table 8.41).

Less important for the perception of sour taste are hydrogen ions (H^+), and correspondingly oxonium cations (H_3O^+) resulting from the dissociation of acids:

$$R\text{–}COOH + H_2O \rightarrow R\text{–}COO^- + H_3O^+$$

The number of oxonium ions, related to pH of the biological systems, is an important criterion as it affects the redox potential of the system, ongoing enzymatic and chemical reactions, growth of microorganisms and likewise the odour, taste and colour of foods. The pH value depends on the concentration of the acids, their dissociation constants and the degree of neutralisation of the acids by basic components. For various reasons (microbiological, technological and others), it is useful to divide foods into:

- very acidic (pH is <4.0)
- less acidic (pH ranges from 4.0 to 6.5)
- non-acidic (pH > 6.5).

Table 8.41 Detection thresholds of selected acids in water according to various workers.

Acid	Detection threshold (mg/l)	Acid	Detection threshold (mg/l)
Acetic	19.9,[a] 54.1,[b] 110, 175[c]	Succinic	556
Lactic	15.1,[a] 133,[b] 200	Malic	110
Pyruvic	22.6,[a] 47.2[b]	Tartaric	80
Oxalic	18.6[a]	Citric	26.4,[a] 100–130, 150, 350[b]

[a]In water, pH 4.3.
[b]In water, pH 6–7.
[c]In beer.

Fruit is, with few exceptions, always very acidic and the maximum acid levels in fruits occur in the period before full maturity. The pH of fruit juices is generally lower than 4.0, but in over-ripe pears, cherries and peaches may increase up to pH 4.5 and in over-ripe elderberries may even reach a value of 4.7. The level of acids in the fruit depends on the type, and is usually 10–30 g/kg, a lower amount of acids (about 1 g/kg) is found in pears, while citrus fruits contain higher amounts of acids (about 80 g/kg). A sour taste is often modified by the presence of carbohydrates, tannins, ethanol or various cations and other substances. Carbohydrates weaken the sour taste of acids and tannins, and alcohol, on the contrary, emphasises their taste.

Fresh vegetables are, in comparison with fruits, relatively poor in acids. The pH values of common vegetables vary, usually from 5.0 to 6.6. An exception is rhubarb, where the pH is around 3.2; tomatoes are also quite acidic with a pH of about 4.3. The content of acids in fresh vegetables usually ranges between 2 and 4 g/kg.

Meat and other animal products are even less acidic (pH = 6.6–7.2) than fresh vegetables. Immediately after slaughter, glycogen in muscles is broken down and the acidity of meat increases somewhat due to a temporary increase in lactic acid content (pH of about 5.8, see Section 2.4.5.1.5), but never reaches the acidity of very acidic food (pH < 4.0).

Fresh milk is a non-acid food (pH varies in the narrow range of from 6.50 to 6.75), while the pH of yoghurt and other fermented dairy products ranges from 4.0 to 4.2. The pH value of a typical hard cheeses is about 5.1.

Chicken egg white is completely non-acidic, but during storage the pH increases from the original value of 7.5 in fresh eggs up to 9.0 or higher. Egg yolk is more acidic, as its pH is around 6.2.

8.3.3.2 Physiology, nutrition and use

Organic acids, hydrogen salts, some mineral acids or hydroxy-carboxylic acid lactones have found use as acidifying agents and acidulants for modifying pH, but they are also used for other purposes (such as antimicrobial agents). Addition of some salts or alkaline agents, on the contrary, reduces the acidity of certain foods (such as acidity of cocoa beans during roasting). The use and medical evaluation of these compounds is described in Section 11.2.4.

8.3.4 Umami and kokumi tastes

The term umami is relatively new in the West, but it is not new to the Japanese, who have used this term since the early 1900s to describe the delicious, full-bodied, savoury or meaty taste bringing a sense of satisfaction and increased viscosity in the mouth, which is translated from Japanese as savoury or yummy. Being able to distinguish the umami taste takes some practice, because it is not as obvious as other tastes, such as sweet or bitter. Umami taste is caused mainly by glutamic acid and its corresponding salt, sodium hydrogen glutamate, which is the predominant form of glutamic acid at pH values ranging from 4.3 to 9.5. The taste intensity of glutamate is quite strong. The detection threshold is 120–170 mg/l with a recognition threshold of 300 mg/l. The word corresponding to umami in Chinese is *xian wei*.

Umami, spicy and meaty tastes are also found in a number of other substances, for example in glycoconjugates of glutamic acid produced in the Maillard reaction, such as *N*-glycoside, *N*-(D-glucose-1-yl)-L-glutamic acid, and the corresponding Amadori compound, *N*-(1-deoxy-D-fructose-1-yl)-L-glutamic acid. Umami taste is also shown by peptides such as Glu-Glu-Leu and lactoyl-Glu, which have been detected in Parmesan cheese, β-alanyl dipeptides found in bouillons (see Section 2.3.3.1.3), *N*-(1-carboxyethyl)-6-hydroxymethylpyridinium-3-ol inner salt (alapyridaine), identified in heated sugar/amino acid mixtures and in beef bouillon, morelid, a malic acid glucopyranoside from morel mushroom and (*R*)-2-(carboxymethylamino)propanoic acid, known as (*R*)-strombine, isolated from dried scallops (**8-217**). Some other amino acids and peptides also show umami taste, but have not found practical applications. An example is ibotenic acid (naturally occurring in fly agaric *Amanita muscaria* and panther cap *A. pantherina*, Amanitaceae) that has umami taste 5–30 times more intense than glutamate. Anomers of (*S*)-malic acid 1-*O*-D-glucopyranoside known as (*S*)-morelid (**8-217**) contribute to the umami taste of morel mushrooms (*Morchella deliciosa*, Morchellaceae). Threshold concentrations for the umami-like, slightly sour taste of morelid is 1.9 g/l.

In the past, sodium hydrogen glutamate was linked with the so-called Chinese restaurant syndrome, which is manifested by fairly typical and unspecific sensations, such as headache, flushing, sweating, facial pressure or tightness, numbness, tingling or burning in the face, neck and other areas, chest pain and nausea. Latterly, sodium hydrogen glutamate has been classified as a food ingredient that is generally recognised as safe, but its use as a flavour enhancer remains controversial. For this reason, when this compound is added to foods, legislation requires that it be listed on the label.

Kokumi (different from umami) is another food attribute identified by the Japanese. It is sometimes translated as heartiness or mouthfulness and describes compounds in food that do not have their own flavour or have a distinct flavour, but enhance the flavours with which they are combined by triggering calcium receptors in the tongue. In foods system, there are three types of flavour sensations attributed to kokumi:

- mouthfulness and continuity (long lasting taste development)
- punch (initial taste and impact)
- mildness (roundness and balance).

Kokumi compounds supposedly include calcium, protamines (found, for example, in fish sperm), histidine, glutathione and other peptides, such as γ-glutamyl peptides or the peptides of mature Gouda cheese. Another example of a mouthfulness (kokumi) enhancing molecule is the bitter hydrophobic compound in thermally processed avocado fruits, (12*Z*,15*Z*)-1-acetoxy-2-hydroxy-4-oxoheneicosa-12,15-diene (see **8-225**, later).

A special group of taste-active compounds are umami and kokumi enhancers used as food additives. Examples of these substances are 5′-nucleotides, such as inosine 5′-monophosphate (5′-IMP, inosinic acid disodium salt) and guanosine 5′-monophosphate (5′-GMP), which is about twice as active in enhancement of the umami taste of glutamate solutions, while xanthosine 5′-monophosphate (5′-XMP) and adenosine 5′-monophosphate (5′-AMP) are less active, showing only about 0.5 and 0.1 times the impact of 5′-IMP (see Section 11.3.5). Umami enhancing molecules are also particular derivatives of 5′-nucleotides arising in the Maillard reaction of 5′-GMP. An example is lactamide N^2-lactoylguanosine 5′-monophosphate found in dried bonito. It is formed in the reaction of 5′-GMP with lactic acid. Another example is (*R*)- and (*S*)-N^2-(1-carboxyethyl)guanosine 5′-monophosphate (**8-217**), which was isolated from yeast extract. It is formed from 5′-GMP and dihydroxyacetone (glyceraldehyde). Active molecules also include many other Maillard reaction products of 5′-GMP and various synthetic derivatives of 5′-nucleotides.

Another group of taste enhancers arises from bitter tasting creatinine and reducing hexoses in the Maillard reaction. The identified compounds include, *N*-(1-methyl-4-oxoimidazolidin-2-ylidene)aminoacetic acid derived from glycine, *N*-(1-methyl-4-oxoimidazolidin-2-ylidene)aminopropionic acid derived from alanine and *N*-(1-methyl-4-oxoimidazolidin-2-ylidene)amino-4,5,6-trihydroxyhexanoic acid (**8-217**) derived from glucometasaccharinic acids, such as 3-deoxy-D-gluconic acid (Figure 4.48). At sub-threshold concentrations these substances and also some other synthesised *N*-(1-methyl-4-oxoimidazolidin-2-ylidene)-α-amino acids enhanced the typical thick-sour and mouth-drying sensation and the mouthfulness imparted by stewed beef juice.

8.3.5 Bitter substances

Bitter substances of foods are usually classified according to the origin into compounds that:

- are characteristic natural components of certain foods and their occurrence is genetically determined;
- are formed during processing and storage of foods by chemical reactions or activities of their own enzyme systems;
- result from contamination by certain organisms growing on food materials;
- have been intentionally added to food as additives.

A number of organic compounds commonly present in foods have a bitter taste, such as certain fatty acids, amino acids, peptides, amines, amides, ketones, nitrogen-containing heterocyclic compounds (including alkaloids) and many other compounds. Their bitter taste in food is usually seen at higher concentrations. Certain inorganic salts are also bitter.

A bitter taste is desirable for some foods, where it is a typical taste. Examples include grapefruits, chicory leaves, cocoa, coffee, beer and tonic drinks. However, sometimes a bitter taste is considered undesirable (off-flavour) and the affected foods can have an unacceptable taste and can be even inedible (such as oranges, carrots

Table 8.42 Detection threshold concentrations of selected bitter compounds according to various workers.

Compound type	Bitter compound	Detection threshold (mmol/l)	Compound type	Bitter compound	Detection threshold (mmol/l)
Inorganic salts	Magnesium sulfate	5	Cucurbitacins	Cucurbitacin C	0.000 2
Amides	Propionamide	52	Floroglucinols	Isohumulone	0.02
	Propylamine	20	Flavonoids	(+)-Catechin	2
	Butylamine	6		Naringin	0.2 (0.04)
	Diethylamine	3		Procyanidin B_3	0.07
Amino acids	L-Tryptofane	4	*N*-Heterocycles	Pyridine	2
	L-Leucine	15		Pyrazine	13
Fatty acids	Oleic acid	9–12		Methylpyrazine	7
	Elaidic acid	22		Acetylpyrazine	1
	Linoleic acid	4–6		Imidazole	6
	α-Linolenic acid	0,6–1,2	Limonoids	Limonin	0.08 (0.003)
	γ-Linolenic acid	3–6	Phloroglucinols	Iso-α-acids	0.02
	Arachidonic acid	6–8		Tetrahydroiso-α-acids	0.007
Alkaloids	Quinine	0.03 (0.025, 0.01, 0.008)	Quassinoids	Quassin	0.0002
	Caffeine	2 (0.7, 0.02)	Secoiridoids	Amarogentin	0.000 03

and cottage cheese). Bitterness is related to the hydrophobicity of the molecules of the bitter compound, the size of the non-polar part of the molecule, its configuration and also the presence of at least one polar functional group is required. Data have been obtained for the results of sensory analysis under defined conditions, often referred to the bitter taste standard, which is usually quinine, or caffeine (which is about 60 times less bitter than quinine). Compounds with the threshold concentrations lower than 0.1 mol/l are generally considered to be very bitter. Table 8.42 gives some examples of threshold concentrations of selected bitter substances.

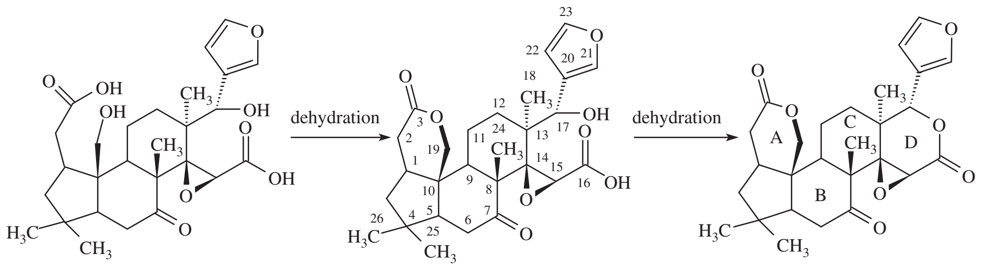
8.3.5.1 Bitter substances naturally present and formed during food processing and storage

8.3.5.1.1 Fruits

The typical natural bitter taste of certain citrus fruits and juices is caused by the presence of flavanone-7-glycosides, which have as a sugar component disaccharide neohesperidose and are therefore known as **neohesperidosides**. Aglycones are not bitter. The bitter component of grapefruits is naringin (naringenin-7-*O*-neohesperidoside). Some bitter odour-active compounds also contribute to the bitter taste of grapefruits, such as the sesquiterpenic ketone nootkatone and other bitter substances. The bitter constituent of bitter oranges also known as bigarade oranges (*Citrus aurantium* subsp. *amara*) is neohesperidine (hesperetin-7-*O*-neohesperidoside).

A bitter taste also often occurs in otherwise sweet oranges during juice processing and storage, due to the presence of metabolically altered (degraded), triterpenoids (tetranortriterpenoids) that are known as **limonoids**. The basic structure consists of four six-membered rings and one furan ring. These secondary metabolites occur as aglycones, glucosides or A-ring lactones. More than 300 limonoids are known, which are found in the rue (citrus) family Rutaceae, to which oranges also belong, in the mahogany family Meliaceae, in the family *Cneoraceae* and in plants of the genus *Harrisonia* of the family Simaroubaceae.

The most abundant aglycone and glucoside for most citrus species are limonin and limonin 17β-D-glucopyranoside with the sugar moiety bound to the C-17 hydroxyl group (the aglycone is called limonoic acid lactone or limonate A-ring lactone) and are biosynthesised by transformation (oxidation, isomerisation, rearrangement and elimination of four carbon atoms of the side chain) of 4,4-dimethylsterol (known as euphol) via butyrospermol and other metabolites, such as non-bitter limonoic acid and its lactone (ring A). The biosynthesis takes place in the leaves and limonoids are then transported to the fruits and seeds in particular. Limonin glucoside is stable in neutral media, but hydrolysis of the sugar moiety in acidic juices under the action of β-glucosidase and dehydration (to form another δ-lactone in ring D) yields intensely bitter limonin (Figure 8.90) and its epimer, which is formed through the inversion of the C-17 substituent. The formation of limonin is accelerated by juice pasteurisation. The bitter taste is reflected at a limonin content higher than 6 mg/l. Limonin can also be found in lemons and grapefruits.



limonoic acid — limonoic acid lactone — limonin

Figure 8.90 Formation of limonin from non-bitter precursor.

Several dozen limonin-related compounds (**8-218**) have been found in citrus fruits. All citrus limonoids contain a furan ring attached to ring D at C-17 and oxygen-containing functional groups in positions C-3, C-4, C-7, C-16 and C-17 and C-14,15 of the epoxy ring. In addition to limonin, only three other limonoids, namely nomilin, ichangin and nomilinoic acid, are bitter compounds. Analogously to limonin, nomilin, nomilinoic acid and other limonin-related compounds occur in citrus fruits as aglycones and 17β-D-glucopyranosides. Of these compounds, only nomilin (which is about twice as bitter as limonin, but occurs in smaller quantities) may be involved in the bitter taste in citrus juices, together with limonin. Limonoids are also reported to possess multiple health promoting properties.

Olives, fruits of the olive tree (*Olea europea*) of the family (Oleaceae), have a markedly bitter taste, because they contain unusual **secoiridoids** (see Section 9.10), and their corresponding β-D-glucosides, known as **oleosides**, which protect the fruit against attack by microorganisms and insects. Small green olives contain the oleoside 11-methyl ester (elenolic acid β-D-glucoside formed by biosynthesis from 7-deoxyloganic acid, **8-219**), hydrolysis of which gives rise to the oleoside demethylelenolic acid β-D-glucoside (**8-220**). Elenolic acid β-D-glucoside is a precursor of ligstroside (**8-221**), which is an ester of tyrosol. A related compound, tyrosol ester oleocanthal (**8-222**), is found in extra virgin olive oil, where it is responsible for its slightly tangy, peppery bite in the back of the throat. Concentrations of oleacanthal, which shows anti-inflamatory properties, in extra virgin olive oils range from 22 to 190 mg/kg. None of the above compounds are bitter, however during fruit growth and maturation, ligstroside is oxidised (hydroxylated) to bitter oleuropein (**8-223**), a compound derived from 3,4-dihydroxyphenylethanol (3-hydroxytyrosol or hydroxytyrosol) and in olives that reach normal size, ligstroside does not occur. Oleuropein is found in green and yellow fruits, where its concentration can reach up to 140 mg/kg dry matter. Its content decreases during fruit ripening and is almost zero in the fully

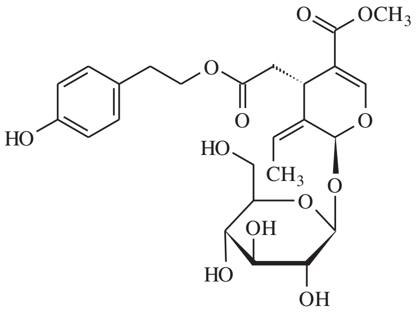
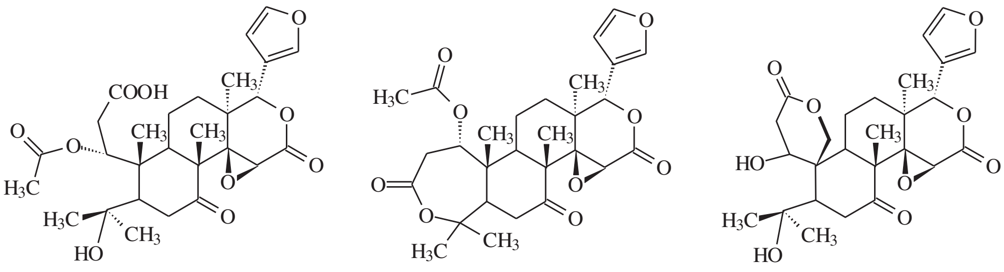
8-220, oleoside

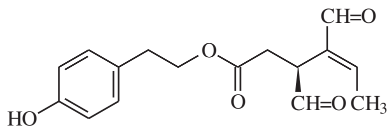


8-221, ligstroside



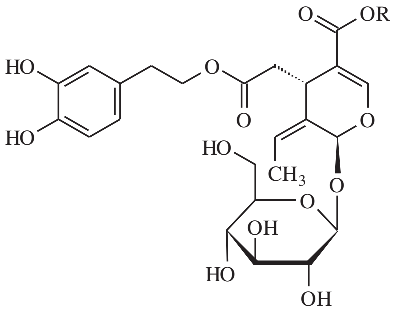
nomilinoic acid — nomilin — ichangin

8-218, minor bitter limonoids of oranges



8-222, oleocanthal

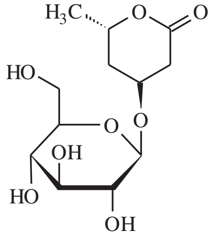
mature blue fruits. Ripe fruits contain only demethyleuropein (**8-223**) formed by hydrolysis of oleuropein. Hydrolysis by esterase yields hydroxytyrosol and elenolic acid β-D-glucoside, which is then hydrolysed by β-glucosidase to elenolic acid and glucose. Hydrolysis of oleuropein by β-glucosidase yields glucose and the corresponding aglycone that is hydrolysed by esterase to 3-hydroxytyrosol and elenolic acid. Small green olives also contain ligstroside, which is a derivative of tyrosol and elenolic acid methyl ester. Tyrosol and hydroxytyrosol also contribute to the bitter taste of olives. Hydroxytyrosol is present in olives likewise as 4-β-D-glucopyranoside. Its amount increases with olive ripeness.



8-223, oleuropein, R = CH_3
demethyloleuropein, R = H

Debittering of immature green olives is done either by lactic acid fermentation or hydrolysis of bitter glycosides by dipping in solutions of sodium hydroxide. Bitter oleuropein is hydrolysed in alkaline media to glucose and the corresponding aglycone, which yields 3-hydroxytyrosol (3,4-dihydroxyphenylethanol), methanol and demethylelenolic acid.

The bitter taste sometimes occurring in stewed sour cherries, plums and other stone fruits of the Rosaceae family is caused by the presence of cyanogenic glycosides, especially prunasin (see Section 10.3.2.3.1). Rowan berries, the fruit of rowan (*Sorbus aucuparia*), which are used to make jam or jelly with a distinctive bitter taste, contain 3-hydroxy-5-hexanolide β-D-glucoside (**8-224**). Enzymatic



8-224, (3*S*,5*S*)-3-(β-D-glucopyranosyloxy)hexano-5-lactone

hydrolysis of this glycoside and dehydration of aglycone yields parasorbic acid, ring opening and further dehydration of parasorbic acid produces sorbic acid. Some selected rowan cultivars have less bitter or non-bitter fruits.

Raw avocado (*Persea americana*, Lauraceae) contains only trace levels of bitter compounds, but heat treatment (canning and preserving fruit) or air-drying induce the development of an unpleasant bitter after-taste. The substances responsible for the bitter taste are mainly various saturated and unsaturated C_{17}–C_{21} fatty acid derivatives with 1,2,4-trihydroxy- (triols), 1-acetoxy-2,4-dihydroxy- (acetates of triols) and 1-acetoxy-2-hydroxy-4-oxo groups (acetates of oxodiols). The most bitter compound is (12*Z*,15*Z*)-1-acetoxy-2-hydroxy-4-oxoheneicosa-12,15-diene, closely followed by other structurally related compounds. Examples of these molecules are given in formulae **8-225**. Natural constituents of avocado fruits of analogous structures are acetates of long-chain unsaturated fatty acids (see Section 3.3.3.2) and furans with long-chain saturated and unsaturated substituents (see Section 8.2.11.1.1).

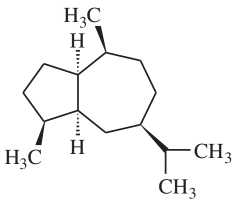
8-225, bitter compounds in avocado

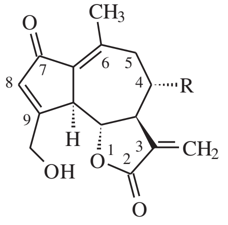
8.3.5.1.2 Vegetables

A number of vegetables from the family Asteraceae have a bitter taste, such as endive (*Cichorium endivia*), the aerial part (leaf rosette) of which is eaten as a salad. Lettuce (*Lactuca sativa*) sometimes has a bitter taste, particularly the stalk and the white milky juice. Chicory (*C. intybus* var. *foliosum*) is slightly bitter, and is cultivated for salad leaves called chicons (etiolated buds) growing from the root vertex in the dark. Roasted chicory root (*C. i.* var. *sativum*) is used in the manufacture of coffee surrogates. Bitter substances of these vegetables are primarily sesquiterpenic

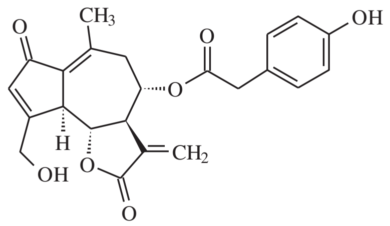
lactones derived from sesquiterpenic hydrocarbon guaiane, known under the systematic name of (1*S*,3a*S*,4*S*,7*R*,8a*S*)-7-isopropyl-1,4-dimethyldecahydroazulene (**8-226**). The main compound is lactucin (**8-227**), whose biosynthesis is based on sesquiterpenic hydrocarbon (+)-germacrene A. The highest concentration of bitter substances is present in the central axis of chicory buds that contain about 100–250 mg/kg, of which approximately 50% is lactucin, 30% 4-deoxylactucin (**8-227**) and 5% lactucopicrin (**8-228**). Their 11,13-dihydro derivatives are present in small amounts. The bitter taste of chicory buds also comes from coumarins and their glycosides (see Section 10.3.2.5.2), especially scopoletin, umbelliferone, aesculin (aesculetin 6-*O*-β-D-glucoside) and cichoriin (aesculetin 7-*O*-β-D-glucoside). The main bitter substance of the leaves of the artichoke thistle, known as cardoon (*Cynara cardunculus*), and of cultured varieties of globe artichoke (*C. c.* var. *scolymus*) of the same plant family, is cynaropicrin (**8-229**), which is also derived from guaiane. Cynaropicrin represents 60–80% of bitter substances of these plants. It is about twice as bitter as quinine and is sometimes used as a bittering substance in citrus drinks.



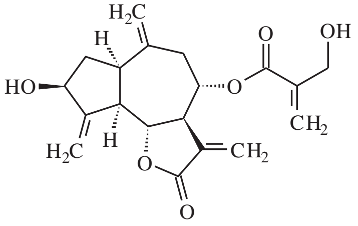
8-226, guaiane



8-227, lactucin, R = OH
4-deoxylactucin, R = H



8-228, lactucopicrin



8-229, cynaropicrin

Vegetables of the cucurbit family (Cucurbitaceae), which includes squashes, melons, pumpkins, cucumbers and gourds of the genera *Benincasa*, *Citrullus*, *Cucumic*, *Cucurbita*, *Lagenaria* and *Luffa*, occasionally show bitter taste in response to various stress factors. The bearers of bitter taste are tetracyclic triterpenoids, called **cucurbitacins**, which are derived from the triterpenic hydrocarbon 5α-cucurbitane (**8-230**). Cucurbitacins are found in vegetables in levels of <0.01% as free compounds (aglycones) or as glycosides. Identified in the Cucurbitaceae family are cucurbitacins A–L (**8-231** to **8-238**), the most common of which are cucurbitacins C and D. The main bitter substance of cucumber is cucurbitacin C, pumpkins contain cucurbitacins E and B, sometimes cucurbitacins D and I, and cucurbitacin E is found in water melons. Cucumber seeds contain cucurbitacins A–I (**8-231** to **8-234**). Cucurbitacins and their glycosides are also found in plants belonging to several other families, such as Brassicaceae, Begoniaceae, Scrophulariaceae Primulaceae and Rosaceae. Their insecticidal, anti-tumour and anti-inflammatory effects are currently being studied. For example, under normal conditions cucumbers contain cucurbitacins throughout the plant (in the stem, leaves, cotyledonary leaves), but not in fruits. Various stress factors, such as significant difference between night and day temperatures, water logging or over-drying, however, manifest themselves with bitter fruits. The threshold levels of the main cucurbitacin C is about 1000 times lower than that of caffeine,

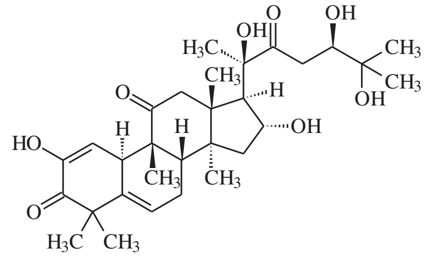
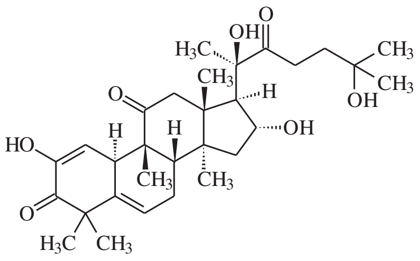
8-236, cucurbitacin J



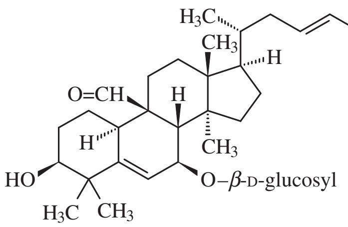
8-237, cucurbitacin K



8-238, cucurbitacin L

about 0.1 mg/l. The highest concentrations of cucurbitacin C in the bitter fruit of cucumbers are found in parts adjacent to the stem (up to 10 mg/kg) and just under the skin. Modern hybrid varieties of cucumbers do not synthesise cucurbitacins.

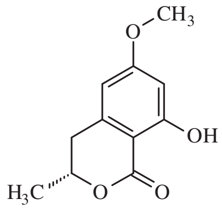
A special group of cucurbitacins are found in bitter melon, also known as bitter gourd or bitter squash (*Momordica charantia*, Cucurbitaceae), which belongs to the most bitter of the edible fruits. The bitter taste of bitter melon is caused by a number of cucurbitane-type triterpenic glycosides called momordicosides, such as momordicosides K and L (**8-239**). Bitter melon originated in India and is now widely cultivated in Asia and Africa. The plant also contains other biologically active compounds for which it is used to treat a number of diseases, such as toothache, diarrhea, furuncle and diabetes.



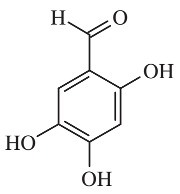
8-239, momordicoside K, R = CH_3
momordicoside L, R = OH

The main contributors to the bitter off-taste of carrots are bisacetylenic oxylipins (see Section 10.3.2.6.5). Infection of carrot roots (*Daucus carota*, Daucaceae) by fungi *Ceratocystis fimbriata*, *Chetomium globosum*, *Botrytis cinerea* and *Thielaviopsis basicola*, produces the bitter phytoalexin (*R*)-6-methoxymellein (8-hydroxy-6-methoxy-3-methyl-3,4-dihydroisocoumarin, **8-240**), which likewise has oestrogenic activity. In carrots marketed in Europe, the levels of 6-methoxymellein ranges from 0.02 to 76.00 mg/kg in fresh carrots and from 0.04 to 15.64 mg/kg in processed carrot products. Levels of 6-methoxymellein are reduced by 69 and 33% in blanched carrots processed by boiling in water or steam treatment, respectively. The recognition threshold concentration of 6-methoxymellein is 20 mg/l. The bitter component of carrot seeds is 2,4,5-trihydroxybenzaldehyde (**8-241**). The bitter taste of some vegetables of the genus *Brassica* (Brassicaceae), such as kohlrabi (*B. oleracea* var. *gongylodes*) and Brussels sprouts (*B. o.* var. *gemmifera*), which sometimes occurs in cooked vegetables, is caused by the presence of goitrin formed by non-enzymatic

decomposition of glucosinolate progoitrin. The bitter taste often occurs during storage of sliced onion (*Allium cepa*). Carriers are probably decomposition products of the lachrymatory factor (*Z*)-thiopropanal sulfoxide that arises from *S*-(prop-1-en-1-yl)cysteine sulfoxide (isoalliin).



8-240, 6-methoxymellein



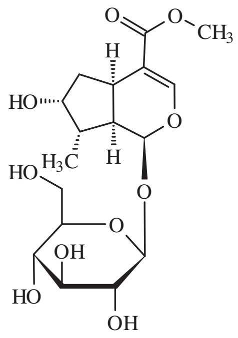
8-241, 2,4,5-trihydroxybenzaldehyde

8.3.5.1.3 Spices and other plant materials

A large number of bitter plants or plant parts (such as roots, rhizomes, bark, leaves, flowers and others) are used as drugs in folk and official medicine, for the manufacture of infusions, tinctures, bitter non-alcoholic and alcoholic beverages, or as a spice for seasoning food.

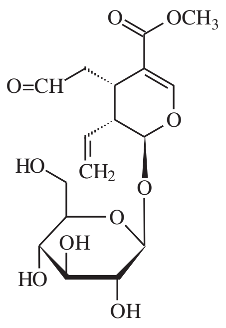
An important bitter substance used for making bitter drinks (such as tonic waters) is the alkaloid quinine, which is obtained from the bark of different species of the genus *Cinchona* (Rubiaceae), especially from the bark of *Cinchona officinalis* native to Amazon rainforest (see Section 10.3.3.1.5).

Many plants used for their bitter taste contain strongly bitter glycosides of **iridoids** (see Section 9.10), which are synthesised by plants as protection against invading microorganisms and grazing herbivores. Iridoids show a number of biological activities (such as cardiovascular, antihepatotoxic, hypoglycaemic, antiviral, anti-carcinogenic and immunomodulatory). For example, the root of *Menyanthes trifoliata* of the Manyanthaceae family contains the bitter iridoid glycoside loganin (**8-242**).



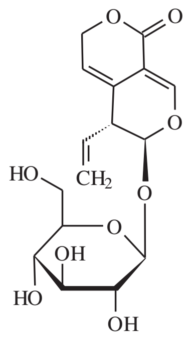
8-242, loganin

Secoiridoids arise from iridoids by cleavage of the cyclopentane ring and other transformations of fission products. Secoiridoid glycosides derived from glycoside of secologanin (**8-243**) occur in the root of yellow gentian (*Gentiana lutea*) and another bitter herb centaury (*Centaurium erythraea* and other plants of the same genus) and almost all plants of the Gentianaceae family.

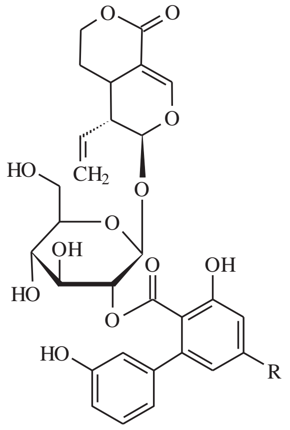


8-243, secologanin

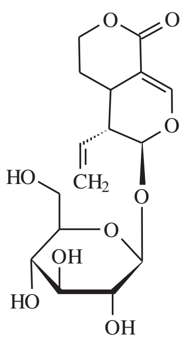
The root of yellow gentian contains several bitter compounds, primarily gentiopicrin (gentiopicroside, **8-244**), amarogentin (amarogentoside, **8-245**) and sweroside (**8-246**). Also present are additional related compounds, such as swertiamarin (swertiamaroside, **8-247**) and deoxyamarogentin (deoxyamarogentoside, **8-245**). Amarogentin is considered the most bitter substance occurring in nature, as its bitter taste is noticeable even at a dilution of 1 : 58 000 000 (which corresponds to a solution prepared by dissolving 17 μg of amarogentin in 1 l of water). The gentiopicrin content in fresh root is 1.5–3.5%, the content of amarogentin is only 0.05%, but due to its low threshold values amarogentin is a significant bitter substance. Swertiamarin is transformed into erythrocentaurin (5-formyl-3,4-dihydroisocoumarin, **8-248**)



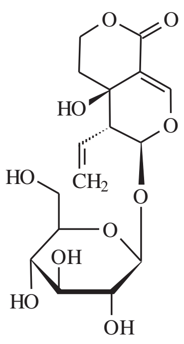
8-244, gentiopicrin



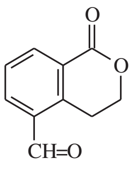
8-245, amarogentin, R = OH
deoxyamarogentin, R = H



9-246, sweroside



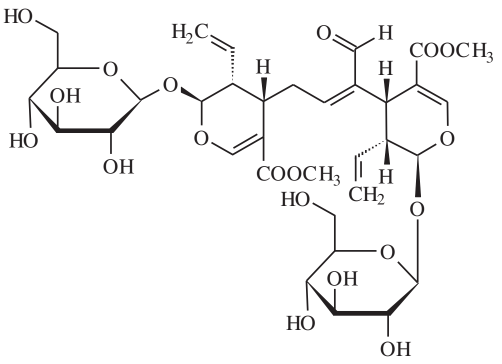
9-247, swertiamarin



8-248, erythrocentaurin

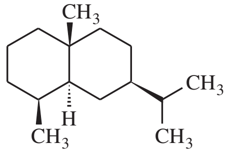
almost quantitatively during isolation of bitter substances in acidic media.

Bitter substances of centaury are similar to bitter substances of yellow gentian. The main component is usually gentiopicin (originally known under the name erytaurin), also present are swertiamarin and amarogentin and other minor bitter substances, such as dimeric centauroside (**8-249**). Some centaury species contain sweroside in almost the same amount as gentiopicrin.

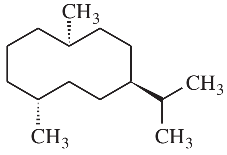


8-249, centauroside

Plants of the family Asteraceae, which are used as a spice and for the production of bitter liqueurs and vermouths (aromatised fortified wine flavoured with various botanicals), contain sesquiterpenic lactones derived from guaiane (**8-226**), eudesmane (**8-250**) and germacrane (**8-251**). Eudesmane (also known as selinene) has the systematic name (*1S*,4a*R*,7*R*,8a*S*)-7-isopropyl-1,4a-dimethyldecahydronaphthalene, germacrane is (1*R*,4*S*,7*S*)-4-isopropyl-1,7-dimethylcyclodecane.

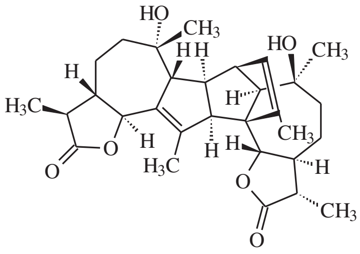


8-250, eudesmane

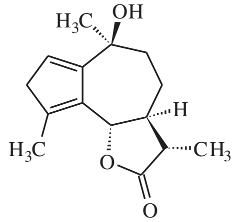


8-251, germacrane

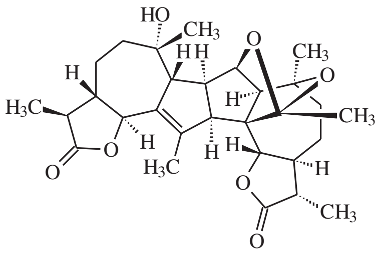
The main bitter component of wormwood (*Artemisia absinthium*) is a dimeric sesquiterpenic lactone absinthin (**8-252**), which is produced by intramolecular cycloaddition (Diels–Alder reaction) probably of two molecules of astabisin (**8-253**), which is derived from guaiane. In wormwood extracts, absinthin is transformed into isomeric anabsinthin (**8-254**). The bitter taste of mugwort (*A. vulgaris*) is derived primarily from the related compounds estafiatin (**8-255**) and balchanin (**8-256**), which are derived from eudesmane. Another bitter substance, which occurs in different plants of the genus *Artemisia*, for example, *A. absinthium*, *A. vulgaris*, *A. pontica* (Roman wormwood) and *A. maritima* (see wormwood) is santonin (**8-257**), which is also derived from eudesmane. It has toxic effects, and therefore safe maximum levels have



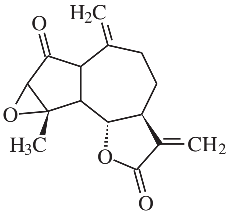
8-252, absinthin



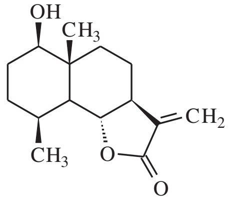
8-253, astabisin



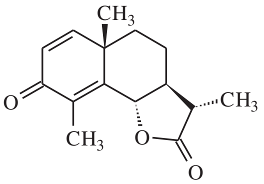
8-254, anabsinthin



8-255, estafiatin



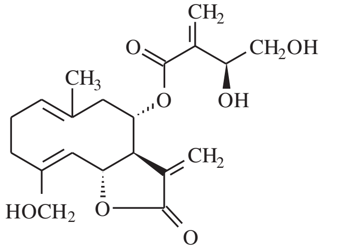
8-256, balchanin



8-257, santonin

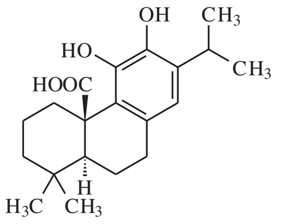
been set for its presence in alcoholic beverages and foods. Toxic components of wormwood essential oil and of some other essential oils are α- and β-thujones (see Section 8.2.13.2).

Another member of the family Asteraceae is St. Benedict's thistle, also known as the blessed or holy thistle (*Cnicus benedictus*), which contains bitter cnicin (**8-258**) derived from germacrane.

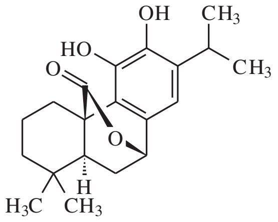


8-258, cnicin

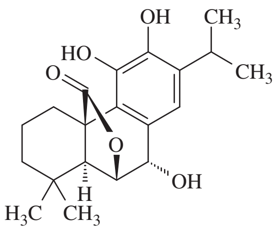
Common sage and rosemary (see Table 8.32), plants of the Lamiaceae family, contain the diterpenes carnosic acid, also known as rosmaricin (**8-259**), derived from *ent*-caurene, and bitter carnosol (picrosalvin, **8-260**), which are potent antioxidants. Carnosic acid is a major component of fresh rosemary tops (1–2%), but is unstable and is enzymatically transformed into carnosol. These two diterpenoids represent about 15% w/w of plants haulm extracts and exhibit about 90% of extract antioxidant activity. Other transformation products of carnosic acid are rosmanol (7α-hydroxy derivative, **8-261**), epirosmanol (7β-isomer, **8-262**) and similar compounds.



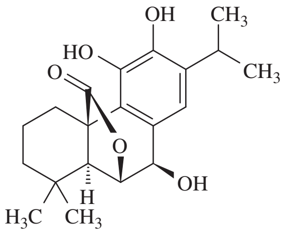
8-259, carnosic acid



8-260, carnosol



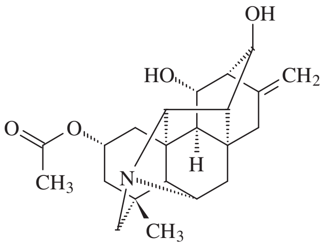
8-261, rosmanol



8-262, epirosmanol

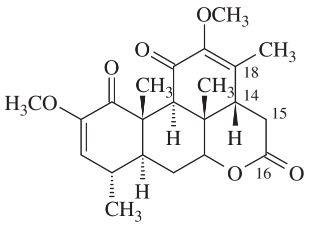
Sweet flag (calamus) rhizome (*Acorus calamus*, Araceae) essential oil contains as the main component toxic β-asaron (see Section 8.2.3.1.2). Other important calamus constituents are bitter alkaloids, of which the most important compound is a glycoside called acorin (**8-263**).

Typical bitter substances of shrubs of the family (Simaroubaceae) are degraded triterpenoids **decanortriterpenoids** related to



8-263, acorin aglycone

limonoids that are called **quassinoids**. The so-called bitter quassia wood from shrubs *Quassia amara*, native to tropical America, contains as the main bitter substance quassin (**8-264**), which is one of the bitterest natural substances. For toxicological reasons (negative effect on fertility of tested animals), flavourings and food ingredients with flavouring properties produced from the source material (and also from the West Indian tree *Picrasma excelsa* of the same family) may only be used for the production of beverages and baked products. Examples of other bitter substances of *Quassia amara* are neoquassin (with a reduced oxo group in position C-16), 14,15-dehydroquassin and 18-hydroxyquassin (with a methyl group in position C-18 replaced by a hydroxymethyl group).



8-264, quassin

The most precious and expensive spice in the world is saffron (dried stigmas of the saffron flower, *Crocus sativus*, Iridaceae), which is used for its bright orange–yellow colour and intense flavour. The bitter substance of saffron picrocrocin is the β-D-glucoside of (*R*)-4-hydroxy-2,6,6-trimethylcyclohex-1-ene-1-carbaldehyde, known as (*R*)-4-hydroxy-β-cyclocitral. Picrocrocin is produced by oxidative cleavage of the carotenoid pigment zeaxanthin by dioxygenase and glycosylation of (*R*)-4-hydroxy-β-cyclocitral (Figure 8.91). Fragments of carotenoids, such as (*R*)-4-hydroxy-β-cyclocitral are called apocarotenoids.

8.3.5.1.4 Other foods and drinks

Dairy products and protein hydrolysates

Precursors of bitter substances in milk and dairy product foods are quite often proteins and mineral salts. Bitter substances are some peptides produced by enzyme proteolysis (see Section 2.3.3.2.1). Bitterness is especially typical for certain dairy products such as cheeses, yoghurt and casein hydrolysates (see Section 2.3.3.2). For example, the bitterness of ripened Gouda cheese was found to be primarily induced by calcium ($CaCl_2$) and magnesium ($MgCl_2$)

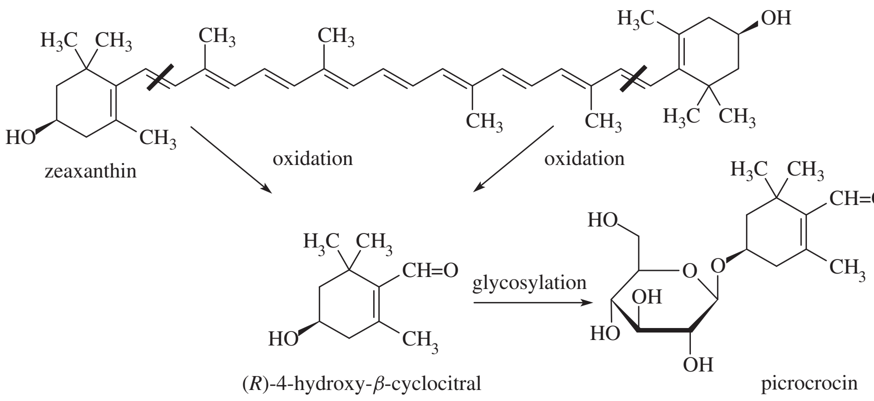


Figure 8.91 Formation of picrocrocin from zeaxanthin.

chlorides, as well as various bitter-tasting free amino acids, whereas bitter peptides were found to influence the bitterness quality rather than the bitter intensity of the cheese. Bitter substances are also formed during pyrolysis of proteins and in reactions of proteins with sugars (in the Maillard reaction).

Legumes and oilseeds

Carriers of bitter and astringent taste of the seeds of plants of the family Fabaceae, for example of certain varieties of pea (*Pisum sativum*) and peanuts (*Arachis hypogaea*) are saponins (see Section 10.3.2.2). The main saponin is sojasaponin B_b (also known as sojasaponin I). The content of saponins in sweet varieties typically ranges between 0.1 and 0.2%, but a higher content is perceived as bitter taste. The content of saponins in peanuts may range from 0.01 to 1.6%. The characteristic bitter and astringent tastes of soy flour (*Glycine max*) are mainly due to isoflavones and their glycosides (daidzein, genistin and glycitein-7-*O*-β-D-glucoside). Compounds responsible for the bitter taste may also be saponins, whose content can range from 0.2 to 5.6%.

The bitter taste of the extraction meal and flour from rapeseeds (*Brassica napus*, Brassicaceae) is caused by sinapine (present as sinapine chloride) and its components choline chloride and sinapic acid, which show about 80% of the sinapine bitterness. Goitrin may also act as a bitter substance as in some *Brassica* vegetables (e.g. in Brussels sprouts).

Hops and beer

Hops (*Humulus lupulus*, Cannabinaceae) are an ingredient with a critical impact on the bitter taste and characteristic odour of beer. Hops also form insoluble complexes with proteins and polypeptides, which contribute to the colloidal stability of beer, the stability of beer foam, and assure the bacteriological stability of beer. Hops are added to the wort, which is boiled for at least 1 hour. After cooling and removal of spent hops, yeast is added to the hopped wort to convert sugars into ethanol and carbon dioxide.

Hops accumulate bitter substances called **bitter acids** in the mature female inflorescences (cones). The level of bitter substances usually amounts to about 5–20% of the cones weight (water content is about 11%). The bitter acids in fresh hops are **phloroglucinols**, derivatives of 1,3,5-benzenetriol, containing a residue of carboxylic acid (acyl) and two to three 3-methylbut-2-en-1-yl (prenyl) side chains as substituents of the aromatic ring. They are therefore prenylated acylphloroglucinol derivatives and, according to the biochemical origin, they are ketides. The so-called hop resins (non-bitter and bitter compounds extractable from hops with diethyl ether and soluble in methanol) were originally divided into:

- soft resins (soluble in hexane), which included α-acids and β-acids;
- non-specific soft resins or resupones that are further divided into α-resupones and β-resupones;
- γ-hard resins (compounds insoluble in hexane) that included water-soluble δ-resins and water-insoluble ε-resins.

At present, the hop bitter acids (soft resins) are divided into two groups:

- humulone homologues called humulones, α-acids or α-bitter acids (with two prenyl substituents);
- lupulone homologues called lupulones, β-acids or β-bitter acids (with three prenyl substituents).

The basic humulone homologues (**8-265**) are cohumulone and adhumulone and minority components are prehumulone and posthumulone. Analogously, the main lupulone homologues (**8-266**) are colupulone, adlupulone, prelupulone and postlupulone. These acids are bitter only by name, but in fact they have an indifferent taste and are almost insoluble in water and have pronounced bacteriostatic activity. The approximate composition of these two groups of bitter acids in different hop varieties is shown in Table 8.43. Their content is about 25% of the dry weight of the hop cones.

Both types of hop bitter acids are very reactive compounds, in particular in the light. During the drying, storage and brewing of hops they isomerise (also in aqueous solutions), oxidise and

Table 8.43 α- and β-bitter acids contents in hops.

Compound	Content (% of α-bitter acids)	Compound	Content (% of β-bitter acids)

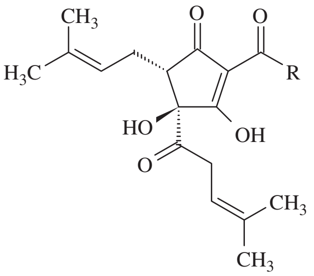
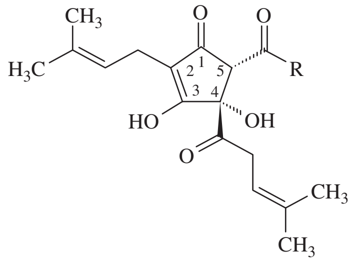
8-267, *cis*-isohumulones



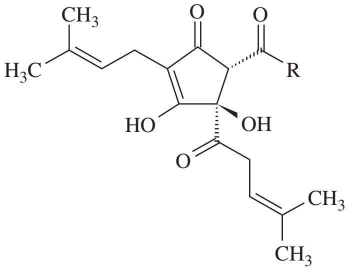
8-268, *trans*-isohumulones

polymerise into a large number of different products. Boiling the wort transforms a part of humulones into isohumulones known as iso-α-acids or iso-α-bitter acids. Their taste perception threshold is about 7 mg/l in water. The remaining α-acids seem not to have any major impact on the taste of the final product. The isomerisation reaction proceeds as a stereoselective tautomerisation of enolate into ketone followed by ring contraction (at C-5 and C-6) of acyloins. Iso-α-acids have two chiral centres and therefore exist as (4*R*,*Z*)-isomers (*cis*-isomers) (**8-267**) and (4*S*,*E*)-isomers (*trans*-isomers) (**8-268**) depending on the spatial arrangement of the tertiary alcohol function at C-4 and the prenyl side chain at C-5. The ratio of these two isomers in wort is about 2 : 1 in favour of the *cis*-isomers. Six major iso-α-acids, namely *cis*-isohumulone, *cis*-isoadhumulone, *cis*-isocohumulone, *trans*-isohumulone, *trans*-adhumulone and *trans*-isocohumulone generally occur in beers at concentrations of 15–80 mg/l or even 100 mg/l in very bitter English ales. Oxoforms of humulones contain a double acyloin system, so by the contraction at C-1 and C-6 of acyloin they produce, to a lesser extent, the so-called anti-isohumulones (anti-iso-α-acids or anti-iso-α-bitter acids), their *cis*-isomers (**8-269**) and *trans*-isomers (**8-270**) as isomerisation products, respectively.

Iso-α-acids are moderately strong acids with pK_a values around 3 (beers of Pilsner type have pH around 5.0–5.2), more soluble than the corresponding humulones (pK_a values are around 5.5) and have an intensely bitter taste. According to the older classification, iso-α-acids are α-resupones, the most important bitter constituents of beer, stabilising the foam and exhibiting bacteriostatic effects.



8-269, *cis*-anti-isohumulones



8-270, *trans*-anti-isohumulones

In direct sunlight or in the presence of photosensitisers (such as riboflavin and polyphenols), the side chain is cleaved, which gives dehydrohumulinic acids (Figure 8.92). Decarbonylation of the formed acyl radical and recombination with a thiol radical, originating from sulfur compounds in beer, yields but-2-en-1-thiol, causing the so-called light-struck off-flavour (Section 8.2.9.1.2).

It has been demonstrated that the aging of beer in brown bottles induces a preferential acid-catalysed degradation of the *trans*-isomers of iso-α-acids, whereas the corresponding *cis*-isomers are more stable. The tricyclic reaction products generated from *trans*-iso-α-acids include the so-called tricyclohumol, tricyclocohumol and tricycloadhumol (**8-271**). In stored hops similar oxidation products of humulones with a cyclised side chain, such as tricyclodehydroisohumulones (**8-272**) have been found. Their bitterness is about 70% of the bitterness of isohumulones. Other products are dihydropyrans (**8-273**) and 2-acyltetronic acids (**8-274**). The storage of beer in polyethylene terephthalate bottles, permeable to oxygen, induces autoxidation of both isomers to *cis*- and *trans*-hydroxyalloiso-α-acids via the corresponding free radicals and *cis*- and *trans*-hydroperoxides (Figure 8.93).

On alkaline treatment, isohumulones are transformed into (4*R*,*Z*)- and (4*S*,*E*)-humulinic acids, also known as *cis*-humulinic

8-274, hops 2-acyltetronic acids

acids (**8-275**) and *trans*-humulinic acids (**8-276**), respectively, and to other products. Related anti-acetylhumulinic acids (**8-277** and **8-278**) are considered the bitterest substances in hops.

β-Bitter acids do not isomerise during the wort boiling and contribute more to the aroma than bittering. Oxidative decomposition

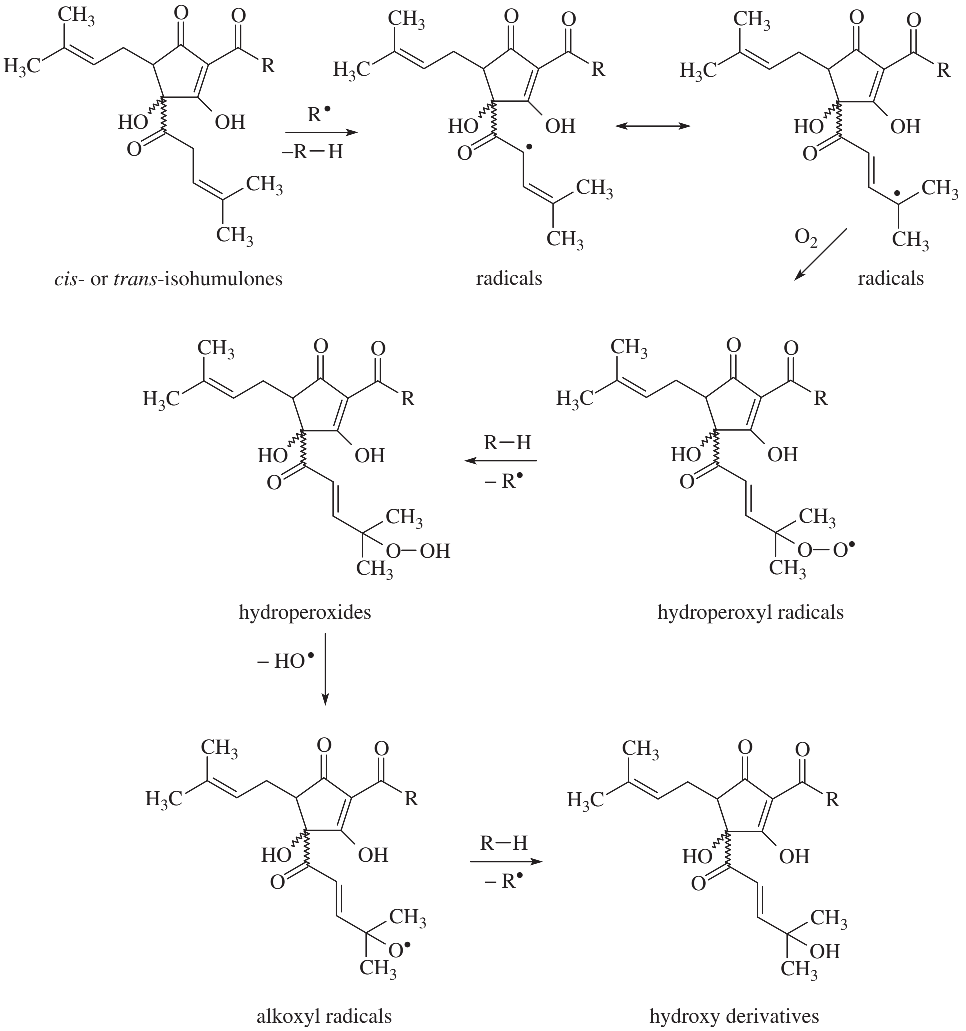

Figure 8.93 Oxidation of isohumulones. Intelmann and Hofmann, 2010, fig 7. Reproduced by permission of the American Chemical Society.

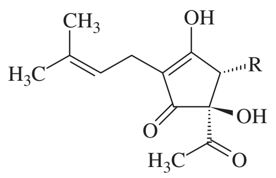
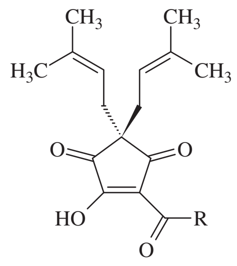
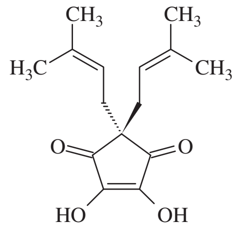


8-278, *trans*-anti-acetylhumulinic acids

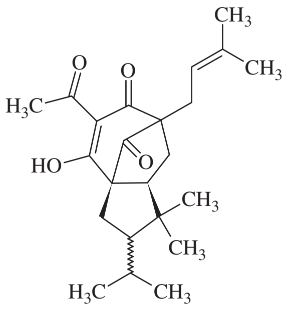
of β-bitter acids is easier and most oxidation reaction products possess unpleasant organoleptic characteristics. Therefore, β-bitter acids are considered a negative factor in brewing and hop varieties with low content of lupulones are preferred. The main bitter transformation products of lupulones are hulupones (such as hulupone, cohulupone and adhulupone, **8-279**), which belong to traditionally recognised β-resupones, hulupinic acids (**8-280**), the corresponding tautomers luputriones, tricyclolupones (**8-281**), nortricyclolupones (**8-282**) and dehydrotricyclolupones (**8-283**).



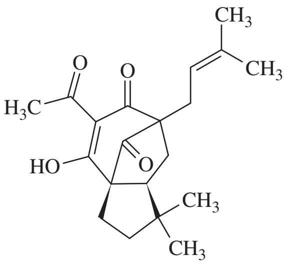
8-279, hulupones



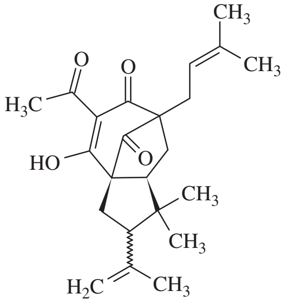
8-280, hulupinic acids



8-281, tricyclolupones

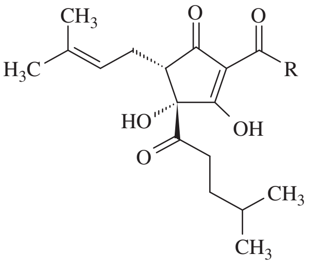


8-282, nortricyclolupones

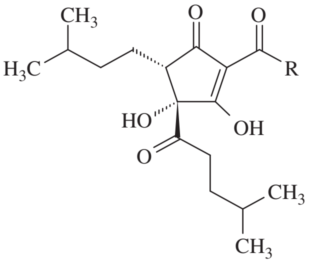


8-283, dehydrotricyclolupones

Easy oxidation of humulones and lupulones in hops is the reason for the use of various hop products, among others, hydrogenated (reduced) iso-α-acids. Examples of hydrogenated substances are *cis*-dihydroisohumulone (**8-284**) and *cis*-tetrahydroisohumulone (**8-285**), the taste threshold of which is 0.007 mg/l in water. Dihydro- and tetrahydro-iso-α-acids are stable even in the light and do not undergo photofragmentation. Beers containing these compounds can be stored in white glass bottles. Dihydroisohumulones are also known as rho-isohumulones. The bitter taste of roasted malt used in the production of dark beers is caused by the presence of 2,5-dioxopiperazines and other products of the Maillard reaction. In comparison with the bitterness of bitter substances of hops, the contribution of these compounds to the bitterness of beer is rather questionable.



8-284, *cis*-dihydroisohumulones



8-285, *cis*-tetrahydroisohumulones

In addition to bitter substances, hop cones contain a number of monoterpenes and sesquiterpenes (0.5–3%) that carry their own characteristic aroma. Some non-volatile components present in the hop, such as polyphenols (3–6%), contribute to a full mouth feel during beer tasting. Important non-volatile components of hop cones are also prenylated flavonoids that show oestrogenic and anti-carcinogenic effects.

Ciders and wines

The bitter and astringent taste of cider from specific varieties of bitter apples is caused by the presence of oligomeric procyanidins, mainly tetramers and higher oligomers. Procyanidins sometimes cause the bitter taste of grape wines, especially white wines.

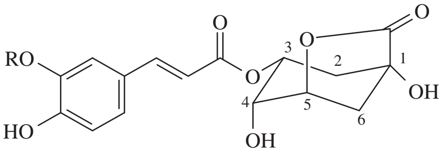
Tea

The bitterness and astringency of tea is related primarily to the presence of phenolic compounds, especially the so-called catechins,

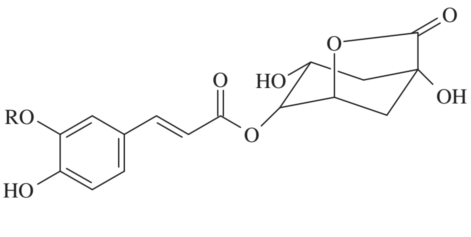
which constitute 10–30% of dry green tea leaves. Black tea contains pigments, mainly theaflavins and thearubigins, which are formed from catechins during fermentation of the tea leaves. Caffeine also plays an important role, particularly in its interaction with phenolic compounds. Additionally involved in the bitter taste of tea are some amino acids (especially L-theanine) and saponins with characteristic aglycones (sapogenols), such as theasapogenols, assamsapogenols and related compounds (see Section 10.3.2.2).

Coffee

The bitterness of roasted coffee is affected by roasting the coffee beans (the degree of bitterness increases with prolonged roasting), preparation of brine, water hardness, temperature and use of sugar and milk. The bitterness of coffee is due to many compounds. The majority of the bitter taste is shown by the transformation products of chlorogenic acids formed during the roasting of the coffee seeds by dehydration, decarboxylation and subsequent reactions. Chlorogenic acids partially dehydrate to form lactones. For steric reasons, the main lactones of roasted coffee are γ-lactones derived from 3-*O*-cinnamoyl-L-quinic (chlorogenic) and 4-*O*-cinnamoyl-L-quinic (cryptochlorogenic) acids. The main products are 3-*O*-L-caffeoyl-quino-1,5-lactone (also known as 3-*O*-caffeoyl-γ-quinide, **8-286**), which are produced from chlorogenic acid, and 4-*O*-caffeoyl-L-quino-1,5-lactone (4-*O*-caffeoyl-γ-quinide, **8-287**) formed from cryptochlorogenic acid. These γ-lactones are followed by γ-lactones derived from 3-*O*- and 4-*O*-feruloyl-L-quinic acid and from other depsides.

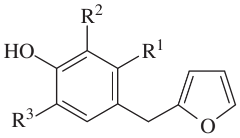


8-286, 3-*O*-caffeoyl-L-quino-1,5-lactone, R = H
3-*O*-feruloyl-L-quino-1,5-lactone, R = CH_3



8-287, 4-*O*-caffeoyl-L-quino-1,5-lactone, R = H
4-*O*-feruloyl-L-quino-1,5-lactone, R = CH_3

Reactions of chlorogenic acids during coffee roasting are very complex. Along with dehydration, chlorogenic acids are also decarboxylated and hydrolysed during coffee roasting. For example, 5-*O*-caffeoyl-L-quinic (neochlorogenic) acid yields, by hydrolysis, caffeic acid, which on decarboxylation or *syn*-elimination of quinic acid gives 4-vinylcatechol. Protonation of 4-vinylcatechol gives the reactive electrophilic cation with a quinone methide structure, which is condensed with 4-vinylcatechol and by subsequent reactions produces a group of polyhydroxylated phenylindans, such as 1,3-bis(3′,4′-dihydroxyphenyl)butane, *trans*-1,3-bis(3′,4′-dihydroxyphenyl)but-1-ene, *cis*- and *trans*-5,6-dihydroxy-1-methyl-3-(3′,4′-dihydroxyphenyl)indane and *cis*- and *trans*-4,5-dihydroxy-1-methyl-3-(3′,4′-dihydroxyphenyl)indane, which exhibit a harsh and lingering bitter taste profile. Subsequent reactions with other 4-vinylcatechol cations yield higher oligomers. Only *cis*-isomers of indanes are listed (Figure 8.94). Dihydroxybenzene and trihydroxybenzene derivatives arising by decarboxylation of phenolic acids, such as catechol (pyrocatechol), 3-methyl- and 4-methylcatechol and pyrogallol, condense with furan derivatives resulting from the Maillard reaction from sugars (such as furfuryl alcohol) to form bitter (furan-2-yl)methylated benzene diols and triols. Compounds of this group identified in coffee included 4-(furan-2-ylmethyl)benzene-1,2-diol formed from catechol, 3-(furan-2-ylmethyl)-6-methylbenzene-1,2-diol formed from 3-methylcatechol, 4-(furan-2-ylmethyl)-5-methylbenzene-1,2-diol formed from 4-methylcatechol and 4-(furan-2-ylmethyl)benzene-1,2,3-triol, which arises from pyrogallol (**8-288**).



8-288, (furan-2-ylmethyl)benzene diols and triols
4-(furan-2-ylmethyl)benzene-1,2-diol, $R^1 = R^2$ = H, R^3 = OH
3-(furan-2-ylmethyl)-6-methylbenzene-1,2-diol, $R^1 = CH_3$, R^2 = OH, R^3 = H
4-(furan-2-ylmethyl)-5-methylbenzene-1,2-diol, $R^1 = CH_3$, R^2 = H, R^3 = OH
4-(furan-2-ylmethyl)benzene-1,2,3-triol, $R^1 = R^2$ = OH, R^3 = H

Quinic acid resulting from chlorogenic acids also has a bitter taste, but the contribution of 2,5-dioxopiperazines (see Section 2.3.3.2.1) and other heterocyclic compounds generated during roasting by the Maillard reaction is not very significant.

Cocoa

The bitterness of cocoa, like the bitterness of coffee, increases with the degree of roasting. The main bitter components are bitter purine alkaloids theobromine and caffeine, as well as cyclic dipeptides (2,5-dioxopiperazines) formed by thermal fragmentation of proteins and products of the Maillard reaction.

8.3.5.2 Methods of debittering and masking the bitter taste

In certain foods a bitter taste is definitely not desirable, therefore different debittering methods have been developed. Methods for removing the bitter taste of enzymatic protein hydrolysates (such as casein hydrolysates) are described in Section 2.3.2.2. These methods are mainly based on controlled proteolysis, plastein reaction, extraction with azeotropic mixtures of alcohols and masking of bitter substances.

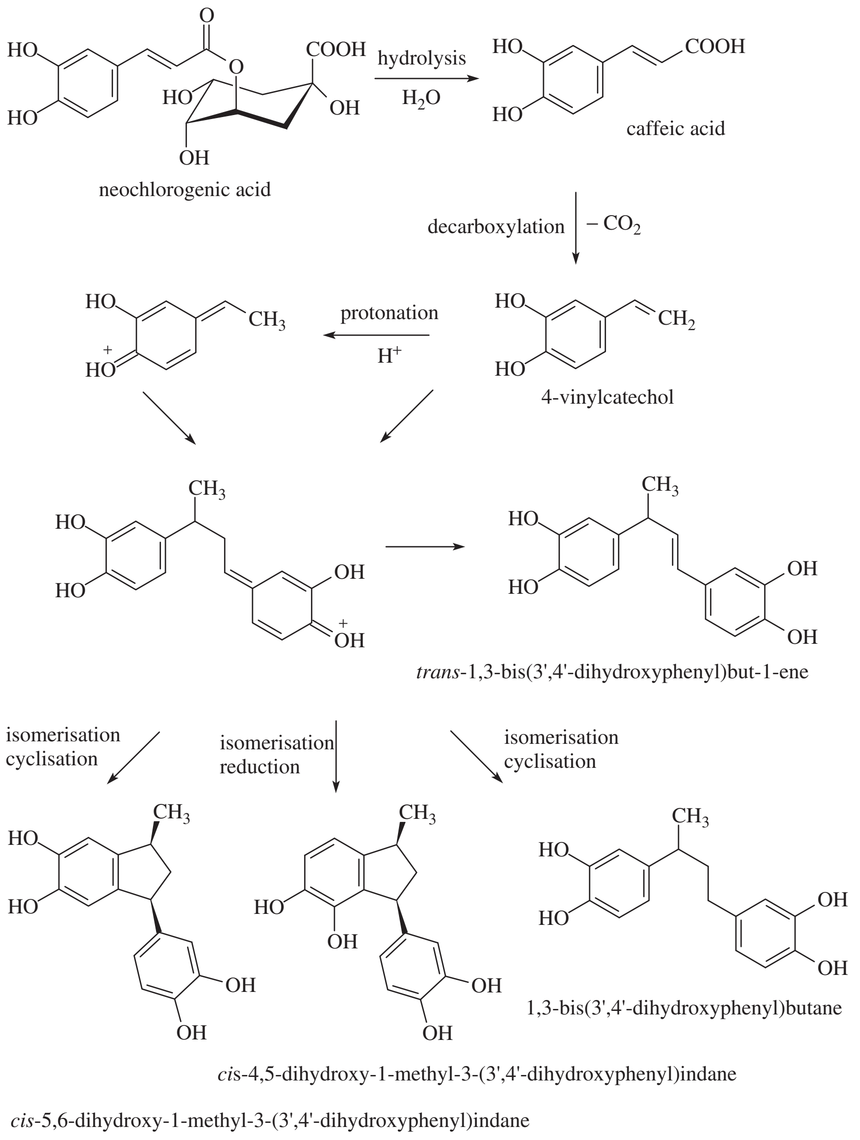


Figure 8.94 Formation of bitter substances from neochlorogenic and caffeic acids.

Debittering of citrus (grapefruit) juices that contain bitter flavanone-7-glucosides is based on enzymatic hydrolysis of the sugar residue in bitter glycosides. The necessary enzymes exhibiting the activities of α-rhamnosidase and β-glucosidase are derived from microorganisms *Phomopsis citri*, *Cochliobolus miyabeanus* and others. Debittering of orange juice (removal of bitter limonin) is done using special enzymes or immobilized cells (such as bacteria *Arthrobacter globiformis*).

Debittering of olives is based on hydrolysis of the bitter oleuropein by fermentation or in alkaline solutions. Hydrolysis of oleuropein in immature green or yellow fruits is done by dipping in a 1.3 to 2.6% sodium hydroxide solution for 6–10 hours. To obtain black unfermented olives from ripe blue olives that are no longer bitter, the fruits are repeatedly soaked in 1–2% NaOH solution with aeration. Under these conditions intense non-enzymatic browning reactions occur, and the dark colour of the fruits is stabilised by the addition of ferrous gluconate that forms black complexes with oxidised polyphenols.

8.3.5.3 Physiology, nutrition and use

Some bitter substances exhibit different physiological effects and may even be highly toxic (e.g. some alkaloids). The bitter taste of food is so often unconsciously associated with the presence of toxic substances, for example in mushrooms, potatoes and lupine seeds. Physiological effects of the bitter substances such as alkaloids, cyanogenic glycosides, saponins, degradation products of glucosinolates (such as goitrin) and plant phenols are discussed in Chapter 10, along with health assessment and appropriate legislation. A number of other bitter compounds have beneficial physiological effects as they act as antioxidants (e.g. many phenolic compounds), and some as anticarcinogens (such as cucurbitacins

and many phenolics). Bitter substances generally support the appetite, which lies in the increased secretion of gastric juices and improved food digestion.

Bitter substances harmless to health have found use mainly in the manufacture of bitter soft drinks, such as bitter lemon (a carbonated drink flavoured with quinine and lemon) and tonic water (a carbonated water flavoured with quinine) and alcoholic beverages, such as beer, specialty wines (vermouths), liqueurs and appetisers.

8.3.6 Astringent substances

Astringency is often accompanied by bitter or sour, or both, taste properties. The different sub-qualities perceived can be caused by different astringent compounds and influences by other food constituents, such as acids and sugars. The primary cause of astringency is the interaction of salivary proteins with certain polymeric phenolic compounds present in foods of plant origin. These interactions lead to denaturation of saliva proteins, loss of their protective effects and astringent compounds may thus consequently interact with the oral cavity proteins, which are perceived as astringency. In addition to phenolic compounds, other compounds can likewise contribute to the astringent taste of food commodities (see Section 8.3.6.5).

Phenolic compounds interacting with proteins are collectively called **tannins**. The common feature of tannins is their ability to react with proteins and precipitate them from aqueous solutions. This reaction is applied *in vivo* in the regulation of enzymatic functions of plant proteins in damaged tissues (structurally similar lignins are missing this feature). The affinity of tannins for proteins depends on the amount of hydroxyl groups and their arrangement, degree of polymerisation of phenols, primary, secondary and tertiary structure of proteins and other factors. In the formation of complexes with proteins, tannins primarily interact via hydrogen bonds and hydrophobic interactions. Particularly strong hydrogen bonds exist between hydroxyl groups of phenols and the secondary amino groups of bound proline (saliva proteins are proline rich) and amide groups of peptide bonds. Ionised hydroxyl groups (in solutions of $pH > 10$) do not react with proteins. Low molecular weight phenolic compounds, such as phenolic acids and simple flavonoids, although reacting with proteins, do not form cross-links between polypeptide chains, which does not result in precipitation of proteins.

Tannins are divided into two large groups:

- **hydrolysable tannins**
- **condensed tannins**.

Hydrolysable tannins are polymers of gallic acid esters, they are polygalloyl esters. Condensed tannins, formerly also known as flavolans, are polymers of some flavonoid compounds with the structure of 3-hydroxyflavan (flavan-3-ol). However, virtually any number of combinations of condensed tannins and hydrolysable tannins, called complex tannins similarly exist.

Owing to their properties, tannins have been used for millennia to tan animal hides into leather. As natural food components, tannins are of great importance as they often substantially affect the desirable and also undesirable taste characteristics. A desirable property is a reasonable astringency of tea, coffee, cocoa (added milk or cream removes the astringency as a result of interaction of tannins with milk proteins), red wine and beer. Undesirable astringency is shown by unripe fruits, such as bananas and persimmons (*Diospyros kaki*, Ebenaceae) and unripe walnuts. In some drinks, such as fruit juices, beer and wine, hazes or sediments are formed, which proteins and tannins participate in. Beer and brewing technology distinguishes between a chill haze and a permanent haze. The polyphenols combine slowly with proteins to form a chill haze when beer is cooled, but the haze redissolves when it is warmed up. As the polyphenols polymerise into larger units, they become insoluble at room temperature to form an irreversible haze. A common practice is, therefore, to eliminate tannins in beer and wine by the use of additives, such as gelatine, polyvinylpolypyrrolidone or polyamide.

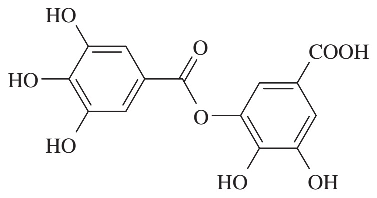
8.3.6.1 Hydrolysable tannins

Hydrolysable tannins are usually divided into:

- **gallotannins**
- **ellagotannins** (or ellagitannins).

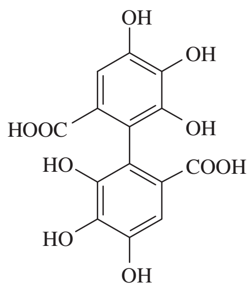
Both groups of hydrolysable tannins are derivatives of 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranose in which gallic acid and products of its biochemical transformations are bound by ester (depside) bonds to glucose.

Gallic acid can bind through hydroxyl groups other molecules of gallic acid to form chains containing 2–5 gallic acid molecules. The depside formed from two molecules of gallic acid is called *m*-digallic acid (**8-289**). Monosubstituted to pentasubstituted glucoses are often called simple galloyl glucoses, unlike the complex molecules that are called gallotannins. Less common components of gallotannins are some other saccharides, quinic acid and other compounds. Hydrolysable tannins have a relative molecular weight up to about 5 kDa. Hydrolysis of gallotannins by acids, alkalis or esterases (tannase, also known as tannin acyl hydrolase) yields D-glucose and gallic acid.

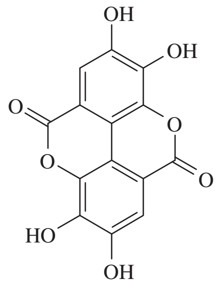


8-289, *m*-digallic acid

Ellagotannins are formed during biosynthesis of hydrolysable tannins by oxidation of two adjacent gallic acid residues and by their combining through covalent bonds. Ellagotannins therefore contain hexahydroxybiphenyl residues derived from the 3,4,5,3′,4′,5′-hexahydroxybiphenylic acid (**8-290**), which arises through their



8-290, 3,4,5,3´,4´,5´-hexahydroxybiphenylic acid

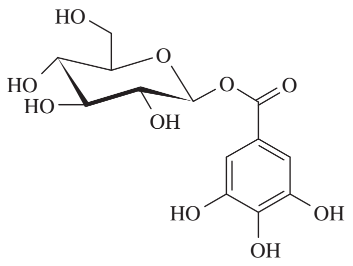


8-291, ellagic acid

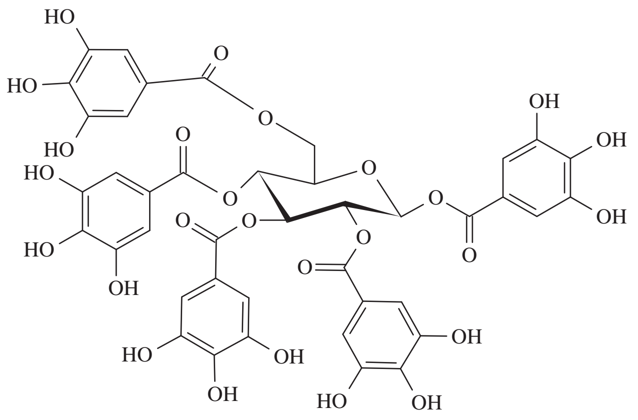
hydrolysis and in acid the hydrolysates spontaneously dehydrate to form ellagic acid (**8-291**).

8.3.6.1.1 Gallotannins

Biosynthesis of gallotannins is based on gallic acid and an activated form of glucose (UDP-glucose). The first intermediate is 1-*O*-galloyl-β-D-glucopyranose (β-glucogallin, **8-292**), which is the donor of the galloyl residue in the biosynthesis of di- to 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranoses (**8-293**). Typical gallotannins are products known commercially as tannin or tannic acid (containing residues of gallic and *m*-digallic acids) that are extracted from oak apples,[6] (*Quercus infectoria*, Fagaceae), tara pods (*Caesalpinia spinosa*, Fabaceae), gallnuts from *Rhus semialata* (Anacardiaceae) or Sicilian sumac leaves (*Rhus coriaria*).



8-292, 1-*O*-galloyl-β-D-glucopyranose



8-293, 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranose

Tannic acid is a mixture of esters containing between 3 and 12 molecules of gallic acid, but also *m*-digallic acid and higher depsides. The composition is highly variable depending on the origin of the tannic acid. Tannic acid has found use as a food additive and an agent to prevent the formation of a chill haze in beer and turbidity in wine and vinegar.

8.3.6.1.2 Ellagotannins

Ellagotannins occur as components of commercial tannic acid, various extracts and infusions (e.g. teas from medicinal herbs and bark of trees) and are also natural constituents of some alcoholic beverages matured in oak barrels,[7] for example high quality wines and spirits, such as cognac, brandy, whisky, bourbon and rum. All components extracted from the wood are then degraded to some extent, which gives rise to various phenolic compounds that have a role to play in the flavour-active components of the alcoholic beverage (Table 8.44).

Monomers

The structures of several hundred simple ellagotannins occurring in nature are known. An example is simple ellagotannin corilagin (**8-294**), which occurs in the leaves of cranberries (*Rhodococcus vitis-idaea*, syn. *Vaccinium vitis-idaea*, Ericaceae). Other examples of ellagotannins found in many plants as monomers or as oligomeric ellagotannins are tellimagrandin I (**8-295**) and tellimagrandin II (**8-296**), which contain one ellagic acid, and pedunculagins (**8-297**) and casuarictin (**8-298**) with two ellagic acids in the molecule. Ellagotannins punicalagins (**8-299**) are found naturally as α- and β-anomers in pomegranate juice at a concentration of about 2 g/l or even higher, depending on the cultivar. Pomegranate ellagotannins

[6]Oak apple is the common name for a large, round (20–50 mm in size) gall commonly found on many species of oak and caused by metabolites injected by the larva of certain kinds of gall wasp, such as *Cynips quercusfolii*, which lay their eggs on oak leaves.

[7]For the production of oak barrels in Europe wood of the English oak (*Quercus robur*) or of the Sessile oak (*Q. petraea*) and in the USA the wood of the white oak (*Q. alba*) are used. In addition to insoluble polymers (cellulose, hemicelluloses and lignin), oak wood contains about 10% of phenolic compounds in dry matter, the predominant part of which are ellagotannins.

Table 8.44 Lignin, ellagotannins and important phenols contents in cognac during aging in oak barrel.

Compound	Content (mg/l)				
	1 year	2 years	10 years	20 years	30 years
Lignin	12	29	127	201	219
Ellagotannins	10	25	31	17	4

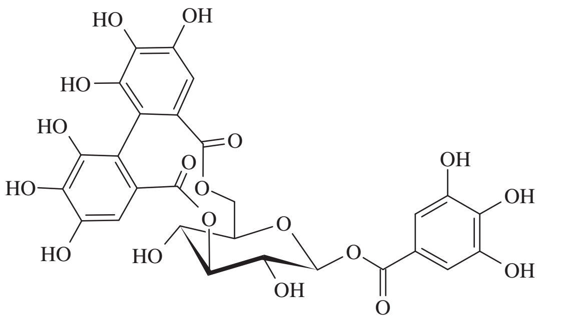
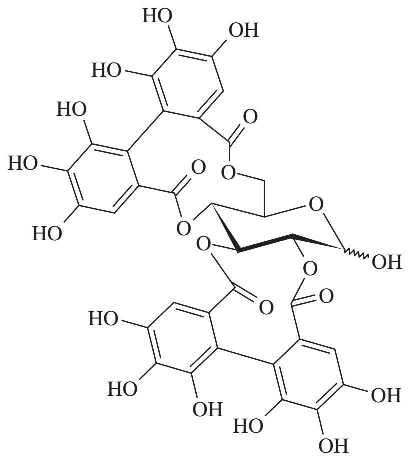
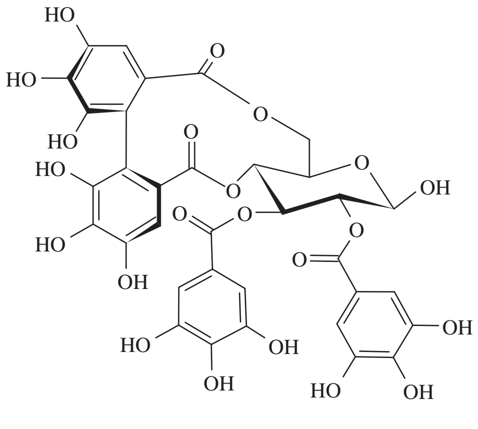
8-296, tellimagrandin II



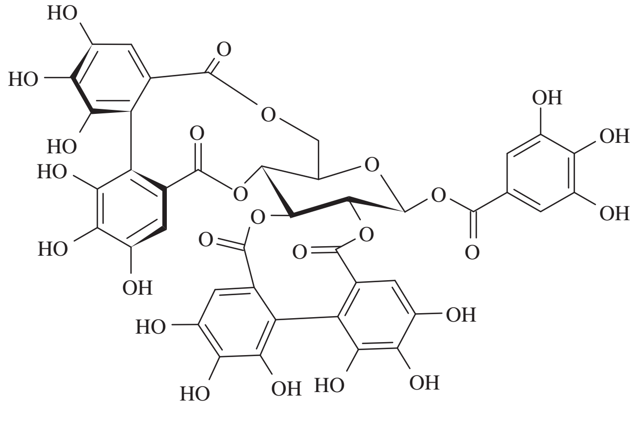
8-294, corilagin



8-297, pedunculagins



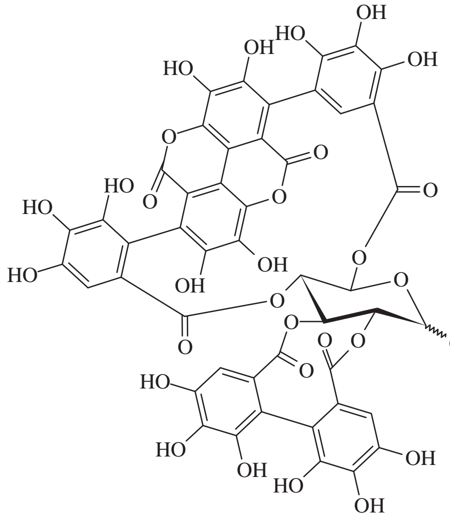
8-295, tellimagrandin I



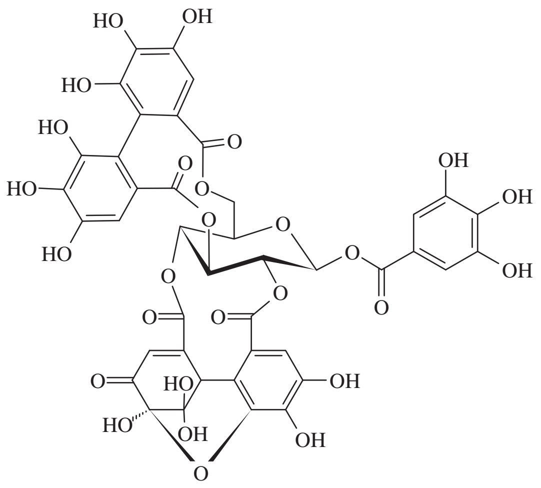
8-298, casuarictin

of similar structure are punicalins with non-esterified C-2 and C-3 glucose hydroxyl groups.

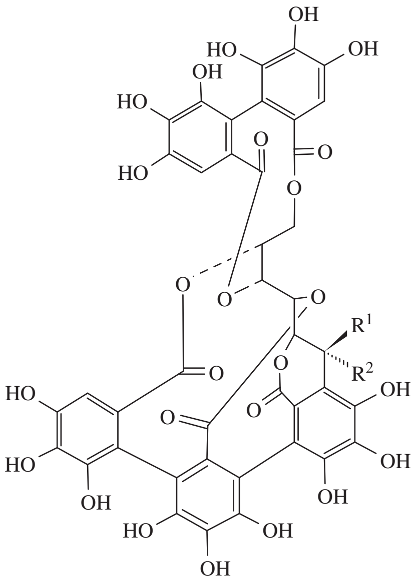
In addition to these compounds, monomers with less common structures also occur in plants, such as geraniin (**8-300**) with dehydrohexahydroxybiphenyl structure, which is classified as dehydroellagotannin. It occurs in many plants of the Geraniaceae and Euphorbiaceae families. Further examples of ellagotannins are the so-called *C*-glucosidic tannins, which are constituents of oak wood. Representatives of these tannins are two diastereoisomers, castalagin and vescalagin (**8-301**). Most of the other known ellagotannins are derived from these two forms.



8-299, punicalagins



8-300, geraniin



8-301, castalagin, R^1 = H, R^2 = OH
vescalagin, R^1 = OH, R^2 = H

Oligomers

Only about 20 monomeric ellagotannins are components of oligomeric ellagotannins that arise from monomers by biochemical reactions (mainly oxidation). The most common oligomers are dimers, trimers and tetramers.

Oligomeric ellagotannins are separated according to their structure into the type GOG (where two galloyl units (G) are connected by an ether bond as in *m*-digalloyl acid, in short *m*-GOG, 1-1′), type DOG (formed by joining hexahydroxybiphenyloyl and galloyl units), type $D(OG)_2$, type *C*-glucosidic oligomers (composed of monomers joined by C–C bonds and so on. An example of a GOG oligomer is agrimoniin (**8-302**), which occurs in many plants of the Rosaceae family, such as the medicinal plant known as common tormentil (*Potentilla erecta*) and some species of agrimony (*Agrimonia* spp.). Another example is sanguiin H-6 (**8-303**) occurring in raspberries and blackberries. Examples of *C*-glycosidic oligomeric ellagotannins are grandinin and roburin A (**8-304**) found in oak wood, where they occur along with many other oligomeric ellagotannins.

8.3.6.2 Condensed tannins

Condensed tannins called **proanthocyanidins**, and sometimes **tannoids**, are structurally diverse oligomers and polymers of flavonoid compounds with the structure of flavan-3-ol. Obsolete names are leucoanthocyanidins, leucoanthocyanins and so on (anthocyanogen, flavolanes, flavylans and flavylogens). The term leucoanthocyanidins is reserved for monomeric flavan-3,4-diols. Proanthocyanidins confer an astringent and bitter taste to fruits, fruit juices, tea, beer and many other foods and drinks. Oligomers resulting from the condensation of 2–10 basic units (the number of hydroxyl groups is also important), whose molecular weight ranges up to about 5 kDa, show this taste. Higher polymers with relative molecular weights up to of 400 kDa do not have the taste of tannins. These polymers, however, have a more important role as the pigments of red wines, and are also involved in the formation of hazes and sediments of wines, beers and fruit juices.

8.3.6.2.1 Monomers

Monomeric units of condensed tannins, which lack their astringent and bitter taste, are colourless catechins, also known as 3-hydroxyflavans or flavan-3-ols (**8-305**). They are intermediates in the biosynthesis of other flavonoids. Flavan-3-ols are found in virtually all fruits, vegetables and other plant materials. Their structure depends on the stereochemistry of the flavan-3-ol units, the number of hydroxyl groups, the stereochemistry of mutual bonds of units forming oligomers, the degree of polymerisation

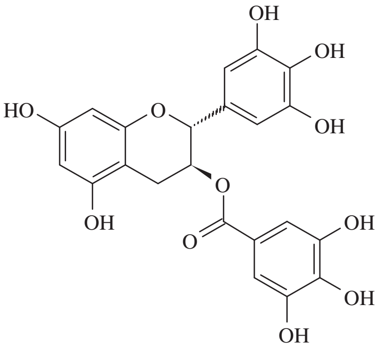
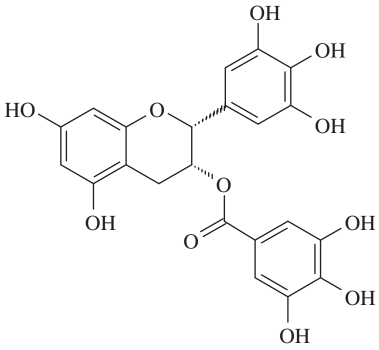
8-305, flavan-3-ols

and possible modification of the C-3 hydroxyl group. Monomeric flavan-3-ols with one hydroxyl group at carbon C-4′ in ring C are called afzelechins (ring B is derived from 4-hydroxybenzoic acid), monomeric flavan-3-ols with two hydroxyl at carbons C-3′ and C-4′ in ring B are called catechins (ring B is derived from protocatechuic acid) and, finally, the monomeric flavan-3-ols bearing three hydroxy groups in ring C (at C-3′, C-4′ and C-5′) are known as gallocatechins (the ring B is derived from gallic acid). Other common compounds include esters of afzelechins, catechins and gallocatechins with gallic acid bound at the C-3 position of ring C, which are called afzelechin-3-*O*-gallates, catechin-3-*O*-gallates and gallocatechin-3-*O*-gallates, respectively (**8-306** and **8-307**).



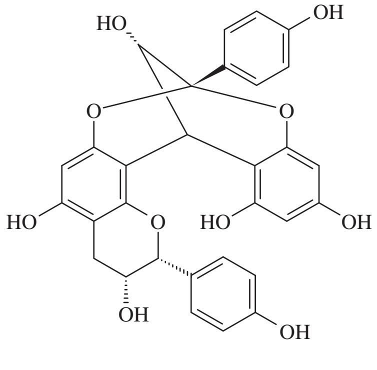
8-306, (+)-gallocatechin-3-*O*-gallate



8-307, (−)-epigallocatechin-3-*O*-gallate

Flavan-3-ols and their gallates have two chiral carbon atoms (C-2 and C-3) in the molecule and may therefore occur in four isomers. The so-called (+)-afzelechins, (+)-catechins, (+)-gallocatechins, (−)-afzelechins, (−)-catechins and (−)-gallocatechins have the C-2 and C-3 hydrogens in the (*E*)-configuration, while the corresponding epicatechins and epigallocatechins have the C-2 and C-3 hydrogen atoms in (*Z*)-configuration. In nature only (+)-afzelechins, (+)-catechins and (+)-gallocatechins that are (2*R*,3*S*)-isomers and (−)-epiafzelechins, (−)-epicatechins and (−)-epigallocatechins that are (2*R*,3*R*)-isomers are found.

(+)-Afzelechins occur abundantly in lichens and in some families of higher plants, such as in the plant families Ericaceae, Aesculaceae, Lauraceae, Rhizophoraceae and Rosaceae. For example, the bark of South African tree *Cassipourea gerrardii* (Rhizophoraceae), which has healing properties, contains afzelechin-3-*O*-α-ʟ-rhamnopyranoside and dimers of afzelechins that also rank among so-called propelargonidins. Afzelechin dimers (proanthocyanidins), such as mahuannin A (**8-308**), occur in the bark of blackthorn (*Prunus spinosa*, Rosaceae).



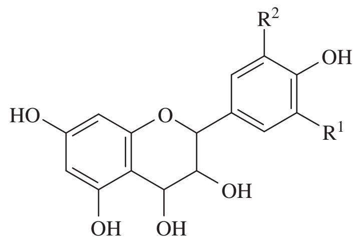
8-308, mahuannin A

The amount of catechins in fruits commonly ranges from units of mg/kg up to hundreds of units of mg/kg. For example, apples contain the major flavan-3-ols (+)-catechin (4–16 mg/kg) and (−)-epicatechin (72–103 mg/kg). Red wines, in addition to (+)-catechin (16–53 mg/l) and (−)-epicatechin (9–42 mg/kg), also contain (−)-epigallocatechin, while the level of (+)-catechin and (−)-epicatechin in white wines is significantly lower (2–6 mg/l and about 1 mg/l, respectively). Cocoa contains (−)-epicatechin,

(+)-catechin, (+)-gallocatechin and (−)-epigallocatechin, in green tea leaves the major component is (−)-epigallocatechin-3-*O*-gallate (about 60% of all catechines), (−)-epicatechin-3-*O*-gallate (10%) and in smaller amounts, as in wine and other materials, virtually all the other catechins are present.

Relatively rare compounds are flavan-3-ol glycosides. For example, (+)-catechin-7-*O*-β-D-glucoside has been isolated from several plant species, such as barley, buckwheat, vigna and rhubarb. Usually, 7-*O*-β-D-glucosides coexists in plants with other isomeric glucosides, such as 5-*O*-, 4′-*O*- and 3′-*O*-β-D-glucosides.

Monomeric flavan-3,4-diols, also known as leucoanthocyanidins (**8-309**), have two hydroxy groups in ring B at carbons C-3 and C-4. On heating in acidic solutions, they are transformed into colourless catechins and coloured anthocyanidins (aglycones of anthocyanins) from which are derived the trivial names of leucoanthocyanidins. Leucoanthocyanidin with one hydroxyl group in ring C at C-4′ is called leucopelargonidin, leucocyanidin has two hydroxyls in ring C (at C-3′ and C-4′) and leucodelphinidin has three hydroxyl groups in ring C (at C-3′, C-4′ and C-5′).



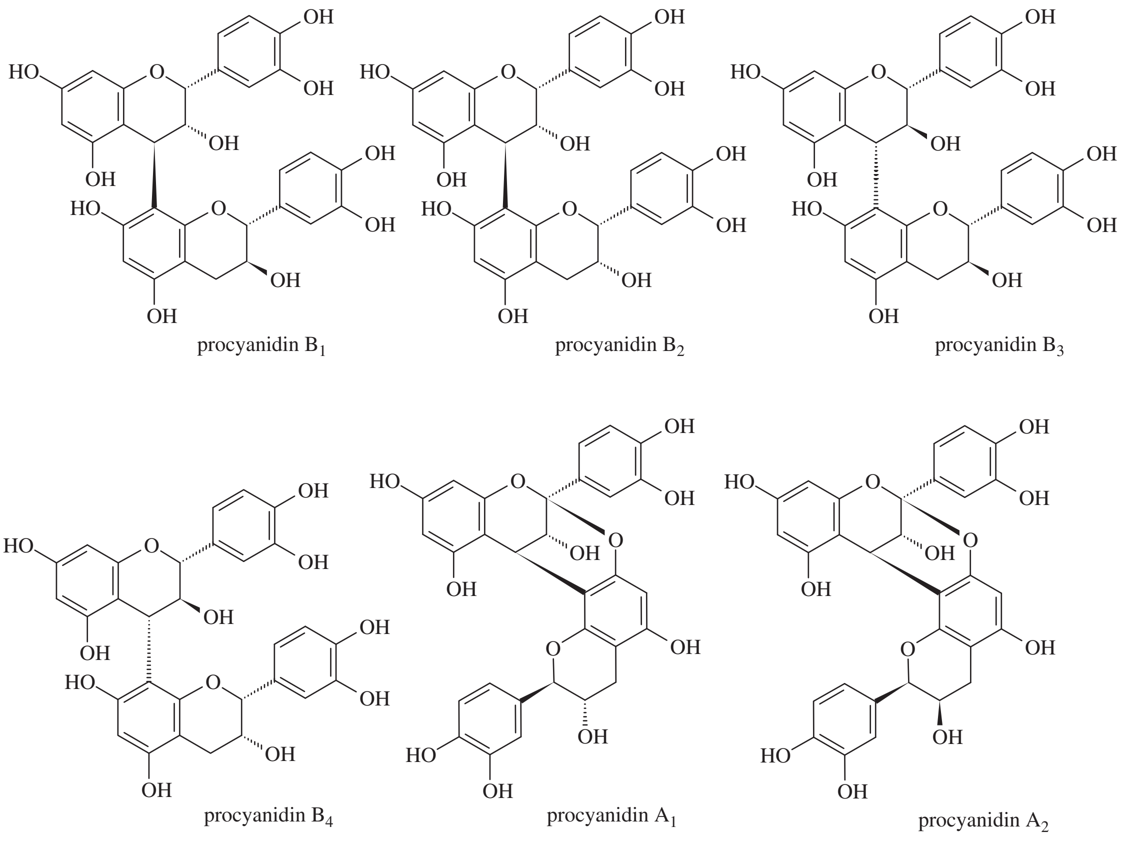
leucopelargonidin, $R^1 = R^2 = H$
leucocyanidin, $R^1 = OH$, $R^2 = H$
leucodelphinidin, $R^1 = R^2 = OH$

8-309, flavan-3,4-diols

8.3.6.2.2 Proanthocyanidins

Monomeric flavanols yield dimeric, higher oligomeric and polymeric procyanidins (proanthocyanidins) of several types. The link between the monomeric units is usually in position C-4 of the upper unit and in position C-8 of the lower unit (bond C4→C8) and can be either α- (below the ring plane) or β- (above the ring plane). These types of dimers are called procyanidins (proanthocyanidins) of type B. Flavanol units can also be linked by a bond in position C-4 of the upper unit and in position C-6 of the lower unit (bonds C4→C6). Type A proanthocyanidins have an additional ether bond between the C-7 hydroxyl of ring A of the lower unit and C-2 of the upper unit (bonds $C_2 \rightarrow O \rightarrow C_7$). Normally, the C-3 hydroxyl group of flavan-3-ol units is esterified, mostly by gallic acid. Type C proanthocyanidins are trimeric proanthocyanidins.

The most common types of dimeric proanthocyanidins have the formulae given in **8-310**. Proanthocyanidin B_1 is epicatechin-(4β→8)-catechin, proanthocyanidin B_2 is epicatechin-(4β→8)-epicatechin, proanthocyanidin B_3 is catechin-(4α→8)-catechin



8-310, common dimeric proanthocyanidins

and proanthocyanidin B_4 is catechin-(4α→8)-epicatechin. The less common proanthocyanidin B_5 is epicatechin-(4β→6)-catechin, proanthocyanidin B_6 is catechin-(4α→6)-catechin, proanthocyanidin B_7 is epicatechin-(4β→6)-epicatechin and proanthocyanidin B_8 is catechin-(4α→6)-epicatechin. Proanthocyanidin A_1 is epicatechin-(4β→8, 2β→*O*→7)-catechin and proanthocyanidin A_2 is epicatechin-(4β→8, 2β→*O*→7)-epicatechin. Examples of trimeric proanthocyanidins are proanthocyanidin C_1, epicatechin-(4β→8)-epicatechin-(4β→8)-epicatechin and proanthocyanidin C_2, catechin-(4α→8)-catechin-(4α→8)-epicatechin.

It is still not known whether the condensation of monomers proceeds by enzymatic or non-enzymatic mechanisms, or by both mechanisms. The main building units are *trans*-2,3-flavan-3-ols, that is (2*R*,3*S*)-isomers and *cis*-2,3-flavan-3-ols that are (2*R*,3*R*)-isomers. The majority of proanthocyanidins arise from (+)-catechin, which is the lower unit and (−)-epicatechin, which is the upper unit in proanthocyanidins. It is assumed that the formation of the upper units involves quinones or carbocations arising from leucoanthocyanidins, anthocyanidins and flavan-3-ols and perhaps some enzymes, such as leucoanthocyanidin reductases and polyphenol oxidases. The expected mechanism of formation of these proanthocyanidin units is outlined in Figure 8.95.

In food raw materials and foods, proanthocyanidins B are the most common types. Plants usually contain different proanthocyanidins. For example, proanthocyanidin B_1 prevails in grapes, cranberries and sorghum, proanthocyanidin B_2 in apples, cherries and cocoa beans, proanthocyanidin B_3 in strawberries and proanthocyanidin B_4 in raspberries and blueberries. In blackcurrants the dimers gallocatechin-(4α→8)-gallocatechin and gallocatechin-(4α→8)-epigallocatechin are present. Proanthocyanidins from hops consist mainly of oligomeric catechins ranging from dimers to octamers, with minor amounts of catechin oligomers containing one or two gallocatechin units. Typical compounds are procyanidin dimers (B_1, B_2, B_3 and B_4) and one trimer, epicatechin-(4β→8)-catechin-(4α→8)-catechin. Proanthocyanidins A_1 and A_2 are found, for example, in the shell of peanuts (*Arachis hypogaea*, Fabaceae), in the textured inedible rind of lychee fruit (*Litchi sinensis*, Sapindaceae) and in the bark and flowers of blackthorn (*Prunus spinosa*, Rosaceae).

Proanthocyanidins and other polyphenols are highly reactive compounds and suitable substrates for numerous enzymatic and chemical reactions. Frequently these compounds are also important components of many plant foods and often have more complex structures. For example, polymeric condensed tannins derived from procyanidin and prodelphinidin units form fibrous tissue filling the shells of hazelnuts (*Corylus avellana*, Betulaceae). The red filling of pecan shells (*Carya illinoensis*, Juglandaceae) is formed exclusively of prodelphinidin polymers. Flavan-3-ol-*C*-D-glycopyranosides, such as (−)-catechin-6-*C*-D-glucopyranoside, (−)-catechin-8-*C*-D-glucopyranoside, (−)-catechin-6-*C*,8-*C*-D-diglucopyranoside (**8-311**) and related (−)-epicatechin-derived compounds, have been shown to exhibit astringent taste and modify the bitter taste intensity of cocoa beverages. In model experiments, these conjugates arise by non-enzymatic *C*-glycosylation of flavan-3-ols by oligo- and polysaccharides.

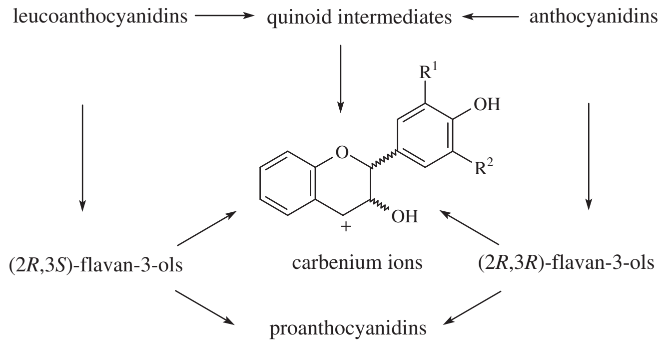


Figure 8.95 Formation of proanthocyanidins.

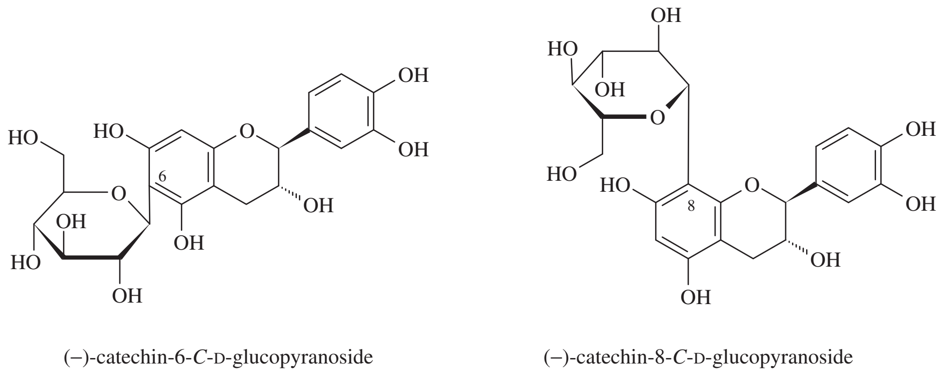
Grapes and wine tannins

The content of proanthocyanidins of the procyanidin type in the seeds of red grapes is 2–5 times higher than in the skin. In the seeds it is mainly oligomers with 2–6 flavanol units that are found, in the skin higher oligomers are also present. The main dimer in the skin of grapes is procyanidin B_1, which is epicatechin-(4β→8)-catechin and the major trimer is epicatechin-(4β→8)-epicatechin-(4β→8)-catechin. The seeds contain mainly procyanidin B_2, which is epicatechin-(4β→8)-epicatechin, and trimer epicatechin-(4β→8)-epicatechin-(4β→8)-epicatechin (procyanidin C_1). In addition to these compounds, other dimers are found in smaller quantities,



8-311, flavan-3-ol-*C*-D-glycopyranosides

such as procyanidin B_2-3′-*O*-gallate, which is epicatechin-(4β→8)-epicatechin-3′-*O*-gallate, trimers and higher oligomers. In addition to procyanidins, prodelphinidins are also present in small amounts. Tannins of red wines have similar composition. Tannins pass to the wine mainly from the grape seeds. Their content in red wines (including monomeric catechins) is about 80–270 mg/l, while levels of tannins in white wines are much lower, at approximately 4–13 mg/l.

Catechins and lower oligomers show low astringency, but have a rather bitter taste. Oligomers containing more than four molecules of monomers are slightly bitter and very astringent. In addition to colourless tannins, red wines contain tannin complexes with polysaccharides and minerals and coloured reaction products of tannins with anthocyanins.

Black tea tannins

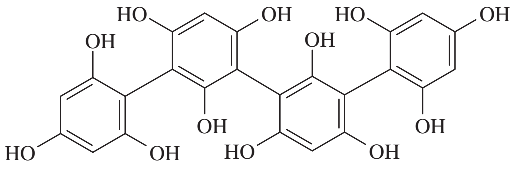
Like other plant materials, fresh tea leaves contain many catechins and proanthocyanidins, which are also found in green tea (see Section 9.12.4.1). The main catechins are epigallocatechin-3-*O*-gallate (7–13%), epigallocatechin (3–6%), epicatechin-3-*O*-gallate (3–6%), epicatechin (1–3%) and catechin (1–3% dry matter). During the fermentation of tea leaves, proanthocyanidins react with proteins, which reduce the original astringent taste of tea leaves, but enzymatic browning reactions create new astringent products.

8.3.6.3 Physiology, nutrition and use

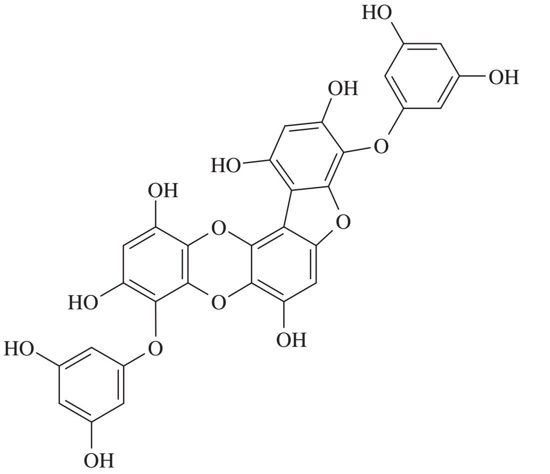
Proanthocyanidins have different physiological effects. Recently acknowledged are their anti-inflammatory and anti-allergic effects, and beneficial effects in the development of atherosclerosis (the effect is related to their reaction with free radicals). Condensed tannins have also found use as food additives. A diet that is high in tannins may, however, also show negative effects, such as lower utilisation of proteins.

8.3.6.4 Phlorotannins

In many fruits, and especially in brown algae (Phaleophyceae), the so-called **phlorotannins** occur, the basic building units of which are, instead of gallic acid, dehydrooligomers or dehydropolymers of phloroglucinols (1,3,5-trihydroxybenzenes) bound in the form of glycosides. They are integral structural components of cell walls in brown algae, but they also play a role in seaweed protection from UV radiation, in osmoprotection and defence against grazing. They may inhibit the formation of advanced glycation end products (AGEs) by scavenging reactive carbonyls. Examples of phlorotannins are tetrafucol (**8-312**) and phlorofucofuroeckol (**8-313**) from brown algae *Fucus vesiculosus* (Fucaceae) known by the common name bladder wrack.



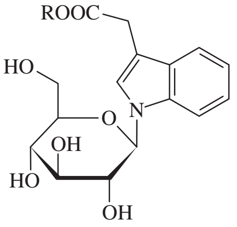
8-312, tetrafucol



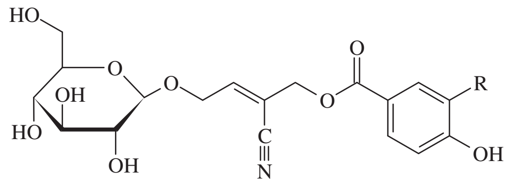
8-313, phlorofucofuroeckol

8.3.6.5 Miscellaneous astringent compounds

Astringency is traditionally thought to be induced by plant tannins in foods through tannin–protein interactions. However, a wide range of other phenolic compounds and some non-phenolic compounds in various foods can elicit astringency. Many ellagitannins that contribute to astringent properties of foods do not interact with salivary proteins and may be directly perceived through some receptors. The astringency of organic acids, such as (*Z*)- and (*E*)-isomers of aconitic acid in red currants, may be directly linked to the perception of sourness. It is mainly isoflavones (see Section 9.4.2.8) and various saponins (see Section 10.3.2.2) that contribute to the astringent taste of soya beans. The key contributors to the astringent taste of rape seeds and meals are some esters of sinapic acid called sinapines (see Section 8.2.7.1.1) and in non-fermented cocoa beans and cocoa products *N*-phenylpropenoyl amino acids (see Section 2.2.1.2.1). In addition to flavan-3-ol glycosides and aconitic acids, the key astringent and mouth-drying compounds in red currants are astringent indoles and nitriles. Examples of these compounds are 3-carboxymethylindole-1-*N*-β-D-glucopyranoside, 3-methylcarboxymethylindole-1-*N*-β-D-glucopyranoside (**8-314**), (*E*)-2-(4-hydroxybenzoyloxymethyl)-4-β-D-



8-314, 3-carboxymethyl-indole-1-*N*-β-D-glucopyranoside, R = H
3-methylcarboxymethylindole-1-*N*-β-D-glucopyranoside, R = CH_3



8-315, (*E*)-2-(4-hydroxybenzoyloxymethyl)-4-β-D-glucopyranosyloxybut-2-enenitrile, R = H
(*E*)-2-(4-hydroxy-3-methoxybenzoyloxymethyl)-4-β-D-glucopyranosyloxybut-2-enenitrile, R = CH_3

glucopyranosyloxybut-2-enenitrile derived from 4-hydroxybenzoic acid and (*E*)-2-(4-hydroxy-3-methoxybenzoyloxymethyl)-4-β-D-glucopyranosyloxybut-2-enenitrile (**8-315**) derived from vanillic acid.

8.3.7 Pungent substances

Burning, stinging, sharp, hot and pungent flavour is a characteristic phenomenon accompanying the consumption of some spices, such as hot chillies, pepper, ginger and cloves, spice mixtures that contain these spices, special sauces, some vegetables of the Brassicaceae family, such as mustard, horseradish, radish, radishes and vegetables of the Amaryllidaceae family, such as garlic and onion.

8.3.7.1 Hot pepper

The substances responsible for the hot taste of different domesticated pepper genera (*Capsicum annuum*, *C. frutescens*, *C. chinense*, *C. pubescens* and *C. baccatum*) and their varieties are protoalkaloids **capsaicinoids** that include a group vanillylamides derived from C_8–C_{11} (*E*)-monoenic branched-chain fatty acids (isoacids and anteisoacids) and saturated fatty acids with branched or straight chains. (Z)-Isomers do not occur in peppers. About 90% of the capsaicinoids are represented, in approximately equal proportions, by capsaicin and dihydrocapsaicin, the rest are other related compounds (see Section 10.3.2.1.6). The capsaicinoids content of fresh bell (sweet) pepper cultivars (*C. annuum*) is often negligible (0.001% or less), but in some varieties of *C. annuum* (such as cayenne and jalapeño peppers) the level is in the range of 0.2–1%, and in others, as well as in some varieties of *C. frutescens* (such as tabasco and chilli peppers), it may be even higher. The hottest peppers are some varieties of *C. chinense* (such as habanero).

The taste recognition threshold of capsaicin is about 0.1 mg/kg and a concentration of 10 mg/kg causes a strong burning sensation. The burning sensation of dihydrocapsaicin is almost the same. The sharpness of both capsaicinoids is about 150–300 times higher than those of the hot components of black pepper and ginger. The pungency of hot peppers is evaluated organoleptically using Scoville heat units (SHU).[8] The taste is evaluated in a series of diluted samples (the more diluted the solution, the higher the score obtained), the last of which has no perceptible pungency. Pure capsaicin has a Scoville rating of 16 000 000, red habanero pepper of 150 000, tabasco pepper of 120 000, jalapeño pepper of 25 000 and sweet bell pepper of 0 SHU. Typical relative pungencies in SHU for the main hot pepper substances capsaicin, dihydrocapsaicin, nordihydrocapsaicin, homodihydrocapsaicin and homocapsaicin are 16 000 000, 16 000 000, 9 000 000, 8 600 000 and 8 600 000, respectively.

[8]The Scoville test was invented by the American pharmacist Wilburg Lincoln Scoville in 1912. Capsaicinoids are now mainly determined by high performance liquid chromatography.

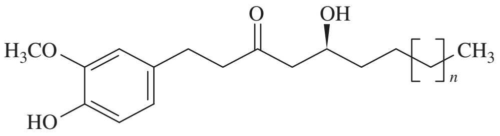
8.3.7.2 Black pepper

Black, white, green and red peppers are fruits of the same plant (*Piper nigrum*, Piperaceae) native to south India that contains protoalkaloid piperine as the major hot component; this is (2*E*,4*E*)-1-piperoylpiperidine, an amide of piperic acid, systematic name (2*E*,4*E*)-5-(1,3-benzodioxol-5-yl)-*N*-piperidinylpenta-2,4-dienamide. Black pepper is obtained from immature, but already fully developed fruits that are fermented during drying. Green peppers are quickly sun-dried unripe berries. White pepper is produced from fully ripe berries by removing the red skin. The content of piperine in black and white pepper is 3–8% (see Section 10.3.2.1.2).

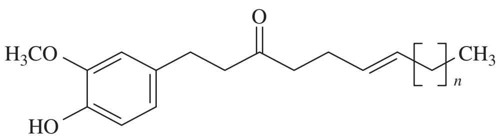
8.3.7.3 Ginger

Ginger is the rhizome of the *Zingiber officinale* (Zingiberaceae) plant native to Southeast Asia. The pungent spicy components of ginger are phenolic alkanones known as gingerols (**8-316**) and shogaols (**8-317**). Their total content in the fresh rhizome is 0.7–0.9% and 1.1–1.6% in dry rhizome.

The main and most important component is the so-called 6-gingerol, (5*S*)-5-hydroxy-1-(4-hydroxy-3-methoxyphenyl)decan-3-one, which represents about 75% of hot substances in oleoresins obtained by extraction with supercritical carbon dioxide. The

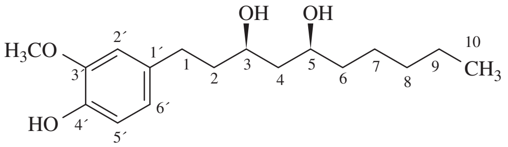


8-316, 6-gingerol, n = 2
8-gingerol, n = 4
10-gingerol, n = 6



8-317, 6-shogaol, $n = 2$
8-shogaol, $n = 4$
10-shogaol, $n = 6$

end of its side chain is derived from C_6 aldehyde (hexanal). 6-Gingerol is accompanied by its homologues 8-gingerol (11%) and 10-gingerol (15%), derived from octanal and decanal, respectively, which occur in smaller amounts in ginger rhizome. Minor pungent components of ginger are 6-shogaol (0.5%), 8-shogaol and 10-shogaol and some other related compounds are found in very small quantities, such as a homologue of 6-gingerol called 12-gingerol, its methyl derivative (methyl 6-gingerol), diketone 10-gingerdione, diol (3*S*,5*S*)-6-gingerdiol (**8-318**) and other products. 6-Gingerdiol occurs in the form of 4′-*O*- and 5-*O*-β-ᴅ-glucopyranosides. The hottest component of ginger is 6-gingerol, its homologues 8-gingerol and 10-gingerol are about 4–15 times less spicy, while 6-shogaol is 2–60 times less pungent than 6-gingerol. Ginger and its components are also known to possess such physiological features as antimicrobial, antioxidative, antitumor and antiplatelet aggregation activaties.



8-318, 6-gingerdiol

The composition of hot ginger rhizome components and ginger oleoresins vary within certain limits, depending primarily on the variety of plant and post-harvest operations. Thermally processed and stored materials, for example, contain significant quantities of shogaols that result from dehydration of gingerols. Retroaldolisation of gingerols yields pungent zingerone and the corresponding alkanals that cause an off-flavour. 6-Gingerol produces hexanal (Figure 8.96), 8-gingerol octanal and 10-gingerol decanal on degradation.

8.3.7.4 Clove

Cloves, dry flower buds of the *Eugenia caryophyllata* (Myrtaceae) tree, native to Zanzibar and other South and Southeast Asia countries, contain 15–20% of the essential oil, the main part (80–90%) of which is eugenol (4-allyl-2-methoxyphenol). Eugenol (see Section 8.2.3.1.2) has a characteristic smell of clove and a slightly pungent taste.

8.3.7.5 Cruciferous vegetables and mustard

The family of the cruciferous plants (Brassicaceae) includes a number of vegetables that have a pungent and spicy taste if eaten raw. Examples of vegetables with extreme burning taste are grated horseradish (*Armoracia rusticana*) root and certain radish varieties (*Raphanus sativus*). A less pungent taste is found in some raw vegetables of the genus *Brassica*, such as cabbage, kale and others, black (*B. nigra*), brown (also known as Indian or Chinese mustard; *B. juncea*) and white mustard seeds (*Leucosinapis album*, syn. *Sinapis alba*) that are used to produce mustard pastes. For example, the French style Dijon mustard is produced from black mustard seeds and some varieties of brown mustard, English mustard is made using white, black and brown mustard seeds (flour), and Krems mustard is made from a mixture of white and black mustard seeds.

The characteristic aroma and pungent taste of these vegetables and mustards is related to the presence of isothiocyanates. Along with other products, isothiocyanates are produced as a result of the enzyme myrosinase (thioglucoside glucohydrolase) activity in damaged plant tissues on sensory indifferent glucosinolates (see Section 10.3.2.4). One of the most common isothiocyanates is allyl isothiocyanate, which is the main pungent and spicy component of horseradish, black and brown mustard seeds and some leafy vegetables, such as cabbage, Savoy cabbage and kale.

Allyl isothiocyanate are produced from glucosinolate sinigrin, the content of which in horseradish is 27–29 g/kg (which roughly

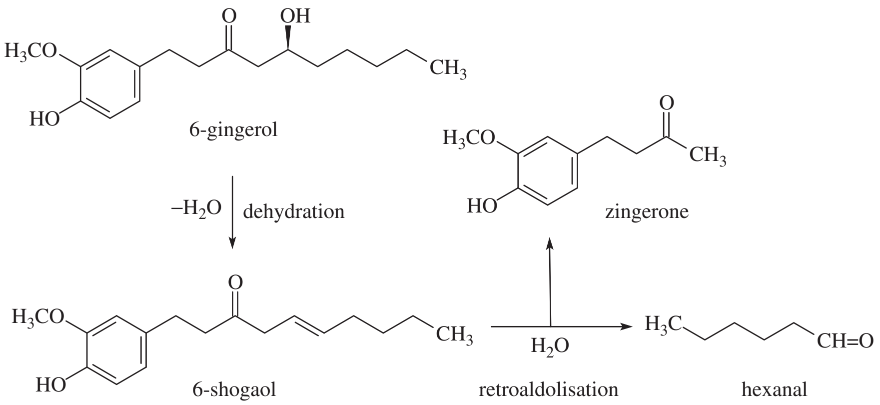


Figure 8.96 Degradation of gingerols.

corresponds to 8–9 g/kg of allyl isothiocyanate). Other isothiocyanates also contribute to the spicy flavour of horseradish, such as 2-phenylethyl isothiocyanate, which arises from glucosinolate gluconasturtiin (the content of which is within 4.2 and 7.2 g/kg), and other minority isothiocyanates. Allyl isothiocyanate is the main pungent and spicy component of Japanese horseradish, called wasabi (*Wasabia japonica*, syn. *Eutrema wasabi*), of the crucifer family (Brassicaceae). Its content in wasabi is 7–10 g/kg. In the cones of cabbage and other cruciferous vegetables, the level of sinigrin and gluconasturtiin is much lower (4–146 and 0.7-6.1 mg/kg fresh weight, respectively). In the case of cabbage, the amount of sinigrin corresponds to 1–45 mg/kg of allyl isothiocyanate.

Allyl isothiocyanate is also the main ingredient of table mustard pastes made from black mustard seeds. The level of sinigrin in seeds is 89–100% of the total glucosinolate content, which corresponds to 18–45 g/kg. The glucosinolates gluconapin (0–11%) and glucobrassicanapin (0–0.3%) are found in lower amounts. The content of allyl isothiocyanate in table mustards made from black mustard seeds is 10–18 g/kg. The brown mustard seed content of allyl isothiocyanate is only 7 g/kg. Another major isothiocyanate of brown mustard seeds is but-3-en-1-yl isothiocyanate, which is present at a concentration of 3–4 g/kg. White mustard seeds contain 4-hydroxybenzyl isothiocyanate as the main substance, which arises from glucosinolate sinalbin. 4-Hydroxybenzyl isothiocyanate is usually only mildly spicy. The sinalbin content in seeds ranges between 20 and 50 g/kg. The content of 4-hydroxybenzyl isothiocyanate in autolysed seeds is 15–37 g/kg.

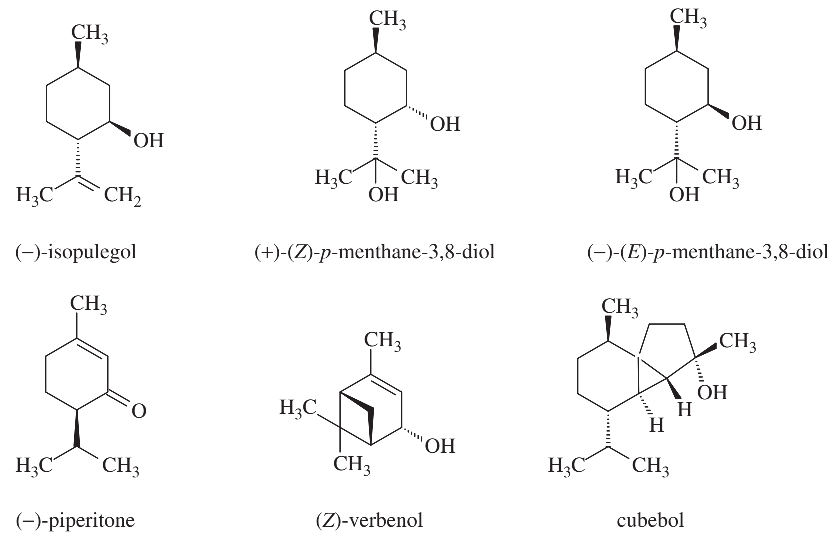
Some radish (*Raphanus sativus*) varieties, such as the grey–black radish with round roots, contain as the main pungent substance (*E*)-4-(methylthio)-but-3-en-1-yl isothiocyanate, which is produced from the glucosinolate glucoraphasatin. Its concentration in radishes is about 1–3 g/kg, resulting in an isothiocyanate content of 0.5–1 g/kg.

8.3.7.6 Alliaceous vegetables

The key flavour precursors of garlic (*Allium sativum*, Amarillidaceae), onion (*A. cepa*), shallot (*A. cepa* var. *aggregatum*), leek (*A. ampeloprasum*), chives (*A. schoenoprasum*) and other alliaceous vegetables are the sulfur-containing amino acids *S*-alk(en)ylcysteine sulfoxides also known as *S*-alk(en)ylcysteine-*S*-oxides (see Section 2.2.1.2.2). The typical aroma of these vegetables develops as a result of decomposition of *S*-alk(en)ylcysteine sulfoxides by the CS lyase called alliinase. In the intact tissue, *S*-alk(en)ylcysteine sulfoxides are located in the cytoplasm, while alliinase occurs in the vacuoles. Cutting or other damage to plants leads to rapid degradation of these amino acids to form pyruvic acid, ammonia and alk(en)yl sulfenic acids that spontaneously condense to the corresponding pungent dialk(en)ylthiosulfinates (see Section 8.2.9.1.4). These substances carry the aroma of freshly cut alliaceous vegetables, while additionally showing significant antimicrobial properties. Dialk(en)ylthiosulfinates, however, are extremely unstable substances, which quickly decompose on prolonged standing, depending on the temperature and polarity of the environment, to form a variety of secondary products (such as thiosulfonates, disulfides, trisulfides and a range of other compounds) that are responsible for the aroma of processed alliaceous vegetables.

8.3.8 Cooling substances

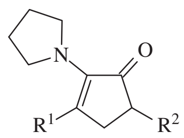
(−)-Menthol (**8-19**) is a common cooling substance used in food products. The effect of coolness evoked through stimulation of the somatosensory system can be produced by several naturally occurring molecules, mainly derived from terpenes and sesquiterpenes. Such a molecule is (−)-isopulegol (**8-319**), occurring, for example, in the essential oil of Australian lemon-scented gum (*Eucalyptus citriodora*, Myrtaceae) trees, which has 20% of the cooling



8-319, cooling-active terpenoids

power of (−)-menthol. Similar cooling agents are (+)-(*Z*)- and (−)-(*E*)-*p*-menthane-3,8-diols (**8-319**). Alternative natural cooling molecules are (−)-menthone (**8-50**) in peppermint oil, (+)- and (−)-piperitone (**8-319**) in mint oils, which are weakly cooling. Several other terpenes, such as (+)-1,8-cineole (eucalyptol, **8-31**), which occurs in essential oils of various spices and trees of the genus *Eucalyptus* and verbenol (**8-319**) from marjoram and sage oils, are slightly cooling substances. The only cooling sesquiterpene is cubebol (**8-319**), which is found in cubeb (tailed pepper, *Piper cubeba*, Piperaceae) essential oil. A considerable number of compounds showing a cooling effect have been synthesised and evaluated for the physiological sensation of cooling. Many artificial cooling compounds are menthol derivatives (esters, ethers and acetals) or have very different chemical structures.

Some cooling compounds are also present in raw food materials and foods. For example, 3-methyl- and 5-methyl-2-(1-pyrrolidinyl)cyclopent-2-en-1-one (**8-320**) were recently identified as intense cooling compounds in roasted dark malt. The cooling thresholds of these 2-aminocyclopent-2-en-1-ones in water were 29–44 and 4.5–9.0 mg/kg, respectively, while the cooling threshold of (−)-methol was 0.9–1.9 mg/kg. It was shown that the identified 2-aminocyclopent-2-en-1-ones were produced by the Maillard reaction from hexose derived cyclotene (2-hydroxy-3-methylcyclopent-2-en-1-one, see Figure 4.62) and 1-pyrrolidine formed by the Strecker degradation of L-proline.



8-320, cooling-active 1-pyrrolidinylcyclopent-2-en-1-ones
3-methyl-2-(1-pyrrolidinyl)cyclopenta-2-en-1-one, $R^1 = CH_3$, $R^2 = H$
5-methyl-2-(1-pyrrolidinyl)cyclopenta-2-en-1-one, $R^1 = H$, $R^2 = CH_3$

8.3.9 Physiology, nutrition and use

The physiological effects of hot piperidine alkaloids (see Section 10.3.2.1.2) and of capsaicinoids (10.3.2.1.7) are described elsewhere. Gingerols have only low acute toxicities, but show carminative (prevent the formation of gas in the gastrointestinal tract), antiemetic (prevents or alleviates nausea and vomiting) and antioxidative effects. Allyl isothiocyanate is used as a food flavouring agent (mayonnaise, horseradish, mustards and various special sauces), as a preservative in animal feed, in medicine as a rubefacient (counterirritant), as a fungicide, in ointments, mustard plasters, as an adjuvant (enhancing the action of medical treatment) and as a repellent for cats and dogs. The average daily intake of individuals in the United States was estimated to be less than 6 mg/day on the basis of exposure to allyl isothiocyanate in foods. Dimethyl sulfide and dimethyl disulfide are not mutagenic in mammalian cells and their acute oral toxicities are low. Physiological properties of other garlic constituents were described in Section 8.2.9.2.2. Pure sulfides, as well as allyl isothiocyanate, are irritating to the skin and the vapour irritates the eyes and nose. Eugenol is potentially hepatotoxic and an overdose may cause a wide range of symptoms. It is subject to restrictions on its use in perfumery as it may cause an allergic reaction in sensitised people.

9

Pigments and other Colorants

9.1 Introduction

The sensory quality of food and its acceptability, aside from odour, taste and texture, is generally based on colour, which is the human perception of coloured materials based on the selective absorption of light. In this chapter, the general term **pigment** is used for a substance whose presence in living cells determines their characteristic colour; in other contexts, a pigment is any material from which a dye may be prepared. The term **dye** refers to a colorant used by the industry to colour or stain various materials using dyestuffs, but not food. The general term **colorant** means any substance, such as a pigment or dye that imparts colour. The harmless substances used to impart colour to food or drink are **colour additives**.

Food pigments are usually divided into three main types:

- natural pigments
- synthetic pigments identical to natural pigments (nature identical pigments)
- synthetic pigments.

Natural pigments are coloured substances synthesised, accumulated or excreted into the environment by living cells. These pigments are:

- natural parts of foods of animal or vegetable origin due to the genetic dispositions of the given organism;
- part of other natural materials (pigments of algae, fungi, lichens or microorganisms), which are obtained in the original state as such or are structurally modified and used for food colouring as colour additives.

Coloured products derived from natural raw materials through various technological processes, such as caramel and malt extract, which contain melanoidins, are also considered natural colorants. Natural colorants additionally include copper complexes of chlorophylls and chlorophyllins, which do not occur in nature (or may be present in foods in negligible amounts), inorganic pigments, such as calcium carbonate, iron(III) oxide (iron trioxide), titanium(V) oxide (titanium dioxide) and nature identical synthetic dyes. Some natural pigments are formed only during the processing and storage of food raw materials and foods, mostly by reactions with amino acids. These adverse reactions and associated changes of natural colour are considered as discolorations and defects. The coloured products of these reactions are referred to as **reaction pigments** or **process pigments** by analogy with reaction or process flavours (process flavourings). For example, a red discoloration originating from amino acids and ascorbic acid is produced in pickled cauliflower (see Section 5.14.6.2.3), precursors of pink discoloration of onion and green to blue discoloration of garlic are amino acids and sulfenic acid resulting from (*E*)-*S*-(prop-1-en-1-yl)cysteine sulfoxide (isoalliin) (see Section 8.2.9.1.4), the precursor of the green to blue discoloration of sweet potatoes (*Ipomoea batatas*, Convolvulaceae) are amino acids and chlorogenic acid (see Section 9.12.4) and the pink and yellow discoloration in *Brassica* vegetables may be caused by reactions of amino acids with isothiocyanates (see Section 2.5.2.4).

Natural pigments are classified according to their structure, occurrence in biological materials or important properties (such as their solubility in water and fat). The following pigments are recognised according to their structure:

- Nitrogenous heterocyclic compounds, to which belong pigments derived from **pyrrole** and pigments derived from **indole**, **isoquinoline**, **pyrimidine**, respectively from **purine**, **pterine** and related **flavin**, **phenazine** and **phenoxazine**; some of these are simultaneously classified as alkaloids; the most important pigments of this group include **haem** and **chlorophyll** pigments derived from pyrrole and **melanins** and **betacyanins** derived from indole.

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

- Heterocyclic compounds containing oxygen include many phenolic compounds, particularly **flavonoids**, the most important pigments of which are **anthocyanins** related to pigments derived from **isochromene** and **xanthone**.

- Other phenols and derived **quinones** include a variety of pigments, their oligomers, condensation and other products, such as **curcuminoids**.

- Terpenoids, which include in particular tetraterpenoid and some other pigments derived from tetraterpenes, known as **carotenoids**, monoterpenic pigments **iridoids** and certain other coloured compounds.

Approximately 1500 coloured compounds, also known as natural food pigments, have been isolated from foods. On the basis of their chemical structure, but also with regard to their importance, these pigments have been grouped into the following ten classes:

- tetrapyrroles (haem pigments, chlorophylls and phycobilins)

- other nitrogenous pigments (indoles and related compounds, melanins, indigoid pigments, betalains, isoquinolines, purines, pterines, isoalloxazines and phenoxazines)

- flavonoids (anthocyanins and other flavonoids, such as flavanones, flavononoles, flavons, chalcones, quinochalcones, dihydrochalcones, aurones and isoflavones)

- xanthones

- curcuminoids

- isochromenes

- quinoid pigments (quinones, such as benzoquinones, terphenylquinones, pulvic acids and troponoids, naphthoquinones, anthraquinones, including emodins, bianthrones and cochineal pigments)

- carotenoids (carotenes, xanthophylls and apocarotenoids)

- iridoids

- other terpenoids pigments.

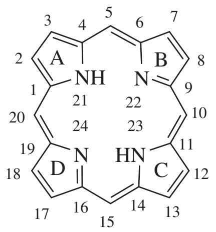
This chapter will describe in detail their occurrence in the individual food commodities, their properties, stability and important reactions, their importance in human nutrition and physiology and their use as food colourings in food technology. A section of the chapter is devoted to the so-called enzymatic browning reactions that proceed as desirable, but also as adverse reactions in many foods of plant origin. Substances used as colour additives are described in Chapter 11, which focuses on food additives. Reaction pigments are mentioned in chapters dealing with the individual nutrients.

9.2 Tetrapyrroles

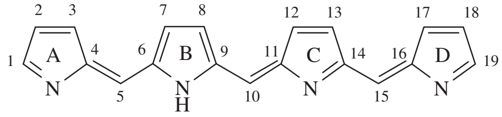
Tetrapyrrole pigments are a numerically small, but very widespread and significant group of differently coloured pigments. Their structure, a resonance-stabilised planar ring system, consists of four pyrrole rings A, B, C and D connected in a tetrapyrrole (porphyrin) circle with a conjugated double bond system through methine bridges in the α-positions of pyrrole structures (**9-1**) or arranged linearly (**9-2**). Accordingly, two basic groups of tetrapyrrole pigments are recognised:

- cyclic **porphyrins** (porphyrin pigments)

- open chain (linear) **bilins** (bilin pigments).



9-1, basic structure of porphyrin pigments



9-2, basic structure of bilin pigments

It has been reported that 28 porphyrin pigments and their precursors occur in nature. Porphyrins are chromophores of two basic groups of metalloproteins:

- pigments of animal tissues, called haem pigments or haems

- pigments of plant tissues, some algae and some microorganisms, called chlorophyll pigments or chlorophylls.

Bilins (there are six known compounds) are usually classified according to their origin as:

- phycobilins, which are pigments of some algae

- bile pigments resulting from degradation of haem pigments (pigments in urine and faeces of mammals).[1]

[1]Endogenous haem is degraded by oxidative cleavage of the porphyrin ring by the enzyme haem oxygenase inside spleen macrophages to blue–green biliverdin IX α (releasing carbon monoxide and Fe), which is reduced by biliverdin reductase to orange bilirubin IX α. Bilirubin forms a conjugate with D-glucuronic acid (diglucuronide binding to propionic acid residues). The

9.2.1 Haem pigments

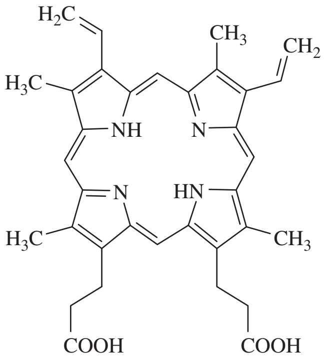
The most important haem pigments are metalloproteins:

- **myoglobin**, the red pigment of muscle tissue
- **haemoglobin**, the pigment of red blood cells (erythrocytes).

The interest in haem pigments is focused primarily on their biochemical properties in relation to the transfer of oxygen in tissues, and also to the metabolism of bile acids. However, food chemists and technologists are mainly interested in the stability and changes of haem pigments during the processing and storage of meat and meat products.

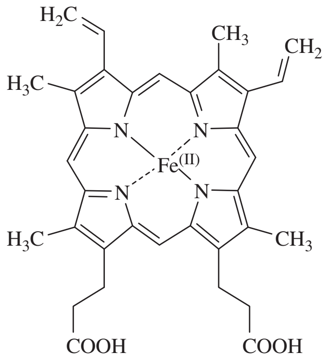
9.2.1.1 Structure and nomenclature

The basis of the structure of myoglobin, haemoglobin and derived pigments is a substituted cyclic tetrapyrrole protoporphyrin IX (**9-3**) with a central atom of divalent iron, which is called **haem** or protohaem (**9-4**). The haem molecule is almost planar. Haem is a conjugated system and although there are two coordination-covalent Fe–N bonds (the bonding electron pair apparently belongs to only one of the atoms), in fact, all four bonds with pyrrole rings are equivalent. The fifth and sixth coordination bonds of iron (above and below the plane of the planar molecule) can be occupied by different ligands. **Haemin** is protoporphyrin IX with Fe (II), where the counter ion is a chloride ion. Protoporphyrin IX with trivalent iron, an oxidation product of haem, is called **haematin**, in which a hydroxyl group is bound to the central Fe (III) atom as a counter ion.



9-3, protoporphyrin IX

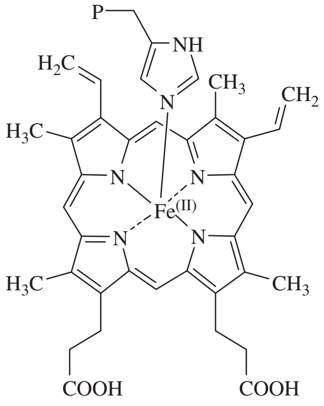
Several other haem pigments also occur in muscle tissue (such as cytochromes that carry out electron transport) containing iron in a similar porphyrin–protein complex to that in myoglobin.



9-4, haem

These pigments contribute to the colour of muscle tissue only very slightly. Haem pigments can similarly be found in the plant kingdom in the form of cytochromes and some oxidoreductases, such as catalase and peroxidase (see Section 6.2.2.7).

In myoglobin (**9-5**) and its derivatives, the fifth ligand is bound to the divalent iron atom via the imidazole group of histidine (His[93]). The fifth ligand is a protein (globin) with a relative molecular weight of 16.8 kDa. The sixth ligand is water, but this may be absent. The molecule of haemoglobin (referrd to as haemoglobin A) includes four polypeptide chains (two pairs of identical subunits α and β, for short $\alpha_2\beta_2$), each containing a single haem molecule (of relative molecular weight 64.5 kDa).



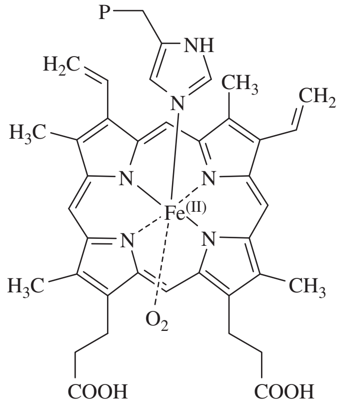
9-5, myoglobin (P = protein residue)

When myoglobin comes into contact with oxygen, it forms a reversible bright red pigment **oxymyoglobin** (**9-6**), where the sixth ligand donating both electrons to iron to form a coordinate bond is oxygen. This reaction, known as oxygenation, proceeds at oxygen partial pressures higher than 70–80 mmHg and its partial pressure in air is always higher, approximately 160 mm Hg.[2] At a very low

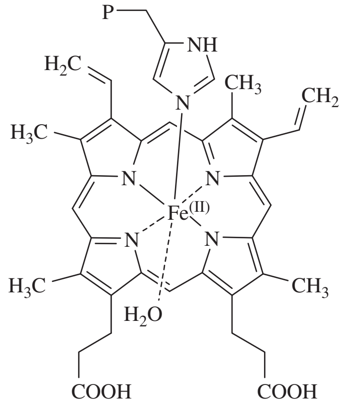
action of bacterial enzymes in the colon creates free bilirubin, which is further converted into other compounds. Of these, the most important compound is colourless urobilinogen. Part of urobilinogen gets to the bloodstream and to the kidneys, where it is oxidised to yellow urobilin IX α, which is the characteristic pigment of urine. Most urobilinogen is oxidised in the intestine to brown–red stercobilin IX α (via colourless stercobilinogen), which stains faeces.

[2]The sea level standard atmospheric pressure is 101.325 kPa, which is equal to 1 atm or 760 mmHg (torr) or 14.696 psi. So, if the air is 20.9% oxygen, the oxygen tension (partial pressure of oxygen) is 21.2 kPa, which corresponds to 159 mm Hg (1 mm Hg = 133.3 Pa).

oxygen partial pressure (<1.4 mmHg) typical of vacuum-packed meat, the electron deficiency of the iron allows it to interact ionically with water in the absence of stronger electron pair-donating ligands, which could form covalent linkages and water becomes the sixth ligand. The relevant purple–red pigment is called **deoxymyoglobin** (**9-7**). Analogously, haemoglobin gives rise to **oxyhaemoglobin** and **deoxyhaemoglobin**.

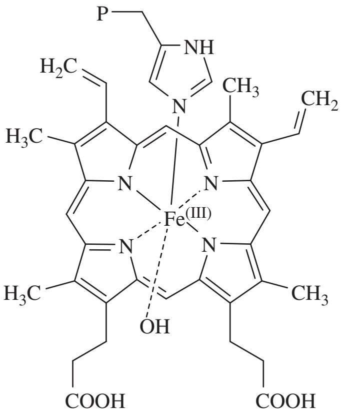


9-6, oxymyoglobin (P = protein residue)



9-7, deoxymyoglobin (P = protein residue)

An oxymyoglobin oxidation product containing trivalent iron is **metmyoglobin** (**9-8**), which is brown or gray–brown. Analogously, oxidation of haemoglobin (a loss of one electron) yields **methaemoglobin**.



9-8, metmyoglobin (P = protein residue)

Haem and its derivatives often have several different trivial names that describe the degree of oxidation of iron and bound ligands. An overview of these names is shown in Table 9.1.

9.2.1.2 Occurrence

Living organisms contain as the main pigment haemoglobin, whereas myoglobin represents only about 10% of the total iron present in the body. After slaughter and bleeding of animals, the predominant muscle pigment is myoglobin (Table 9.2). The content of myoglobin depends not only on the type of animal, but also on its age and the type of muscle (Table 9.3). The total average content of haem pigments in meat of various animals is given in Table 9.4. Dark meat (e.g. horse meat) contains more myoglobin than light meat (such as pork or veal). The meat colour is also linked to some meat defects. The levels of haem pigments in the dark and light muscle of some fish are given in Table 9.5.

Table 9.1 Nomenclature of haem pigments.

Name	Synonym	Oxidation degree Fe/other ligand	Name	Synonym	Oxidation degree Fe/other ligand
Haem	Ferroprotohaem IX	Fe(II)/H_2O	Haematin	Ferriprotohaem IX	Fe(III)/OH
	Protohaem			Hydroxyferriprotoporphyrin	
	Ferroprotoporphyrin IX			Alcaline haematin	
	Ferrous protoporphyrin IX		Haemin	Protohaemin IX	Fe(III)/Cl
	Reduced haematin			Chlorohaemin	
				Chloroferriprotoporphyrin	

Table 9.2 Haem pigments contents in beef and pork.

Meat	Myoglobin in mg/kg	Haemoglobin (mg/kg)	Proportion of myoglobin (%)
Beef	3140–7020	340–520	90–94
Pork	790–2320	360–1200	50–75

Table 9.3 Myoglobin content in beef and pork.[a]

Meat	Animal age	Muscle	Myoglobin (mg/kg)
Veal	12 days	*Longissimus dorsi*	700
Beef	3 years	*Longissimus dorsi*	4600
Pork	5 months	*Longissimus dorsi*	300
Pork	7 months	*Longissimus dorsi*	440
Pork	7 months	*Rectus femoris*	860

[a]For example, the muscle *Longissimus dorsi* is a muscle of pork loin (cutlet) and the muscle *Rectus femoris* is the main muscle of pork leg (oyster piece).

Table 9.4 Haem pigments contents in various animals.

Meat	Haem pigments (mg/kg)	Meat	Haem pigments (mg/kg)
Beef	1700–7 500	Boar	5500
Veal	438–1490	Deer	6000–7000
Pork	254–3500	Whales	9100
Horse	3620–8 000	Chicken	126–158
Lamb	2500	Turkey	125–456
Goat	6350	Goose	1586
Rabbit	200	Duck	1168

Fish	Haemoglobin (mg/kg)		Myoglobin (mg/kg)	
	Dark	Light	Dark	Light
Chub mackerel (*Scomber japonicus*)	5700	100	3900	<10
Pacific saury (*Cololabis saira*)	4800	350	270	10
Pacific bluefin tuna (*Thunnus orientalis*)	4900	1700	3200	700

9.2.1.3 Use

The natural content of myoglobin is particularly important for the colour of meat and meat products. The colouring properties of pork blood haemoglobin are also employed throughout the world in some speciality products, such as blood soup, blutwurst, blood pudding, black pudding and others. The blood has to be aseptically collected from healthy pigs and swiftly processed. In China, Thailand and Vietnam, pig, chicken, duck and goose blood is used in soups and other dishes. Drinking blood from cattle is a part of the traditional diet of Maasai people.

9.2.1.4 Biochemistry, physiology and nutrition

Biosynthesis of porphyrins is based on 5-aminolaevulinic acid (5-amino-4-oxopentanoic) acid, which is synthesised from succinic acid and glycine in animal cells, and from glutamic acid in plant cells. Condensation of two molecules of 5-aminolaevulinic acid yields a straight-chain pyrrole derivative porphobilinogen that condenses to form a cyclic tetrapyrrole derivative hydroxymethylbilane, which is the precursor of uroporphyrinogen III, the common intermediate of porphyrins and corrinoids. Through a sequence of subsequent reactions, uroporphyrinogen III gives rise to protoporphyrin IX, the common intermediate of biosynthesis of haem and chlorophyll pigments, which is subsequently transformed into haemoproteins haemoglobin and myoglobin.

Haemoproteins are a large group of proteins performing different functions in animal and plant organisms. In animals, haemoglobin plays a fundamental role as a carrier of oxygen and carbon dioxide, while myoglobin is a reservoir of oxygen. Haem pigments also play a key role in energy conversion in cytochromes, and are responsible for the procuring the energy that animals produce by oxidation of nutrients in the respiratory chain and plants by photosynthesis.

As well as oxygen, myoglobin and haemoglobin can also bind other compounds. For example, poisoning by carbon monoxide (CO) transforms myoglobin into carbonylmyoglobin and haemoglobin into carbonylhaemoglobin, as the affinity of these pigments for carbon monoxide is about 130 times higher than their affinity for oxygen, therefore oxygen is displaced by the new ligand carbon monoxide. The same pigments are formed in meat packaged in a carbon monoxide atmosphere. Poisoning by cyanides leads analogously to the formation of cyanomyoglobin and cyanohaemoglobin.

From the nutritional point of view, haem pigments are of considerable importance in the supply of iron to the human organism. The so-called haem iron, which includes iron bound in myoglobin and haemoglobin and iron bound in muscle respiratory enzymes, is absorbed in the body at a level of 10–30%, while non-haem iron from only 1–5%.

9.2.1.5 Properties and reactions

The colour of meat and meat products depends on many factors, especially on the oxidation level of the central iron atom, the ligands that surround the central atom and the structure of the protein moiety.

9.2.1.5.1 *Pigments of raw meat*

Consumers usually consider the bright red colour of meat as a sign of freshness. The colour of freshly cut or minced meat comes from two types of pigments, myoglobin/oxymyoglobin and metmyoglobin. After several hours or days of exposure, oxymyoglobin can convert into metmyoglobin, which has a brown–grey colour. The colour of vacuum packed meat containing deoxymyoglobin is purplish–pink. The colour of meat packaged in an atmosphere of carbon monoxide is clearly cherry-red (typical CO concentrations range from 0.4 to 0.5%).

Atmospheric oxygen diffuses from the air into the surface layer of meat (with a thickness of up to 10 mm); myoglobin is transformed by oxygenation into bright red oxymyoglobin, and so meat acquires an attractive bright red colour (Figure 9.1). The binding of oxygen is enabled by the second histidine residue of the myoglobin molecule (His^{64}, the so-called distal histidine) through hydrogen or O–N bonds (Figure 9.2). The reaction is reversible, since oxygen dissociates from oxymyoglobin continuously. At a higher oxygen partial pressure, oxymyoglobin is fairly stable since the ligand oxygen is stabilised by a three-dimensional structure of apoprotein surrounding the haem. At low oxygen tension, however, which occurs at the interface between the oxymyoglobin and myoglobin layers during meat storage in the air, both meat pigments are slowly oxidised by air oxygen to the brown–grey, unattractive metmyoglobin, as the binding of oxygen in oxymyoglobin involves a charge migration from the haem to oxygen, probably via superoxoferrihaem $[Fe^{3+}\ O_2^{-}]^{2+}$ intermediate, which dissociates to metmyoglobin and superoxide radical (Figure 9.3).

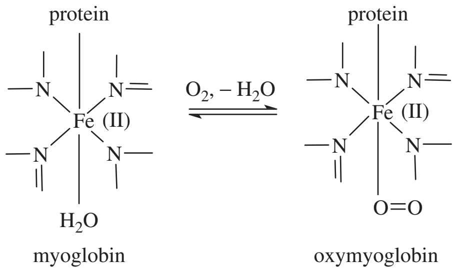

Figure 9.1 Formation of oxymyoglobin from myoglobin.

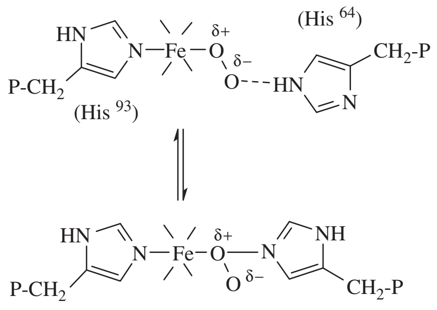

Figure 9.2 Oxygen binding and its stabilisation in myoglobin molecule (P = protein residue).

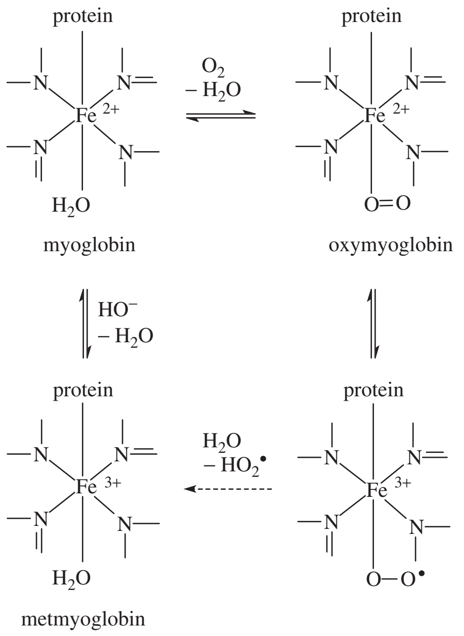

Figure 9.3 Formation of metmyoglobin in meat.

Fresh meat contains reducing agents (e.g. thiol groups of proteins and oxidoreductases with NADH as cofactors), which continuously reduce metmyoglobin to myoglobin. After oxidation of these reducing substances, a brown layer of metmyoglobin is gradually formed below the surface of the meat, and eventually the entire surface turns brown. Browning is an indication that the meat is not particularly fresh. The autoxidation of haemoglobin to methaemoglobin occurs in the same way. The colour of vacuum-packed meat, and of meat packaged in a carbon monoxide atmosphere, is more stable.

The oxidation of Fe^{2+} to Fe^{3+} is accelerated by light and at higher temperatures and lower pH. For example, the oxidation is faster after *rigor mortis* dissipates (when the pH of the meat is 5–6), than immediately post-mortem, when the pH of the meat is almost neutral. Oxidation is also accelerated by certain metal ions, especially Cu^{2+} ions; other metals, such as Fe^{3+}, Zn^{2+} and Al^{3+} are less active.

In addition to the change in meat colour, autoxidation of meat pigments has other undesirable consequences. Oxygen bound in oxymyoglobin dissociates after protonation, and autoxidation of oxymyoglobin to metmyoglobin produces free superoxide radicals (Figure 9.3). The distal histidine acts as a proton donor, as do certain protein functional groups of the environment. Superoxide free radicals and the eventually formed hydroxyl radicals can initiate autoxidation of fatty acids, which can lead to rancidity in fatty parts of the meat. In all organisms *in vivo* (except bacteria) the superoxide radical is removed by the action of superoxide dismutase, which catalyses the dismutation of superoxide radical into oxygen and hydrogen peroxide. Hydrogen peroxide is then decomposed to water and oxygen by catalase. In meat, superoxide radical rapidly dismutates to oxygen and hydrogen peroxide.

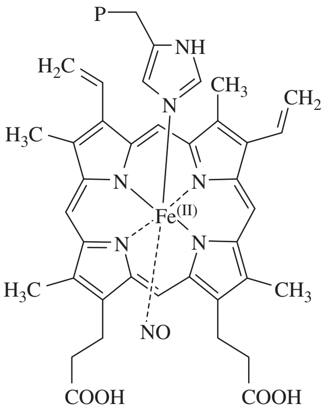
9.2.1.5.2 Meat colour stabilisation

Salt has been used in the practice of meat preserving for centuries because of its ability to draw out moisture and prevent microbial growth. Long before refrigeration and freezing, salt was the preservative of choice for ancient civilisations, as well as sailors and early pioneers. Salt preservation is still a valid method that is widely used. The prevention of changes in colour during heat treatment and simultaneous inhibition of the growth of bacterial pathogenesis is achieved by the addition of curing salts. Curing salts, usually containing salt (sodium chloride) in a mixture with either nitrites or nitrates, are often used in combination with other features, such as smoking. In most cured meat products, the addition of nitrites and/or nitrates is necessary to prevent the growth and toxin production by the bacteria *Clostridium botulinum*. Nitrates have no direct activity against *C. botulinum*, but they act as reservoirs of nitrites that are generated from nitrates by microbial activity. The use of nitrates and nitrites in cured meat and meat products must comply with the EU legislation.[3]

The reaction of meat pigments with nitrites and/or nitrates, which provides the cured meat colour and flavour, is very complex. Typically, the product is cured by injection with the curing salt solution, followed by immersion in brine, or simply immersion only is used. The dry curing process involves the dry application of the curing mixture containing nitrites and/or nitrates, salt and other components to the surface of the meat, followed by a period of stabilisation/maturation. Nitrites are first reduced to nitrogen monoxide (nitric oxide) by myoglobin and other reducing agents, while myoglobin is oxidised to metmyoglobin:

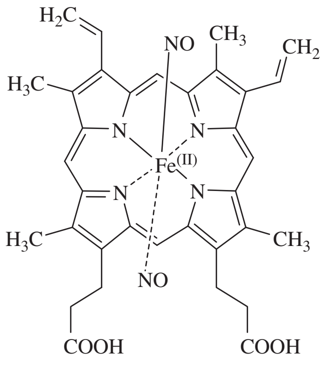
$$\text{myoglobin} + NO_2^- \rightarrow \text{metmyoglobin} + NO$$

The resulting nitrogen monoxide reacts with another molecule of myoglobin to form a red pigment **nitrosomyoglobin** (formerly also called nitroxymyoglobin or nitrosylmyoglobin, **9-9**). The reaction of nitrogen monoxide with metmyoglobin yields nitrosometmyoglobin that can also be formed by reaction of nitrogen monoxide with metmyoglobin nitrite (**9-8**, instead of N=O is the NO_2^- anion is present). Nitrosomyoglobin also occurs in meat, which does not contain nitrites, when smoking meat in the home, as flue gas contains various nitrogen oxides. Metmyoglobin formed by oxidation of myoglobin is reduced back to myoglobin either chemically (the electron donors are thiol groups of proteins and other thiols) or by the system of dehydrogenases containing NAD as a cofactor. In the same way nitrosometmyoglobin is also reduced to form nitrosomyoglobin. The reaction of nitrites with oxymyoglobin in the surface layers of meat leads to oxidation of nitrite, and even of haem iron (the oxidising agent is oxygen bound in oxymyoglobin). This reaction explains the grey–brown colour of the surface layers of cured meat, while meat is pink inside.



9-9, nitrosomyoglobin (P = protein residue)

Nitroxymyoglobin is a very stable pigment at normal temperatures as the bound ligand nitrogen monoxide is stabilised, as oxygen in oxymyoglobin, by the N–N bond with the distal histidine (His[64]). During heat treatment, nitroxymyoglobin is denatured, splits off the globin and the vacant coordination bond of iron is occupied by another nitric oxide molecule, which yields the most important pigment of heat-treated cured meat and meat products with NO ligands in both axial positions that is called **nitrosohaemochrome** (also nitroxyhaemochrome and nitrosylmyochromogen, **9-10**). At the same time other meat proteins denature, and their accessible thiol groups then reduce the metmyoglobin that are produced back to myoglobin, which can then be used for the formation of a further portion of nitrosohaemochrome.



9-10, nitrosohaemochrome

Better colour of smoked meat products is achieved by adding reducing agents together with nitrites. The most commonly used agents are L-ascorbic acid, sodium L-ascorbate, L-ascorbyl

[3]The use of nitrates and nitrites in cured meat products must comply with the provisions set out in Directive 2006/52/EC, which amends Directive 95/2/EC on additives other than colours and sweeteners. Currently authorised as food additives are sodium and potassium nitrites and sodium and potassium nitrates that may be sold only in a mixture with salt or a salt substitute. The indicative ingoing amount of potassium and sodium nitrites that are authorised for use are 150 mg/kg and the residual amount is 50 mg/kg (KNO_2) in non-heat-treated, dried meat products, 100 mg/kg ($NaNO_2$) in other cured meat products, canned meat products and 175 mg/kg ($NaNO_2$) in cured bacon. The indicative ingoing amount of potassium and sodium nitrates is 300 mg/kg in all cured products and the residual amount in cured and canned meat products is 250 mg/kg, in pickled herring and sprat 200 mg/kg and in hard, semi-hard and semi-soft cheeses and dairy-based cheese analogues 50 mg/kg.

palmitate or sodium L-isoascorbate (erythorbate). The addition of ascorbate is preferred because it does not impair the pH of the meat. Reducing agents reduce metmyoglobin back to myoglobin and also produce nitrogen monoxide from nitrites without the participation of myoglobin (H_2A = ascorbic acid, A = dehydroascorbic acid):

$$2\ \text{metmyoglobin} + H_2A \rightarrow 2\ \text{myoglobin} + A$$

$$2NO_2^- + H_2A + 2\ H^+ \rightarrow 2NO + A + 2H_2O$$

If nitrates are used instead of nitrites, they are reduced to nitrites by the microflora that are present. If ascorbic acid is used, it reduces nitrates to nitrites as follows:

$$2NO_3^- + H_2A + 2H^+ \rightarrow 2NO_2^- + A + 2H_2O$$

If protected from light, nitrosohaemochrome is stable to oxidation even at elevated temperatures, but in light the molecule dissociates to nitrogen monoxide, which is oxidised to nitrogen dioxide, and the haem produced is rapidly oxidised to haematin or further degraded in the presence of oxygen or other oxidising agents. Meat products then become greyish and fade.

Myoglobin can degrade through a number of pathways producing dark brown, yellow and even green pigments that may cause colour defects, for example, in minced meat and some meat products. The colour change can be also caused by air oxygen, fatty acid hydroperoxides or hydrogen peroxide generated, for example, from added ascorbic acid or by lactobacilli in fermented salami. The oxidation occurs even when nitrites or ascorbic acid are over-dosed and in the absence of reducing substances in meat, which leads to grey and green pigments.

Myoglobin readily reacts with hydrogen peroxide and fatty acid hydroperoxides. The oxidation of myoglobin by hydrogen peroxide starts with the formation of a radical in the globin portion of the molecule and conversion of the haem Fe^{3+} iron into the Fe^{4+} state. The reaction probably proceeds via a red radical intermediate **perferrylmyoglobin** (containing tetravalent iron), which rapidly breaks down to green **ferrylmyoglobin** (containing tetravalent iron, native globin and oxygen atom as the ligand):

$$\text{myoglobin } (Fe^{2+}–O_2) + H_2O_2 \rightarrow \text{perferrylmyoglobin}^\bullet$$
$$\rightarrow \text{ferrylmyoglobin } (Fe^{4+}–O_2) + H_2O + O_2^-$$

Hydrogen peroxide can also irreversibly oxidise the porphyrin ring in myoglobin, yielding green **choleglobin** (containing native globin, Fe^{3+} or Fe^{2+} and a covalently or ionically bound hydroperoxide O–OH group as the ligand). Choleglobin is rapidly degraded to yield globin, iron and a tetrapyrrole.

In the presence of sulfhydryl substances, myoglobin can be reversibly reduced at one double bond by the reaction with sulfane and oxygen (via ferrylmyoglobin) to green **sulfmyoglobin** containing native globin, Fe^{2+} and covalently bound SH group as the ligand:

$$\text{ferrylmyoglobin } (Fe^{4+}–O_2) + HS^-$$
$$\rightarrow \text{sulfmyoglobin } (Fe^{2+}–SH) + HO^-$$

Oxidation of sulfmyoglobin (loss of one electron) yields red metsulfmyoglobin containing Fe^{3+} and an ionically bound SH group as the ligand. During heat treatment, the globin of green pigments is denatured and split off with the formation of green **verdochrome** (containing Fe^{3+} and ionically bound water as the ligand) with porphyrin ring opening.

9.2.1.5.3 Pigments of heat-processed meat

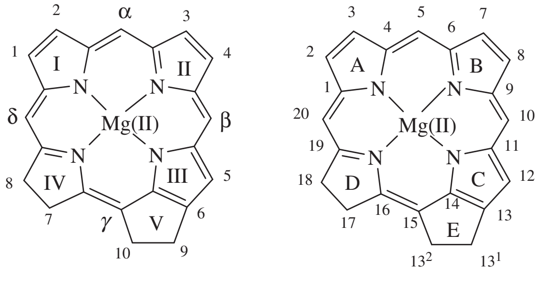
When meat is cooked, globin denatures at temperatures above about 65 °C (along with other proteins) to a degree that depends on pH and the intensity and time of thermal processing, but the haem portion remains intact. The colour of the haem pigments containing denatured globin is determined by the oxidation state of haem iron and the sixth ligand molecule, which is attached to haem. The denatured globin cannot actually maintain iron in the reduced state, therefore haem is oxidised to haematin (metmyoglobin with denatured globin) and the red meat colour is changed to brown and then even further to grey–brown.

9.2.2 Chlorophylls

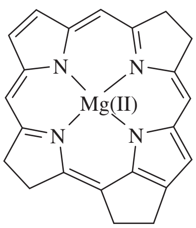
Chlorophyll pigments or **chlorophylls** are a group of green pigments, which are found in tissues of organisms providing photosynthesis. Originally the name chlorophylls were only used for green pigments involved in photosynthesis in higher plants, but later it was extended to all photosynthetic porphyrin pigments that occur in almost all higher plants, mosses and algae. Some bacteria also contain pigments known as **bacteriochlorophylls**. Several different types of chlorophylls have been described and it is assumed that other pigments may yet be found in the lesser-known species of algae.

9.2.2.1 Structure and nomenclature

The structural base of most chlorophylls is the cyclic tetrapyrrole **17,18-dihydroporphyrin** (**9-11**) derived from protoporphyrin IX. Unlike haem pigments, chlorophylls have a partially reduced ring D (they are 17,18-dihydroporphyrins), another ring E generated by cyclisation of the propionic acid residue in position C-13 and as the central atom they have chelated magnesium (magnesium ion of oxidation number +2). Bacteriochlorophylls are **7,8,17,18-tetrahydroporphyrins** (**9-12**).



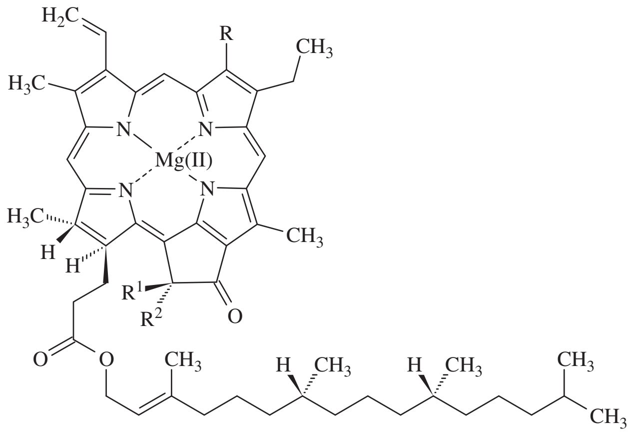
9-11, basic structure of dihydroporphyrin pigments by the older Fischer system (left) and the IUPAC recommended system (right)



9-12, basic structure of tetrahydroporphyrin pigments

From the food perspective, the most important chlorophylls are chlorophyll *a* and chlorophyll *b* and their degradation products **phaeophytins**, respectively, 17,18-dihydrophaeophytins (phaeophytin *a* and phaeophytin *b*). Some other products of chlorophyll biosynthesis and degradation are also components of foods, such as **chlorophylides**, respectively, 17,18-dihydrophaeophorbideato-Mg(II) (chlorophylide *a* and chlorophylide *b*), and **phaeophorbides**, respectively, 17,18-dihydrophaeophorbides (phaeophorbide *a* and phaeophorbide *b*).

Chlorophyll *a*, 17,18 dihydrophaeophytinato-Mg(II), is 17,18-dihydroporphyrin substituted in positions C-2, C-7, C-12 and C-18 by methyl groups, in position C-3 by a vinyl group and in position C-8 by an ethyl group. In position C-17 there is a residue of propionic acid esterified by diterpenic alcohol phytol, (2*E*,7*R*,11*R*)-3,7,11,15-tetramethylhexadec-2-en-1-ol, which constitutes a lipophilic side chain of the chlorophylls. In position C-13^1 of ring E there is an oxo group and in position C-13^2 a carboxymethyl group (**9-13**). Chlorophylls *a* and *b* differ only by the substituent at C-7: a methyl group in chlorophyll *a* and a formyl group in chlorophyll *b*. Chlorophylls *a*′ and *b*′, which differ in their configuration of C-13^2 substituents, arise by epimerisation of chlorophyls *a* and *b* in thermal processes and, particularly, in alkaline media. The structures of all currently known chlorophylls and bacteriochlorophylls are listed in Table 9.6.



9-13, chlorophylls

chlorophyll *a*, R = CH_3, R^1 = H, R^2 = $COOCH_3$
chlorophyll *b*, R = CH=O, R^1 = H, R^2 = $COOCH_3$
chlorophyll *a*´, R = CH_3, R^1 = $COOCH_3$, R^2 = H
chlorophyll *b*´, R = CH=O, R^1 =$COOCH_3$, R^2 = H

Phaeophytins are derived from chlorophylls, with hydrogen replacing magnesium (**9-14**). Hydrolysis of phytol in chlorophylls

Table 9.6 Overview of chlorophyll and bacteriochlorophyll structures.

Pigment	Substituent at carbon[a]					
	C-3	C-7	C-8	C-17	C-18	C-20
Dihydroporphyrins						
Chlorophyll *a*	CH=CH_2	CH_3	CH_2CH_3	Phytyl and H	CH_3 and H	
Chlorophyll *b*	CH=CH_2	CH=O	CH_2CH_3	Phytyl and H	CH_3 and H	
Chlorophyll *d*	CH=O	CH_3	CH_2CH_3	Phytyl and H	CH_3 and H

Chlorophyll *c*	Algae (*Phaeophyta*, *Pyrrophyta*, *Bacillariophyta*, *Chrysophyta*, *Prasinophyta*, *Cryptophyta*, *Xanthophyta*)
Chlorophyll *d*	Algae (*Rhodophyta, Chrysophyta*)
Bacteriochlorophyll *a*, *b*	Bacteria (*Chromatiaceae*, *Rhodospirillaceae*)
Bacteriochlorophyll *c*, *d*, *e*	Bacteria (*Chlorobiaceae*, *Chloroflexaceae*)

9.2.2.2 Occurrence

Chlorophylls are found in all green plants, algae and also in some microorganisms (Table 9.7). Germ cells of flowering plants (angiosperms, Angiospermae) that grow in the dark lack chlorophyll, because the enzyme protochlorophylide reductase (which reduces the colourless intermediate protochlorophylide to chlorophylide) requires light. These so-called etiolated plants will start to synthesise chlorophyll after exposure to light. Anoxygenic photosynthetic bacteria do not need light to catalyse this reaction, as they contain other enzymes. Cyanobacteria, algae, lower plants and gymnosperms (Gymnospermae), such as conifers, synthesise chlorophyll even in the dark.

Food contains mainly chlorophyll *a* and chlorophyll *b* originating from higher plants. These two forms are present in the ratio of about 3 : 1. The total chlorophyll contents in the green parts of plants are very different. Grapes, for example, only contain chlorophyll at a level of about 6 mg/kg, whereas spinach contains up to 790 mg/kg of chlorophyll, while the ratio of concentrations of both compounds ranges from 2.4 to 3.1.

Chlorophylls in living cells are located in chloroplasts (the thylakoid membrane, which is a lipid double layer consisting mainly of galactolipids and a small amount of membrane phospholipids containing higher amounts of linoleic and linolenic acids). Chlorophylls in chloroplasts are associated by non-bonding interactions with proteins with a relative molecular weight of 26–28 kDa. These complexes are further associated along the phytol chain

with carotenes, xanthophylls and tocopherols. Ten molecules of chlorophylls are associated with about one lipophilic molecule.

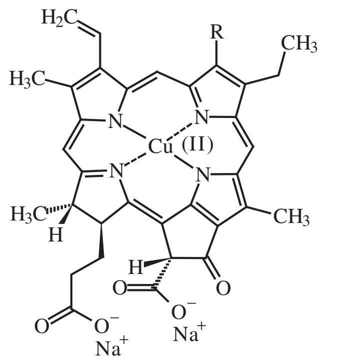
9.2.2.3 Use

Chlorophylls are practically the only natural green pigments that occur naturally in almost unlimited quantities. The total amount of chlorophylls that are produced annually on Earth is estimated at 11.5×10^8 tons, of which 2.9×10^8 tons arise on land and 8.6×10^8 tons in the oceans. They mainly occur as natural food pigments, because their great instability prevents further utilisation. For example, chlorophylls *a* and *b* are not used as such (underivatised), since their acquisition from natural resources is costly and the product is not stable enough.

The most common forms of green pigments used as food additives are fat-soluble mixtures of green pigments, commercially known as chlorophylls or chlorophyll copper complexes. Chlorophylls are mixtures of products consisting mainly of phaeophytins *a* and *b* and their epimers (known as phaeophytins *a′*and *b′*) differing in the arrangement of position C-13^2. Most of the chlorophylls for food use are obtained from edible plants growing on land, mainly nettles, alfalfa, parsley leaves and others. In Japan, chlorophylls are extracted from green silkworm (*Bombyx mori*) excrements. A promising procedure is the isolation of chlorophylls from unicellular phytoplankton.

The water-soluble greyish-green semi-synthetic mixture of pigments called **chlorophyllins** (or phytochlorins) is prepared by alkaline hydrolysis of chlorophylls, which results in hydrolysis of methyl and phytyl esters. Chlorophyllins contain a central magnesium atom and sodium or potassium salts of various products resulting from chlorophylls after alkaline hydrolysis, such as salts of phaeophorbides *a* and *b*, salts of phaeophytins *a* and *b* and their *allo*-forms (diastereoisomers), pigments with a carboxyl group at position C-13 and a carboxyethyl group at position C-17 and products with an opened cyclopentanone E ring that contains a newly formed carboxymethyl group in position C-15. Other products may include compounds with an oxidised ring D not connected to ring E, and possibly a reduced vinyl group in position C-3. These products were previously known, for example, as chlorins, purpurins and rhodins. Typically chlorin e_6 is a phaeophorbide derived product (it does not contain a magnesium ion or bound phytol) with a carboxyl group at position C-13, a carboxyethyl group at position C-17 and a carboxymethyl group in position C-15. Instead of chlorophyllin, the recommended name is now rhodochlorin. Stable bright green pigments with the trade name **chlorophyllin copper complex** are obtained by acidification of chlorophyllins in the presence of copper salts. Instead of magnesium, these products contain Cu(II) as the central atom. An example of a trisodium salt of chlorophyllin copper complex is given in formula **9-17**.

Chlorophylls are used as food pigments, for example, for dyeing pasta products, beverages, sweets, soups, frozen yoghurts and creams. These dyes are used most heavily in cosmetic products. The use of a chlorophyllin copper complex (under the name of natural green 3) is usually limited to certain products, such as chewing gum. These pigments have also found use in alternative medicine, such as odour control of wounds, injuries and radiation burns and treatment of calcium oxalate kidney stones.



9-17, trisodium chlorophyllin copper complex

9.2.2.4 Biochemistry, physiology and nutrition

The common intermediate of haem and chlorophyll pigments biosynthesis, protoporphyrin IX, is transformed into chlorophylide by a sequence of several reaction steps. Chlorophyll *a* arises from chlorophylide in a reaction with phytyl diphosphate that is produced by the reduction of geranylgeranyl diphosphate. Oxidation of the C-7 methyl group in chlorophyll *a* to a formyl group yields chlorophyll *b*.

Chlorophylls, as catalysts of photosynthesis, are normal constituents of foods of plant origin, and are ingested daily over a lifetime by both animals and humans without any appreciable health risks. In people with certain genetic abnormalities such as albinism, also called achromia (a disorder characterised by the complete or partial absence of pigment in the skin, hair and eyes, due to the absence or defect of tyrosinase producing pigments called melanins), inflammation of the skin (dermatitis) is observed after exposure to sunlight. Photosensitivity is associated with the presence of chlorophylides, particularly phaeophorbides, methylphaeophorbides and hydroxyphaeophorbides (having a hydroxyl group on C-13^2 instead of H atom), which are found in certain foods and food supplements (such as products containing algae of the genus *Chlorella*).

9.2.2.5 Properties and reactions

Chlorophylls and phaeophytins are fat-soluble pigments. Chlorophylides and phaeophorbides are hydrophilic pigments soluble in water due to the absence of phytol. The colours of chlorophylls and derived products are given in Table 9.8.

An overview of the main reactions of chlorophylls and their degradation products is shown in Figure 9.4. The most important reaction occurring during food processing is the replacement of the central magnesium atom by hydrogen and the formation of phaeophytins. This reaction, called **phaeophytinisation**, proceeds even in weakly acidic media, which are normally found in fruits and vegetables, such as sweet pickled greengages and sour pickled cucumbers. The action of the enzyme chlorophyllase or strong acids

Table 9.8 Colour of chlorophylls and some of their degradation products.

Pigment	Colour	Pigment	Colour
Chlorophyl *a*	Blue-green	Bacteriochlorophyll *c*	Green
Chlorophyl *b*	Green	Bacteriochlorophyll *d*	Green
Chlorophyl c_1	Yellow-green	Bacteriochlorophyll *e*	Green

Bacteriochlorophyll *b*	Brown-pink	Open ring products	Colourless

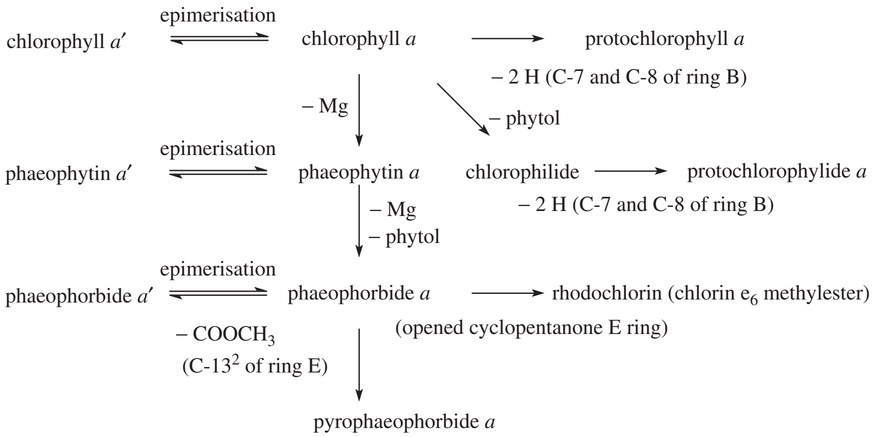

Figure 9.4 Main reactions of chlorophylls during food processing.

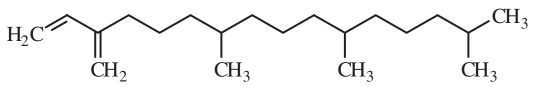
results in phytol hydrolysis in phaeophytins and the formation of phaeophorbides. In enzymatically active plant tissues, the hydrolysis of phytol in chlorophylls by chlorophyllase yields chlorophylides. Replacing magnesium with hydrogen in chlorophylides in weakly acidic media leads to phaeophorbides, which are coloured like phaeophytins. This is one of reasons why green vegetables (such as beans, peas and broccoli) have to be blanched to destroy the enzyme activity before preservation by freezing.

Phytol formed by hydrolysis of chlorophylls can further dehydrate to various phytadienes, an example of which is neophytadiene (**9-18**). Microbial degradation of phytol in the rumen of ruminants gives branched fatty acids (see Section 3.3.3.3.2).



9-18, 7,11,15-trimethyl-3-methylidenehexadec-1-ene

The majority of manufacturing processes and storage of green fruits and vegetable result in a greater or lesser extent of chlorophylls degradation, which is accelerated by temperature, light and ionising radiation, the presence of acids and some enzymes. The rate of chlorophyll degradation depends on the blanching or sterilisation time and temperature before freezing. Changes occurring during blanching of green beans and sterilisation of spinach are evident from the data presented in Table 9.9. Some degradation of chlorophylls occurs even during cold storage of vegetables. Deeper changes take place when the material is exposed to heat in an acidic environment, which results in the formation of phaeophytins and other degradation products. For example, the main pigments in fermented cucumbers are phaeophorbides, followed by phaeophytins, chlorophylls and chlorophylides. Phaeophorbides and phaeophytins are also the main pigments in fermented olives.

The negative effect of light is reflected especially during drying. Fruits and vegetables pre-treated with sulfur dioxide to prevent enzymatic browning reactions are much more sensitive. If the vegetables are stored in transparent containers, photooxidation continues. Ionising radiation also has a negative effect. Chlorophyll degradation is also affected by certain enzyme systems. For example, changes in chlorophyll pigments during storage of green beans and peas are attributed to degradation of chlorophyll pigments by lipoxygenase, which leads to the formation of free radicals and chlorophyll degradation.

Phaeophytinisation and other reactions described above negatively affect the sensory quality of foods containing chlorophyll pigments. The main principles of colour stabilisation are based on the positive effect of added alkaline agents (such as carbonates),

Table 9.9 Changes in chlorophylls and phaeophitins in vegetable processing (% of total pigment content in the original material).

Pigment	Green beans		Spinach	
	Raw	Blanched (100 °C/240 s)	Raw	Sterilised (127 °C/96 s)

HTST (High Temperature Short Time) sterilisation and enzymatic conversion of chlorophylls to chlorophylides or a combination of these methods. It is also necessary to combine these procedures with storage of products at low temperatures.

Chlorophyll pigments are readily extracted with the oil from oil seeds and impart a greenish colour to the crude oil. If this oil is then processed by conventional refining techniques, chlorophylls are converted into phaeophytins, which gives the oil a dark, dull brown colour and contributes to an off-flavour. In the light, chlorophyll pigments may promote formation of oxygen radicals and speed up oil oxidation and reduce its storage stability. In oils protected from light, however, chlorophylls act as primary antioxidants. Chlorophyll pigments also act as catalyst poisons in oil hardening. Together with other undesirable substances, chlorophylls are therefore removed during refining (bleaching). Chlorophylls, however, are prominent pigments in extra virgin and virgin olive oils that are not refined. The chlorophyll content in olive oil depends on genetic factors (olive variety), geographical origin, stage of fruit ripeness (olives picked green produce greener oil), environmental conditions, the extraction process and storage conditions. A component of the unsaponifiable fraction of oils (especially of olive oils) is phytol.

For example, the main pigments of rapeseeds are chlorophyll *a* and *b*, minority pigments are phaeophytin *a*, phaeophorbide *a* and methylphaeophorbide *a*. Crude rapeseed oils contain as the main pigment phaeophytin *a*, smaller amounts of pyrophaeophytin *a* and the minority pigments are phaeophorbide *a*, methylphaeophorbide *a* and phaeophytin *b*. The total content of chlorophyll pigments in crude oils is 5–50 mg/kg. Refined (bleached) rapeseed oils may typically contain only traces (<1 mg/kg) of chlorophyll pigments. Soya oil typically contains less than 1 mg/kg of chlorophylls. The olive oil concentrations of chlorophylls vary over a wide range, from 2 to 76 mg/kg.

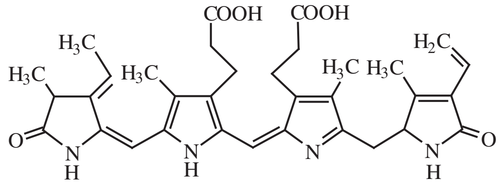
Chlorophylls form complexes with certain metals, for example, with Zn^{2+}, Cu^{2+} and Sn^{2+} (Figure 9.5), in which these metals, unlike magnesium, are bound tightly and are not released during manufacturing processes. The complexes are not cleaved even in the human digestive tract, and the metals are therefore not utilised. In earlier technological practice, the transformation of chlorophyll to phaeophytin and the related undesirable colour changes were prevented by the exchange of magnesium ion for copper ion in a solution of cupric sulfate. Today, this procedure is not used for health reasons, but the use of a chlorophyllin copper complex is permitted in some countries for food colouring. Grey–brown Sn^{2+} complexes sometimes occur in canned fruits and vegetables in containers made of tinplate. Phaeophytins, chlorophylides and phaeophorbides may also react with metal ions.

9.2.3 Phycobilins

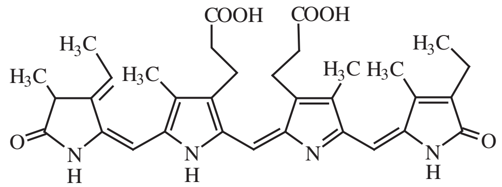
Algal bilins (phycobilins or phycobiliproteins) are fluorescent, water-soluble linear complexes of tetrapyrrole with proteins. The range of colours of phycobilins is extremely wide and depends on the source and other factors. Pigments obtained from blue–green algae (of the class Cyanophyta) were originally called C-phycobilins, and pigments of red algae (of the class Rhodophyta) were R-phycobilins. Phycobilins are divided into three main groups:

- red **phycoerythrins**
- blue **phycocyanins**
- blue **allophycocyanins**.

Phycoerythrins include four groups of compounds: C-, R- and B-phycoerythrins of red algae of the order Bangiales and cryptomonad erythrins of the algae class Cryptophyta. Also identified are C-, R- and cryptomonad phycocyanins (algae of the class Cryptophyta contain only phycoerythrins). Allophycocyanin is the only pigment. The native forms of phycobilins are composed of several bilin chromophores attached to one or two apoproteins (called α and β). Chromophores of red phycoerythrins are called phycoerythrobilins (**9-19**), chromophores of blue phycocyanins and allophycocyanins are called phycocyanobilins (**9-20**). The structure of phycobilins is very similar to the structure of mammalian bile pigments biliverdin and bilirubin, which arise as products of the catabolism of haem pigments. To date, phycobilins have not been used for food colouring in practice, but are regarded as promising pigments.



9-19, phycoerythrobilin



9-20, phycocyanobilin

9.3 Other nitrogen pigments

In addition to tetrapyrrole pigments, foods contain many other nitrogenous pigments. These pigments are theoretically derived from:

- indole
- isoquinoline
- pyrimidine.

The indole pigments include widespread animal pigments **melanins**, but also dyes of plant origin, such as **indigo**, which is not used for colouring food. Other significant indole (dihydroindole or derived dihydropyridine) pigments are water soluble red and yellow plant pigments, which are collectively called **betalains**. The only important pigment of isoquinoline type is the yellow alkaloid berberine. Substituted pyrimidines include three main groups of pigments with four nitrogen atoms in the molecule:

- purines
- pterines
- isoalloxazines.

Compounds structurally related to pterines are **phenazine** and **phenoxazine** derivatives; the most prominent representative of **isoalloxazines** is riboflavin.

9.3.1 Indoles and related compounds

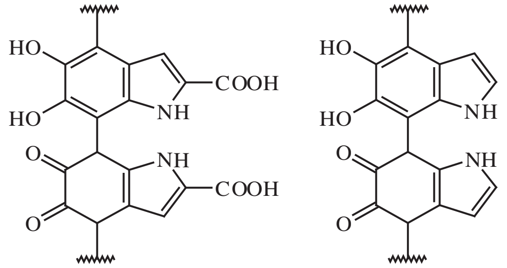
9.3.1.1 Melanins

Melanins are an important group of pigments found in all living organisms. They are divided into three basic groups (combined melanins are products of co-polymerisation of nitrogen-containing and sulfur-containing melanogens):

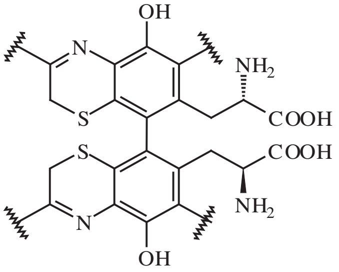
- **eumelanins** (polymerisation products of nitrogen melanogens)
- **phaeomelanins** (polymerisation products of sulfur melanogens)
- **allomelanins** (polymerisation products of polyphenols).

Melanins are formed by radical reactions *in vivo* in a process called melanogenesis, probably as a protection against harmful environmental effects upon the organism. For example, mammalian eumelanins efficiently absorb UV radiation and protect cells against reactive forms of oxygen and peroxyl radicals arising from lipids. Melanogenesis in pathogenic fungi and bacteria is associated with increased virulence, and melanins in bacteria are involved in fixation of atmospheric nitrogen.

Brown to black eumelanins (**9-21**) and yellow to red phaeomelanins (**9-22**) in various stages of oxidation and polymerisation are common pigments of skin, hair, eyes, feathers and scales of mammals, birds, reptiles, amphibians, fish and other organisms. Eumelanins and phaeomelanins in human skin arise in the basal layer of epidermis in the specialised cells melanocytes. In melanocytes, melanins occur in the cytoplasmic vacuoles, melanosomes, often in complexes with metals (Fe, Cu and Zn) and proteins. Melanins are often accompanied by other pigments, resulting in countless shades of black, brown, yellow and red colours. Phaeomelanins and eumelanins also contribute to the anomalous colour effects, such as iridiscence (interference) of colours often seen in the butterflies, reptiles and fish (they look and act like a transparent pearl, but play with the light and reflect colour with mysterious effects). Their biosynthesis, as well as biosynthesis of betalains, starts from L-tyrosine and continues via



9-21, basic structures of eumelanins



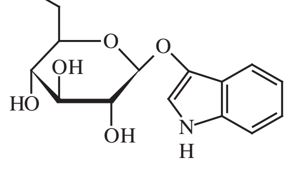
9-22, basic structure of phaeomelanins

3,4-dihydroxy-L-phenylalanine (known as L-DOPA or L-dopa) and other intermediates. Important intermediates are L-dopaquinone, 5,6-dihydroxyindole-2-carboxylic acid, its decarboxylation product 5,6-dihydroxyindole and related quinones (melanogens), which are further oxidised and polymerised to eumelanins. In the presence of thiols, such as cysteine and reduced glutathione, dopaquinone yields cysteinyl-L-dopa and its oxidation leads to benzothiazines, which polymerise to phaeomelanins.

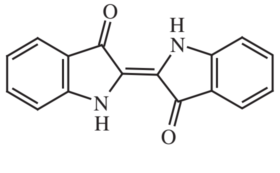
Brown to black allomelanins are a heterogeneous group of melanin pigments, which are common in many fungi, higher plants and even in some animals. They include nitrogen-free polymeric products formed from phenols and quinones that are located, for example in nut shells, leaves of plants in the final stage of evolution (senescence), and the bark of trees. Some allomelanins formed by condensation of quinones with amino acids (proteins) may also contain nitrogen and sulfur. Many plant materials form allomelanins during storage (such as bananas), tissue injury (such as apples and potatoes) or processing (e.g. during green tea fermentation) in enzymatic browning reactions. Quinones formed by oxidation of phenols and by activity of soil microorganisms are precursors of high molecular weight humic acids and related compounds. Structurally similar, but simpler brown melanins also have other functions. Such melanins are, for example, components of the dark brown pigments derived from the ink sac of some cephalopods, such as the common cuttlefish (*Sepia officinalis*) and squids (of the order Teuthida) that can be found in special sauces consumed in the Mediterranean region.

9.3.1.2 Indigoid pigments

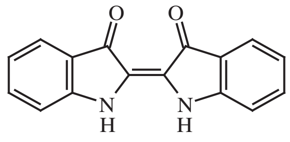
Indigo, also known as *trans*- or (*E*)-indigo or 2,2′-bis(2,3-dihydro-3-oxoindolylidene), has been valued since ancient times as a natural blue textile dye. It occurs in various types of indigo trees (such as true indigo *Indigofera tinctoria*, Fabaceae) naturalised to tropical and temperate Asia and Africa. Indigo may be also obtained from European woad (*Isatis tinctoria*), a plant native to south-eastern Europe and western Asia. True indigo trees contain the colourless indigo precursor indoxyl-β-D-glucopyranoside called indican (**9-23**). In addition to (*E*)-indigo (**9-24**), some other structurally related minor compounds include blue *cis*- or (*Z*)-indigo (**9-25**), red indirubin (**9-26**) and isoindirubin (**9-27**) and brown isoindigo (**9-28**). Fermentation (hydrolysis by saccharases) yields an unstable 3-hydroxyindol (indoxyl), which oxidises in air and provides indigo. The main precursor of indigo in woad is isatan B (isatan-β-D-gluconic acid), while indican is a minor component.



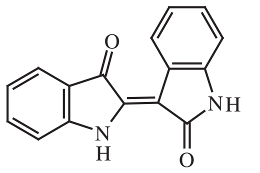
9-23, indican



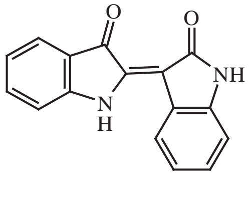
9-24, (*E*)-indigo



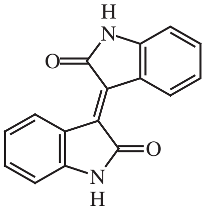
9-25, (*Z*)-indigo



9-26, indirubin



9-27, isoindirubin



9-28, isoindigo

The starting compound for the biosynthesis of indican is probably tryptophan, from which 1-(2-carboxyphenylamino)-1′-deoxy-D-ribulose 5′-phosphate, indole and 3-hydroxyindole are formed.

Sulfonation of natural indigo produces the dark blue, water soluble pigment known as indigo carmine. Indigo carmine is used in some countries as a food colorant, but its use in the EU is not permitted. Indigo carmine is possibly a weak local sensitiser (slightly irritating to the eyes) and is harmful to the respiratory tract if inhaled (occupational asthma has been reported).

9.3.1.3 Betalains

Betalains are a group of about 100 water-soluble purple, red, orange and yellow pigments of higher plants and some higher fungi. Two groups of betalains are differentiated:

- **betacyanins** (formerly called nitrogen anthocyanins) resembling anthocyanins with their purple and red colour
- yellow and orange **betaxanthins**.

9.3.1.3.1 Structure and nomenclature

All betalains have the same basic structure. The chromophore system of conjugated double bonds is derived from dihydropyridine (Figure 9.6). The individual compounds differ from each other by the structure of substituents R and R^1, which are aliphatic or part of the nitrogen heterocycles.

Betacyanins

All known betacyanins (about 50 compounds) are found exclusively as glycosides and acylated glycosides. The main aglycone of the important betacyanins is betanidin (**9-29**). In small quantities, betanidin is accompanied by its C-15 epimer isobetanidin (**9-30**), while neobetanidin (14,15-dehydrobetanidin, **9-31**) and

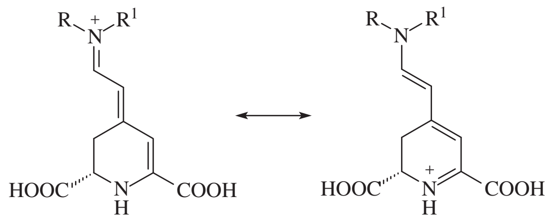


Figure 9.6 Basic structure of betalains.

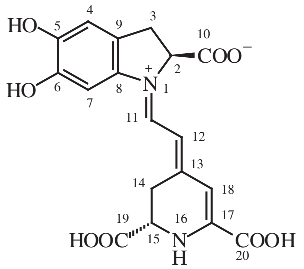
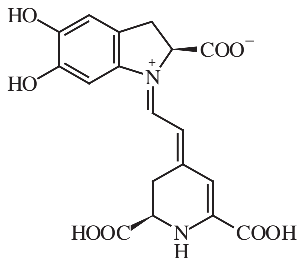
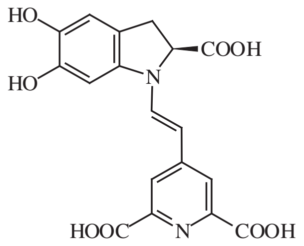
2-decarboxybetanidin (**9-32**) occur sporadically. Recent publications demonstrated the possibility of the generation of neoderivatives and 2-decarboxylated derivatives during heating of red beet and purple pitaya. Various other decarboxylated pigments may also be produced.



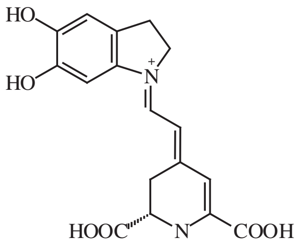
9-29, betanidin



9-30, isobetanidin



9-31, neobetanidin



9-32, 2-decarboxybetanidin

The dominating betacyanin is 5-*O*-β-D-glucoside of betanidin, (15*S*)-betanidin-5-*O*-β-D-glucopyranoside, which is called betanin (**9-33**). It is usually accompanied by isobetanin, which is the (15*R*)-isomer of betanin. Other minor pigments are 6-sulfates of betanin and isobetanin that are known as prebetanin and isoprebetanin, respectively. A less common pigment is 6-*O*-β-D-glucoside of betanidin, gomphrenin I (**9-34**).

Less common sugars bound in betacyanins include L-rhamnose, D-glucuronic acid and β-sophorose. Amaranthin is an example of a pigment where bound at position C-5 of betanidin is the disaccharide β-D-Glc*p*A-(1→2)-β-D-Glc*p*, which is related to sophorose, β-D-Glc*p*-(1→2)-β-D-Glc*p*. The sugar component of betalains can be esterified with malonic, ferulic, *p*-coumaric, sinapic, caffeic, citric and 3-hydroxy-3-methylglutaric acids. For example, phyllocactin is betanin, which has glucose at position C-6 esterified with malonic acid, hylocerenin is esterified at position C-6 with 3-hydroxy-3-methylglutaric acid and gomphrenin II is gomphrenin I esterified with *p*-coumaric acid at position C-6 of glucose (**9-34**).

9-34, gomphrenin I, R = H
phyllocactin, R = $COCH_2COOH$
hylocerenin, R = $COCH_2CH(OH)(CH_3)CH_2COOH$

Betaxanthins

Betaxanthins are dihydropyridine derivatives (Figure 9.6) that arise as condensation products of betalamic acid (Figure 9.7) with amino acids or biogenic amines. Examples of such, mainly yellow, pigments are vulgaxanthin I, which is (*S*)-glutamine-betaxanthin (R = H and R^1 = glutamine residue), vulgaxanthin II (R = H and R^1 = glutamic acid residue, **9-35**), vulgaxanthin III (R = H, R^1 = asparagine residue) and vulgaxanthin IV (R = H, R^1 = leucine residue). The R^1 substituents of other pigments are derived from methionine sulfoxide (miraxanthin I), aspartic acid (miraxanthin II), tyramine (miraxanthin III), tyrosine (portulaxanthin II) or dopa (dopaxanthin). Less widespread is indicaxanthin, which is

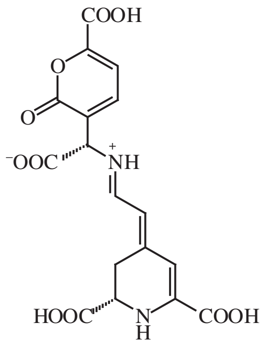
9-37, muscaurin I



9-38, muscaurin II

9.3.1.3.2 Occurrence

Betalains occur in nature in a relatively small number of plant genera belonging to the order of flowering plants Caryophyllales. The only exceptions are plants of the pink (carnation) family (Caryophyllaceae) and of the family Molluginaceae that accumulate anthocyanins instead of betacyanins. These two types of plant pigments never occur together in one plant. The most important sources of betacyanins are the cultivated red varieties of beetroot (cultivars of *Beta vulgaris*, Amaranthaceae, formerly Chenopodiaceae), according to which these pigments were named, and a shrub with red berries known as American pokeweed (*Phytolacca americana*) of the family *Phytolaccaceae*, which is native to eastern North America.

Beetroot has an average betalains content of 0.1%. Some varieties, however, contain up to twice as much pigment, which is

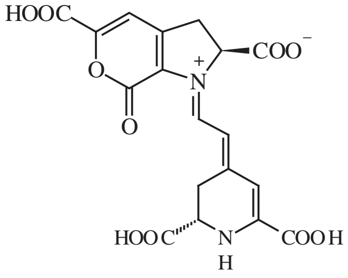
about 2 g/kg (in fresh matter). Betanin represents about 75–95% of all betacyanins of beetroot and dominates significantly over yellow betaxanthins. The main yellow pigment is vulgaxanthin I, which represents about 95% of yellow pigments, the rest are vulgaxanthin II and betalamic acid, a key intermediate of the biosynthesis and degradation of betalains (Figure 9.7). The pigment of American pokeweed was originally called phytolaccanin, but it was later identified as betanin.

The main pigment of red flowers, leaves and stems of the ornamental plant *Amaranthus tricolor* and of other species of the family Amaranthaceae, some of which are consumed for their seeds, leaves and stems, is amaranthin derived from betanidin, which is accompanied by isoamaranthin derived from isobetanidin. The main red pigments of seeds of Indian (Ceylon) spinach (*Basella alba*, Basellaceae), whose leaves are eaten as a vegetable, are gomphrenin I and gomphrenin II. Betalains also occur in edible fruits of some cacti (nopales) of the genus *Opuntia* (Cactaceae). Fruits of *O. ficus-indica*, referred to as prickly pear or Indian fig, contain yellow indicaxanthin (yellow fruits) and red betanin (red fruits). Betanin together with acylated betacyanins hylocerenin and phyllocactin occurs in fruits of pitaya (*Hylocereus polyrhizus*), also known as dragon fruit, and other domesticated species of the genus *Hylocereus* (such as *H. costaricensis* with red pulpa). Phyllocactin also occurs in flowers of several cacti, such as *Epiphyllum hybridum* (syn. *Phyllocactus hybridus*).

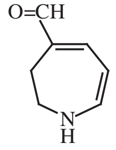
Betalains are also pigments of flowers in some plants. Flowers of the American plant four o'clock flower (*Mirabilis jalapa*, Nyctaginaceae) contain miraxanthins. 6-*O*-β-Sophorosides and other glycosides of betanidin and isobetanidin are pigments of paper-like bracts that surround flowers of the Brazilian paper plant *Bougainvillea glabra* from the same plant family. The pigment of flowers of moss-rose purslane (*Portulaca grandiflora*, Portulacaceae) native to South America is portulaxanthin.

Betalains are also pigments of some mushrooms. For example, the common mushroom (*Agaricus bisporus*, Agaricaceae) supposedly contains small quantities of the same pigments as beetroot. Following tissue damage, the light pink colour of the fungus changes to grey–black since L-dopa is oxidised to melanin pigments.

The striking orange–red pigment of the cap of fly agaric *Amanita muscaria* (Amanitaceae) is a mixture of the purple betacyanin muscapurpurin (**9-39**), orange betaxanthins muscaurins I–VII and yellow muscaflavin (**9-40**). Muscaurin I (**9-37**) and muscaurin II (**9-38**) are derived from unusual mushroom non-protein amino acids ibotenic and stizolobic acids, respectively, which are the major agaric pigments. Pigments termed muscaurins III–VII were later identified as mixtures of pigments derived from common protenogenous amino acids. Muscaurin III is a mixture of vulgaxanthin I (**9-35**), known as (*S*)-glutamine-betaxanthin, miraxanthin III, known as (*S*)-aspartic acid-betaxanthin and betaxanthin derived from 2-aminoadipic acid. Muscaurin IV is a mixture of vulgaxanthin I (**9-35**) and miraxanthin III. Muscaurin V is a mixture of vulgaxanthin II (**9-38**), known as (*S*)-glutamic acid-betaxanthin, indicaxanthine (**9-36**), known as (*S*)-proline-betaxanthin, and betaxanthins derived from valine and leucine (vulgaxanthin IV). Muscaurin VI is a mixture of vulgaxanthin II (**9-38**) and indicaxanthin (**9-36**). One of the dominant pigments, muscaurin VII, is derived from histidine.

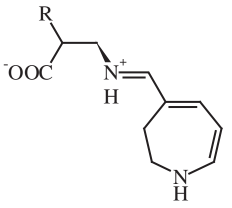


9-39, muscapurpurin



9-40, muscaflavin

Fly agaric and mushrooms of the genus Hygrocybe (*Hygrophoraceae*), such as *H. conica*, commonly known as the witch's hat, synthesise a yellow isomer of betalamic acid called muscaflavin (**9-40**), which is derived from dihydroazepine, and store it in the cup skin. In the same way that betalamic acid is involved in the formation of various betalains, muscaflavin can spontaneously condense with amino acids, with the formation of aldimine bonds, yielding yellow hygroaurins (**9-41**).



9-41, hygroaurins (R = amino acid residue)

9.3.1.3.3 Use

Only pigments from beetroot have found significant practical use, and are commercially called betanin or beetroot red. Owing to its low stability, the beetroot red is used for colouring foods with a shorter shelf-life, such as dairy and meat products (e.g. sausages from poultry meat that has a light colour), acidic beverages, such as soft drinks and some sweets. The pigment is supplied as a concentrated syrup or powder. The juice of the American pokeweed was used in the past to colour wine, which is considered falsification and is illegal.

9.3.1.3.4 Biochemistry, physiology and nutrition

The precursor of betacyanins is amino acid L-tyrosine, and correspondingly, 3,4-dihydroxy-L-phenylalanine (L-dopa) resulting from its oxidation. By a sequence of oxidation reactions via 4,5-seco-L-dopa, betalamic acid (Figure 9.7) and cyclo-3-(3,4-dihydroxyphenyl)-L-alanine (L-cyclodopa) are produced. Condensation of betalamic acid with cyclodopa yields betacyanins, while its condensation with amino acids produces betaxanthins. Muscaflavin in fungi also arises from dopa, but through the 2,3-seco-L-dopa spontaneous cyclisation. Reaction of muscaflavin with amino acids yields hygroaurins (Figure 9.8).

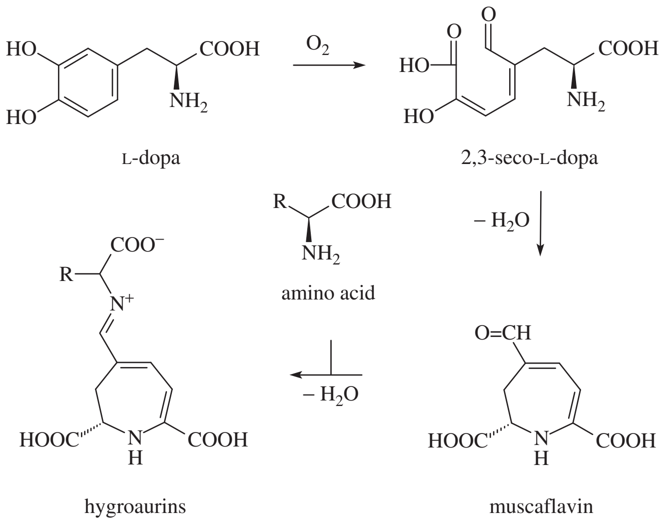


Figure 9.8 Biosynthesis of muscaflavin and hygroaurins.

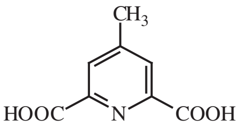
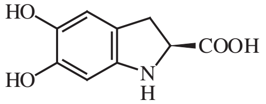
Betalains exhibit antioxidant activity and also react with free radicals. Their adverse effects were not detected; therefore beetroot pigments are generally accepted as safe food colorants. Furthermore, the maximum amount of added beetroot red is far less than the amount normally consumed by eating beetroot.

9.3.1.3.5 Properties and reactions

Beetroot betacyanins have a very intense colour, but are sensitive to oxidation (on light and especially in the presence of divalent and trivalent metals) and the presence of sulfur dioxide (that decolourises betacyanins). In the absence of these agents, the rate and extent of betacyanin degradation depends mainly on water activity and pH (Figure 9.7). They exhibit the highest stability in solutions of pH 4–5, but at pH > 7 are rapidly degraded. In acidic solutions, betacyanins hydrolyse to the corresponding aglycones and glucose. The degradation products in alkaline solutions are 4-methylpyridine-2,6-dicarboxylic acid (**9-42**), formic acid and (*S*)-5,6-dihydroxy-2,3-dihydroindole-2-carboxylic acid (1*H*-indole-2-carboxylic acid, **9-43**). The latter compound also arises, together with the corresponding amino acids or amines, as a degradation product of betaxanthins in aqueous solutions.



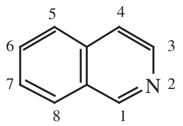
9-42, 4-methylpyridin-2,6-dicarboxylic acid



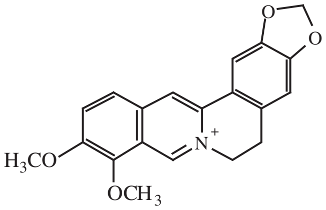
9-43, (*S*)-5,6-dihydroxy-2,3-dihydroindole-2-carboxylic acid

9.3.2 Isoquinolines

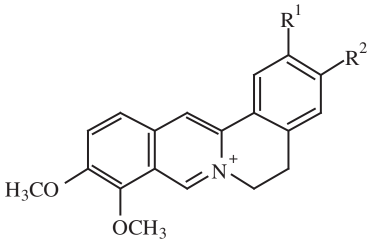
The isoquinoline (**9-44**) or benzyltetrahydroisoquinoline skeleton, respectively, can be found in the tetracyclic alkaloid berberine, also called umbellatin (**9-45**). Together with related alkaloids, berberine occurs in all parts of the European barberry shrub (*Berberis vulgaris*, Berberidaceae) as the main component, especially in the cortex, but also in leaves and immature fruits. Barberry alkaloids are carriers of the characteristic yellow colour of barberry wood and bark, but do not practically influence the colour of edible berries. The mildly poisonous cortex of the roots, containing 12–15% of alkaloids, was used in the past as a drug for medical purposes (the bark of stem contains 5.5–8% and the bark of branches about 3.5% of the mixture of alkaloids). The main components of the root bark are quaternary bases berberine (**9-45**), jatrorrhizine, columbamine, palmatine (**9-46**) and tertiary bases oxyacanthine (**9-47**) and berbamine (**9-48**).



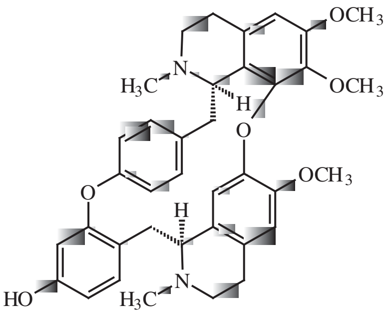
9-44, isoquinoline



9-45, berberine

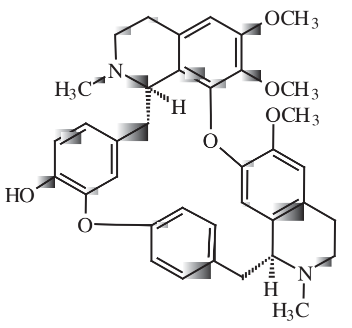


9-46, jatrorrhizine, $R^1 = OCH_3$, $R^2 = OH$
columbamine, $R^1 = OH$, $R^2 = OCH_3$
palmatine, $R^1 = OCH_3$, $R^2 = OCH_3$



9-47, oxyacanthine

Berberine also occurs in a widespread evergreen shrub called Oregon-grape (*Mahonia aquifolium*, Berberidaceae) related to the barberry and in goldenseal, also known as orangeroot (*Hydrastis canadensis*, Ranunculaceae).



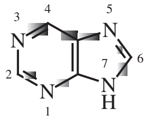
9-48, berbamine

Biosynthesis of berberine and related alkaloids is based on the transformation of phenylalanine. The tetracyclic skeleton (derived from benzytetrahydroisoquinoline) arises by incorporation of the *N*-methyl group (so-called berberine bridge) in alkaloid reticulin, which is the immediate precursor of berberine.

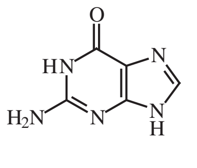
Various Asian species of barberry, such as *B. amurensis* and *B. asiatica*, are used in medical preparations in India and the Far East. Berberine reportedly promotes the excretion of urine and the relief of smooth muscles (spasmolytic effect) in renal diseases and urinary tract infections, increases production and secretion of bile (choleretic effect). Also important are its sedative effect and activity during violent diarrhoea. Berberine also acts against infections caused by amoebas and parasitic trypanosomes (causing sleeping sickness), and has been used in the treatment of psoriasis. Overdose or overuse leads to transient irritation of the central nervous system, stupor and diarrhoea and can cause kidney damage. Because of its relative toxicity and side effects, the use of drugs containing berberine is restricted in many countries. The use of berberine as a yellow food pigment and bittering agent for liqueurs and spirits was reported by a Japanese company, Kakko Honsha, in 1980. In the EU, the berberine content in aromatised foods is restricted by law. The tolerated content (maximum level), originating exclusively from natural sources, is for alcoholic beverages 10 mg/l, and 0.1 mg/l (0.1 mg/kg) for other foods and beverages.

9.3.3 Purines

Pigments derived from purine (**9-49**), for example guanine (**9-50**), xanthine (**9-51**) and uric acid (**9-52**), are very important pigments of the animal kingdom. The actual compounds are colourless, but in the form of granules or microcrystals are the bases of white, cream and silvery semi-transparent pigments that are found, for example, in fish scales.

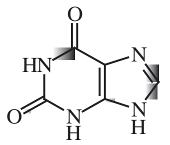


9-49, purine

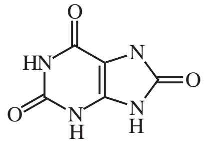


9-50, guanine

Biosynthesis of purines proceeds by a multi-step mechanism via inosine 5′-monophosphate (IMP). Free purines are formed by



9-51, xanthine

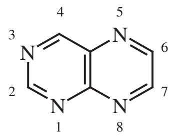


9-52, uric acid

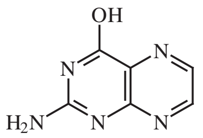
hydrolysis of the corresponding nucleotides; uric acid is a product of their catabolism.

9.3.4 Pterines

The basic skeleton of pterine pigments is pteridine (**9-53**). Pteridine substituted in position C-2 with an amino group and in position C-4 with a hydroxyl group (tautomeric oxo group) is called pterine (**9-54**). Many biologically active forms of pteroylglutamic (folic) acid are natural pterines, and have the function of vitamins, but due to the quantities in which they occur in foods they have no importance as yellow food pigments.

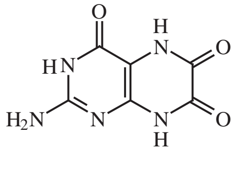


9-53, pteridine

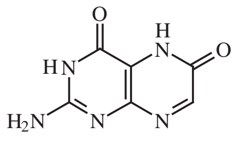


9-54, pterine

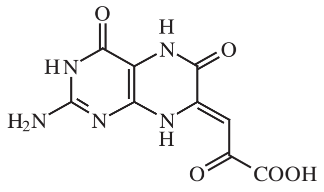
Important coloured pterines include white leucopterine (**9-55**), yellow xanthopterine (**9-56**) and red-orange erythropterine (**9-57**), which are pigments of butterfly wings. Leucopterine is found in wings of white butterflies of the genus *Pieris* (such as small white), xanthopterin in yellow butterflies of the genus *Gonepteryx* (brimstones) and erythropterin is a pigment of butterflies of the family *Nimphalidae* (such as Red Admiral, *Vanessa atalanta*) and some insects (e.g. wasps, *Vespula* spp.). Yellow, orange and red pterine pigments also occur in some shellfish, fish, amphibians and reptiles. Pteridines also act as shielding pigments of eyes in some invertebrates.



9-55, leucopterine



9-56, xanthopterine

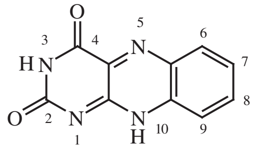


9-57, erythropterine

Biosynthesis of pteridines is based on guanosine 5′-triphosphate transformation. Compounds belonging to folacins arise analogously.

9.3.5 Isoalloxazines

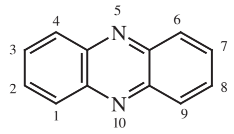
Numerous flavins (and flavoproteins) that are derived from isoalloxazine (**9-58**) are also biologically significant pigments. The most important representative of this group of pigments is riboflavin (vitamin B_2), which is also used as a yellow food pigment.



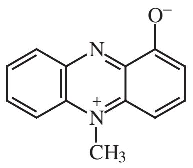
9-58, isoalloxazine

9.3.6 Phenazines

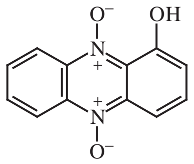
Pigments derived from phenazine (**9-59**) are related to flavin and isoalloxazine pigments. They are synthesised by some bacteria, mainly by bacteria belonging to the genera *Pseudomonas* and *Streptomyces*. With the exception of dark blue pyocyanin (**9-60**) and blue–violet iodinin (**9-61**), most phenazines are yellow pigments. Occasionally, these pigments may be found in animal tissues in relation to the invasion of microorganisms (e.g. in infected wounds).



9-59, phenazine



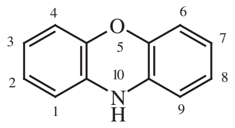
9-60, pyocyanin



9-61, iodinin

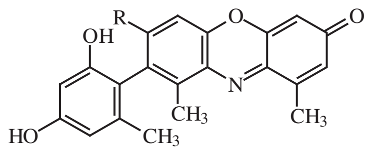
9.3.7 Phenoxazines

Phenoxazine (**9-62**) pigments are compounds structurally similar to phenazines. Phenoxazines occur mainly in lichens (symbiotic organisms of fungi belonging to the phylum Ascomycota, algae or cyanobacteria), mostly in the form of uncoloured precursors (different depsides). To a lesser extent, phenoxazines occur in higher fungi of the Polyporaceae family. Pigments extracted from lichens with urine (a source of ammonia) or ammonia solutions and oxidised by air oxygen have been used as textile dyes from time immemorial. Another pigment of the same type acquired from the same lichen species, such as *Roccella tinctoria* (Roccellaceae) is litmus (a mixture of several related compounds), one of the oldest pH indicators, which was once used to colour various drinks.

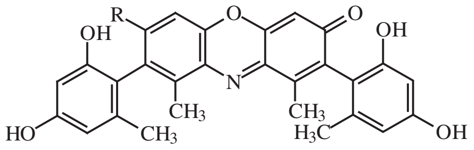


9-62, phenoxazine

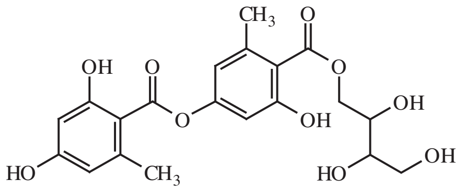
An important group of phenoxazine pigments are orcein pigments known as orcein or orchil, which occur in many parts of the world, but come mainly from the Azores and the Canary Islands. Orcein is a purple-to-red pigment extracted from lichens (orchella weeds) of the genera *Roccella* and *Orchella*. It is a mixture of different hydroxyphenoxazones and aminophenoxazones. Examples of these components are α-hydroxy and α-amino orceins (**9-63**) and β-hydroxy and β-amino orceins (**9-64**). Their precursors in lichens are some aromatic acid depsides, such as lecanoric acid (**9-65**) and erythrin (**9-66**) that produce as a degradation product orcinol (**9-67**) and analogous products, which on condensation produce orcein pigments. The dye is very slightly soluble in water, but soluble in ethanol. Orcein (orchil) can be used to dye wool and silk, and is also approved as a food colorant (with E number E121), but is banned throughout the EU. Sulfonation of orcein produces a water-soluble pigment, which is used for colouring soft drinks and confectionery.



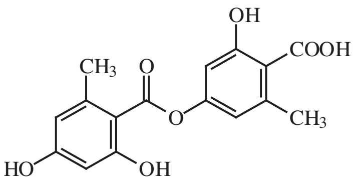
9-63, α-hydroxy orcein (R = OH)
α-amino orcein (R = NH_2)



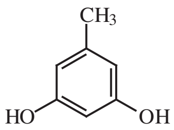
9-64, β-hydroxy orcein (R = OH)
β-amino orcein (R = NH_2)



9-65, lecanoric acid

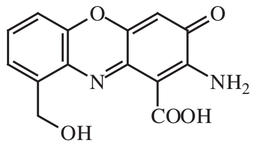


9-66, erythrin



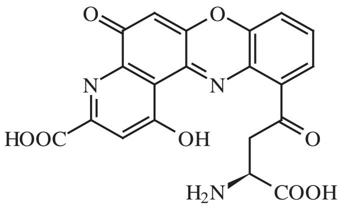
9-67, orcinol

An example of a phenoxazine pigment occurring in higher fungi is the cinnabar red pigment of the wood-rotting fungus *Pycnoporus cinnabarinus*, 2-amino-3*H*-phenoxazin-3-one-1,9-dicarboxylic acid named cinnabaric acid (**9-68**).



9-68, cinnabaric acid

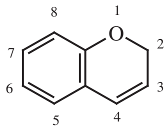
Phenoxazines also include yellow-to-brown and brownish-red pigments found in invertebrate animals and some vertebrates, for example as shielding pigments of eyes. The most important pigments are **ommochromes** that arise from tryptophan via kynurenine and 3-hydroxykynurenine. An example is a yellow pigment xanthommatin (**9-69**) containing bound aspartic acid.



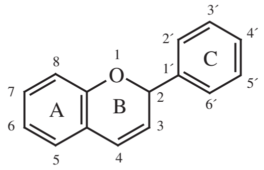
9-69, xanthommatin

9.4 Flavonoids

Flavonoids or flavonoid substances are a very large group of plant phenols containing two benzene rings (ring A and C) in the molecule, associated by a three-carbon chain. The number of flavonoid compounds is now estimated at 5000 and new compounds are still being found in various plant sources. Most flavonoid compounds have the C_3 chain as a part of a heterocyclic ring derived from 2*H*-pyran (ring C). These flavonoids are therefore derived from the oxygen-containing heterocyclic compounds 2*H*-chromene (**9-70**), substituted in position C-2 by phenyl group, which is called flavan (**9-71**) having an arrangement of C_6–C_3–C_6. Compounds of this type are often called 1,3-diarylpropanoids. Typically, all three rings of flavonoids are substituted with hydroxyl or methoxyl groups, and individual derivatives differ only in the degree of substitution and oxidation. Flavonoids occur as free compounds, but more frequently as glycosides, acylated glycosides, and polymers. The properties of flavonoids are very different from those of other phenolic pigments; therefore flavonoids are described as a separate group of plant pigments. Other important plant phenols are included in the sections dealing with quinoid pigments, natural antioxidants, natural toxicants and various flavour-active substances.



9-70, 2*H*-chromene



9-71, flavan

Depending on the degree of oxidation and C-3 chain substitution the following basic structures of flavonoids can be identified:

- **catechins** (flavan-3-ols)
- **leucoanthocyanidins** (flavan-3,4-diols)
- **flavanons**
- **flavanonols**
- **flavons**
- **flavonols** (dihydroflavones)
- **anthocyanidins**.

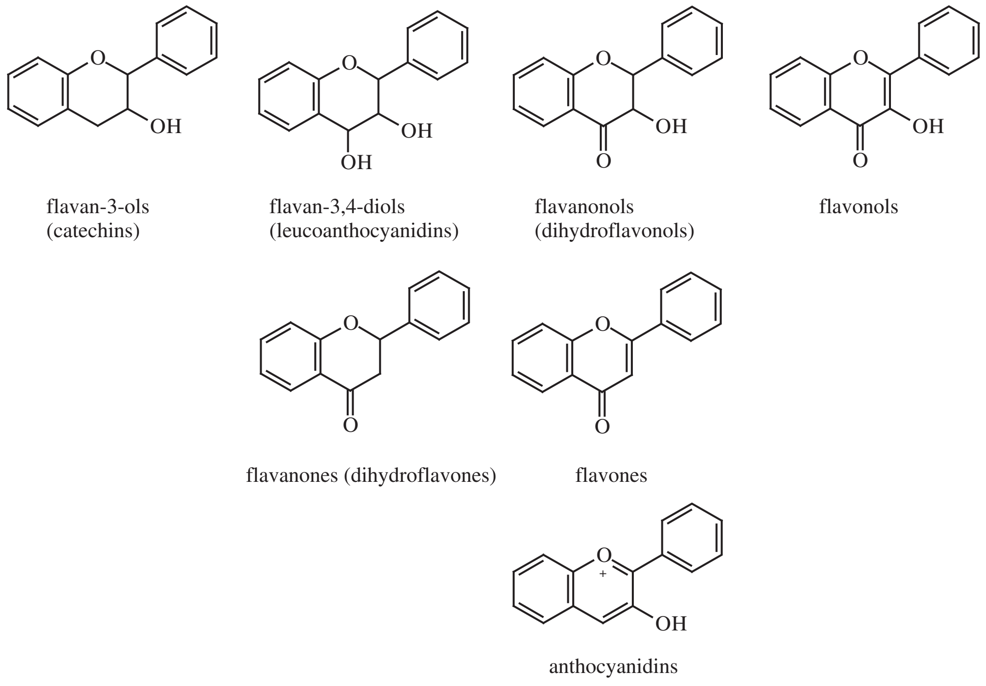
The basic structure of these flavonoid compounds is shown in formulae **9-72**. Their degree of oxidation increases along the row from left to right, along with the colour intensity. The compounds listed in the columns below have the same degree of oxidation. A special case are anthocyanidins that contain a system of conjugated double bonds, therefore they are flavylium or 2-phenylbenzopyrylium (2-phenylchromenylium) cations.

In several cases, the six-membered heterocyclic ring B exists in the isomeric open form, or can be substituted by a five-membered heterocyclic ring. The structurally related compounds, in which an aliphatic C-3 chain or a chain, which is partially included into the furan ring, connects the rings A and C are divided into:

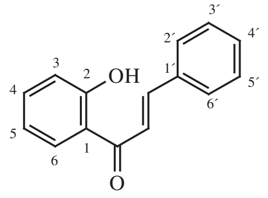
- **chalcones** and **dihydrochalcones**
- **aurones**.

Structures of these flavonoids are given in formulae **9-73**, **9-74** and **9-75**.

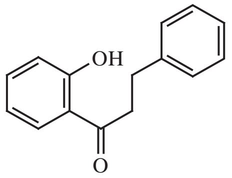
Less common compounds with ring B associated with pyran ring C in position C-3 (derived from isoflavan) are called **isoflavonoids** (also known as 3-phenylchromen-4-ones or 1,2-diarylpropanes, **9-76**). If the connection between these two rings is in position C-4, the corresponding compounds, derived from neoflavan, are called **neoflavonoids** or 4-phenylcoumarins, 5,6-benzo-2-pyrones or 1,1-diarylpropanes (**9-77**).



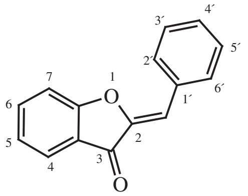
9-72, common structures of main flavonoid compounds



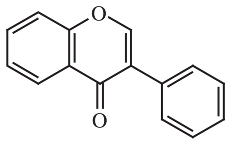
9-73, chalcones



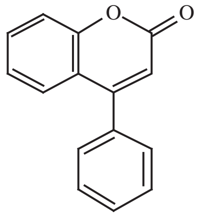
9-74, dihydrochalcones



9-75, aurones



9-76, isoflavonoids



9-77, neoflavonoids

Only certain flavonoids are important as natural plant pigments; others act as taste-active compounds, as they are precursors of astringent and bitter substances or have various important biological effects. All coloured flavonoids were previously logically divided into two large groups according to their colour, the red and blue **anthocyanins** and yellow **anthoxanthins**. Their names were derived from the Greek word flower (anthos), blue (cyaneos) and yellow (xanthos). Names of flavones and other yellow flavonoids are derived from the Latin word flavus (yellow). Chalcones and aurones were previously called anthochlor pigments or **anthochlors** (the Greek word chloros means green).

Catechins and leucoanthocyanidins are colourless compounds, but the brown pigments that arise from these flavonoids in enzymatic browning reactions are important pigments of many foods. Colourless leucoanthocyanidins also give rise to the corresponding coloured anthocyanidins during processing of fruits and vegetables in acidic solutions. Oligomers of catechins and leucoanthocyanidins with bitter taste are classified as condensed tannins. Flavanones and flavanonols are colourless or pale yellow compounds, and do not have great significance as plant pigments. Some flavanones, however, are important bitter components of grapefruits. The most important flavonoid pigments are yellow flavones and flavonols and anthocyanins in particular that are mostly red (also yellow or orange), purple and blue anthocyanins. Chalcones and dihydrochalcones are yellow pigments, aurones are golden yellow pigments mostly of plant flowers, but as food pigments they are not particularly important. Other pale yellow pigments, isoflavones, similarly have negligible importance as pigments, but they show important biological properties (oestrogenic activity, see Section 10.4). They are found only in certain commodities (notably soya beans and derived products).

9.4.1 Anthocyanins

Anthocyanins are the most widespread and numerically a very large group of hydrophilic plant pigments. So far about 300 different anthocyanins have been identified in nature. Many fruits, vegetables, flowers and other plant materials owe their attractive orange, red, purple and blue colour, which increases their consumer popularity, to this group of water-soluble pigments.

9.4.1.1 Structure and nomenclature

Anthocyanins are glycosides of different aglycones that are called anthocyanidins. All anthocyanidins are derived from one basic structure, which is flavylium (2-phenylbenzopyrylium or 2-phenylchromenylium) cation (**9-72**). It is reported that 17 different anthocyanidins exist in nature. All compounds are substituted in position C-4 by a hydroxyl group and they mutually differ by substitutions at positions C-3, C-5, C-6, C-7, C-3′ and C-5′ and in positions C-5, C-7, C-3′and C-5′ methoxyl groups may occur. Table 9.10 lists the 15 most common anthocyanidins, the last two compounds are 6-hydroxyanthocyanidin (abbreviated 6-OHCy) and 5-methylcyanidin (5-MCy). The most important compounds occurring in foods are six anthocyanidins (**9-78**) with a hydroxyl

Table 9.10 Overview of anthocyanidin structures.

Name[a]	Abbreviation	Substituents					
		C-3	C-5	C-6	C-7	C-3′	C-5′
Apigeninidin	Ap	H	OH	H	OH	H	H
Luteolinidin	Lt	H	OH	H	OH	OH	H
Tricitinidin	Tr	H	OH	H	OH	OH	OH
Pelargonidin	Pg	OH	OH	H	OH	H	H
Aurantinidin	Au	OH	OH	OH	OH	H	H
Cyanidin	Cy	OH	OH	H	OH	OH	H

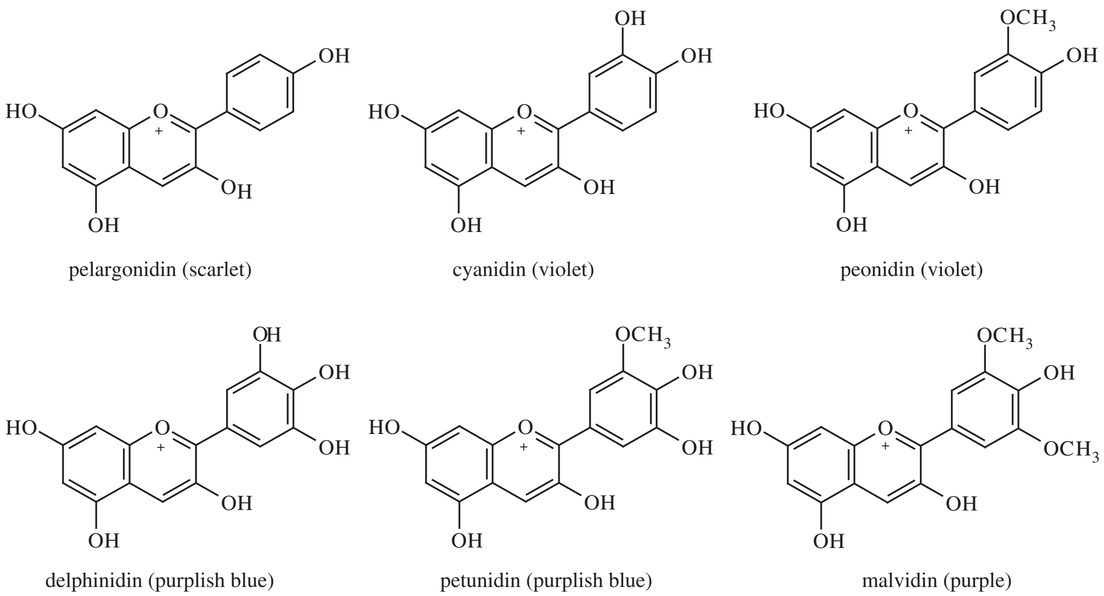
Hirsutidin	Hs	OH	OH	H	OCH_3	OCH_3	OCH_3
Capensinidin	Cp	OH	OCH_3	H	OH	OCH_3	OCH_3

[a] Most important anthocyanidins are indicated in bold.



9-78, common anthocyanidins

group at position C-3. In descending frequency of occurrence these anthocyanidins are: cyanidin (named after the Latin name for the cornflower (*Centaurea cyanus*, Asteraceae), pelargonidin (found in geraniums, *Pelargonium* spp., Geraniaceae), peonidin (found in peonies, *Paeonia* spp., Paeoniaceae), delphinidin (occurring in delphiniums, *Delphinium* spp., Ranunculaceae), petunidin (found in petunias, *Petunia* spp., Solanaceae) and malvidin (found in mallow, *Malva* spp., Malvaceae), formerly also known as oenidin.

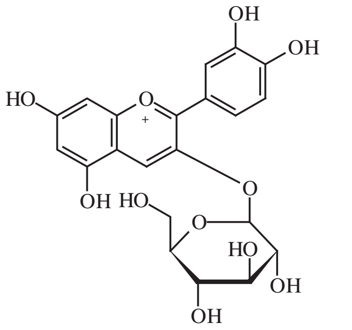
Materials that contain anthocyanins generally have the colour of their aglycones. Free aglycones of anthocyanidins occur in plant tissues rarely and only in trace amounts as anthocyanin hydrolysis products and products derived from leucoanthocyanidins. In all plant materials, the main pigments are glycosides and acylated glycosides of anthocyanins. Present in some fruits and vegetables are anthocyanins derived from a single anthocyanidine (e.g. in apples, red cabbage varieties and elderberries these are cyanidin glycosides), but sometimes pigments are derived from several different anthocyanidins. For example, blackcurrant anthocyanins are delphinidin and cyanidin derivatives, while strawberry anthocyanins are derived from pelargonidin and cyanidin.

The anthocyanin pigments contain five monosaccharides that include, in descending order of frequency, D-glucose, L-rhamnose, D-galactose, D-xylose and L-arabinose. Sugars are always bound in position C-3, and if another hydroxyl group is glycosylated, it is the hydroxyl at C-5 (the bound sugar is glucose and less often rhamnose). Free hydroxyl at C-3 destabilises the anthocyanidin chromophore, so the hydrolysis of sugar bound as *O*-glycoside at C-3 results in rapid and irreversible decomposition of anthocyanidin, and leads to discoloration. In exceptional cases, sugars are also bound in positions C-7, C-3′, C-5′ and C-4′ as mono- (mainly glucose), di- or trisaccharides. The most common disaccharides are rutinose, sambubiose, sophorose, laminaribiose and gentiobiose.

Depending on the number of bound sugar molecules, anthocyanins are divided into 18 groups, of which the most important are:

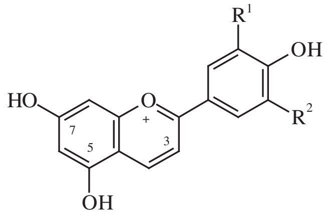
- monosides with glucose, galactose, rhamnose or arabinose in position C-3 (3-monosides);
- biosides with disaccharides (such as rutinose, sambubiose, sophorose, gentiobiose, neohesperidose, laminaribiose, robinobiose and other disaccharides) bound in position C-3 (3-biosides);
- triosides with linear or branched trisaccharides bound in position C-3 (3-triosides);
- 3,5-diglycosides with monosaccharides at positions C-3 and C-5;
- 3,7-diglycosides with monosaccharides at positions C-3 and C-7;
- 3-biosides-5-monosides with disaccharide in position C-3 and monosaccharide in position C-5.

The most frequently occurring anthocyanine pigments are cyanidin-3-*O*-glycosides, which occur approximately three times more frequently than 3,5-di-*O*-glycosides. The type of sugar has little effect on the chemical properties of pigments, but much more significant is the position in which the sugar is bound. An example of 3-*O*-glycosides is cyanidin-3-*O*-β-D-glucopyranoside (**9-79**).



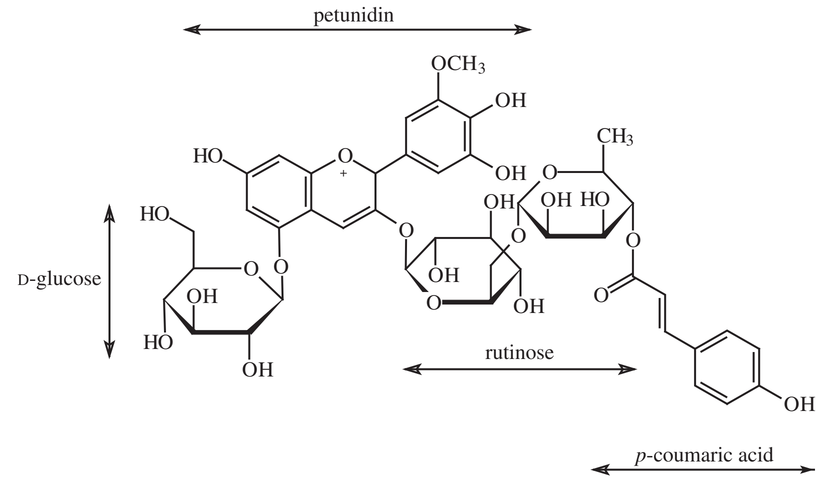
9-79, cyanidin-3-*O*-β-D-glucopyranoside

Besides the common anthocyanins, some unusual compounds differing from the normal structures in the substituent position are also found in nature. Examples of rare **3-deoxyanthocyanins** lacking C-3 hydroxyl group are apigeninidin, luteolinidin (**9-80**), related 5- and 7- methoxylated derivatives and glycosides. These 3-deoxy forms have yellow to orange colour in acidic media and, unlike the red 3-hydroxy derivatives, they are stable even as aglycones. Red tricetinidin (**9-80**) is found in black tea infusions as a product of epigallocatechin gallate degradation.

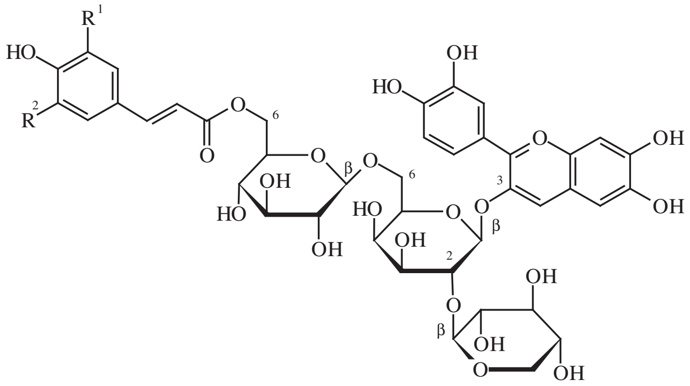


9-80, apigeninidin, $R^1 = R^2 = H$
luteolinidin, $R^1 = OH$, $R^2 = H$
triacetinidin, $R^1 = R^2 = OH$

Sugars bound in anthocyanins are often acylated by phenolic acids (*p*-coumaric, caffeic, ferulic and sinapic acids, less frequently by *p*-hydroxybenzoic acid), malonic acid and acetic acid. Acids are usually linked to the C-6 hydroxyl group of glucose and the C-4 hydroxyl group of rhamnose. 3-Glycosides are only rarely acylated. An exception is delphinidin-3-*O*-rutinoside-5,3′,5′-tri-*O*-glucoside, which contains four molecules of phenolic acids, some of which are bound to glucose occurring in other positions. An example of acylated pigments is (*E*)-petunidin-3-*O*-[6-*O*-(4-*O*-*p*-coumaroyl-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-β-D-glucopyranoside, trivially called petanin (**9-81**), which is the characteristic pigment in the skin of red potato varieties. Other examples of acylated anthocyanins are pigments of black or purple carrots (*Daucus carota* ssp. *sativus* var. *atrorubens*). In recent years, many new varieties with an extremely high content of pigments



9-81, petanin



9-82, (*E*)-cyanidin-3-*O*-[2-*O*-β-D-xylopyranosyl-6-*O*-(4-*O*-*p*-coumaroyl)-β-D-glucopyranosyl]-β-D-galactopyranoside, $R^1 = R^2 = H$

have been cultivated. The anthocyanin content of several of these black carrot cultivars was reported to be in the range of up to 1750 mg/kg fresh weight. The dominating anthocyanins of these varieties are (*E*)-cyanidin-3-*O*-[2-*O*-β-D-xylopyranosyl-6-*O*-(4-*O*-*p*-coumaroyl)-β-D-glucopyranosyl]-β-D-galactopyranoside and related pigments derived from caffeic and sinapic acids (**9-82**).

Many other anthocyanins were known by trivial names in the past. Examples of these anthocyanins are cyanidin-3-*O*-glucoside or chrysanthemin, cyanidin-3-*O*-galactoside or idaein, cyanidin-3-*O*-rutinoside or ceracyanin, cyanidin-3-*O*-sambubioside or sambycyanin, cyanidin-3-*O*-(2-glucosyl)rutinoside or mecocyanin, delphinidin-3-*O*-glucoside or myrtillin, malvidin-3-*O*-glucoside or oenin and malvidin-3,5-di-*O*-glucoside or malvin.

9.4.1.2 Occurrence

Anthocyanins are found in many plant species located in cell vacuoles and stabilised by interactions of the type ion–ion with organic acids (malonic, malic and citric acids). The main sources of anthocyanin pigments that are used as food are fruits of plants of the grapevine family Vitaceae, which includes grapes, and of the rose family (Rosaceae), to which cherries, plums, raspberries, strawberries, blackberries, apples, pears and many other fruits belong. Other significant plants containing anthocyanine pigments belong to other plant families, such as eggplants (aubergines) and potato varieties with red skin (Solanaceae), black- and redcurrants and red varieties of gooseberries (Grossulariaceae), blueberries and cranberries (Ericaceae), olives (Oleaceae) and red cabbage, radishes and red varieties of other cruciferous vegetables (Brassicaceae). Lists of the main sources of anthocyanins and the individual main pigments of fruits, vegetables and other plant materials are given in Tables 9.11 and 9.12. The number of anthocyanins present in individual fruits and vegetables is variable and ranges from a few (e.g. in strawberries, blackberries and red cabbage) to more than ten different pigments (in blueberries and red varieties of grapes and maize). In addition to anthocyanins, many fruits and vegetables also contain yellow-to-orange carotenoids and anthoxanthins, green chlorophylls and other pigments, but never betalains, and the presence of these pigments often affects the resulting colour.

3-Deoxyanthocyanins are not commonly found in higher plants. They occur in higher quantities primarily in ferns and mosses and in sorghum cereal crops (such as *S. bicolor*, Poaceae). Apigeninidin and luteolinidin represent on average 36–50% of the total black and brown sorghum anthocyanins (2.8–4.3 g/kg).

Table 9.11 Main anthocyanins of selected fruits.

Fruits	Latin name	Main anthocyanins[a] [b]
Apples (skin)[c]	*Malus pumila*	**Cy-3-galactoside**, 3-glucoside, 3-xyloside, 3- and 7-arabinosideand acyl derivatives
Apricots (skin)	*Armeniaca vulgaris*	**Cy-3-glucoside**
Bilberries	*Vaccinium myrtillus*	**Df-3-galactoside** and 3-glucoside, **Cy-3-galactoside** and 3-glucoside, Pt, Pn and Mv glycosides
Blackberries	*Rubus* sp.	**Cy-3-glucoside**, 3-rutinoside, 3-xyloside, 3-(6-malonylglucoside), 3-[6-(3-hydroxy-3-methylglutaroyl]glucoside, Pg-3-glucoside
Blueberries	*Vaccinium myrtilloides*	**Mv-3-glucoside, 3-galactoside**, 3-arabinoside, **Pt-3-glucoside**, 3-arabinoside, 3-(malonoyl)glucoside, Cy-3-(malonoyl)glucoside, Dp-3-(malonoyl)glucoside
Cherries (sour)	*Cerasus vulgaris*	**Cy-3-(2-glucosyl)rutinoside**, **3-glucoside**, 3-rutinoside, 3-sophroside, 3-sambubioside, Pn-3-glucoside and other pigments
Cherries (sweet)[c]	*Cerasus avium*	**Cy-3-rutinoside**, **3-glucoside**, 3-sophoroside (some varieties), Pn-3-glucoside and 3-rutinoside, acyl derivatives
Chokeberries	*Aronia melanocarpa*	**Cy-3-galactoside**, **3-arabinoside**, 3-glucoside, 3-xyloside
Cornel berries	*Cornus mas*	**Cy-3-galactoside**, **Pg-3-galactoside** 3-rhamnosylgalactoside, Dp-3-galactoside
Cranberries	*Rhodococcus vitis-idaea*	**Cy-3-galactoside**, **3-arabinoside**, 3-glucoside and 3-xylosylglucoside, Df-3-glucoside, Mv-3,5-diglucoside
Currant (black)	*Ribes nigrum*	**Dp-3-rutinoside**, **3-glucoside**, **Cy-3-glucoside**, 3-rutinoside, Pt-3-rutinoside, Pn-3-rutinoside
Currant (red)	*Ribes silvestre*, syn. *R. rubrum*	**Cy-3-xylosylrutinoside**, **3-sambubioside**, **3-rutinoside**, 3-glucoside, 3-sophoroside, 3-glucosylrutinoside
Elderberries	*Sambucus nigra*	**Cy-3-glucoside**, **3-sambubioside**, 3-sambubioside-5-glucoside, 3,5-diglucoside
Figs (skin)	*Ficus carica*	**Cy-3-rutinoside**, 3-glucoside and 3,5-diglucoside, Pg-3-rutinoside
Gooseberries[c]	*Grossularia uva-crispa*	**Cy-3-rutinoside**, **3-glucoside**, 3-(6-*p*-coumaroyl)-glucoside, Pe and Pn-3-glucosides
Grapes[c]	*Vitis vinifera*	**Mv-3-glucoside**, **Mv-3-*p*-coumaroylglucoside** (in some varieties), **Mv-3-acetylglucoside** and Pt, Pe, Df and Cy glucosides and their acyl derivatives
	Vitis labrusca	Cy, **Dp**, Pt, Pn and **Mv-3-(*p*-coumaroyl)glucosides-5-glucosides**, 3,5-diglucosides, 3-*p*-coumaroylglucosides, **3-glucosides**
Lichee (skin)	*Litchi chinensis*	**Cy-3-rutinoside**, 3-galactoside, 3-glucoside, Pg-3,5-diglucoside, 3-glucoside
Mango	*Mangifera indica*	**Pn-3-galactoside**
Mulberries	*Morus nigra*	**Cy-3-glucoside**, **3-rutinoside**, 3-sophoroside, Pg-3-glucoside, 3-rutinoside,
Olives	*Olea europea*	**Cy-3-glucoside** and **3-rutinoside** and acyl derivatives
Oranges[c]	*Citrus sinensis*	**Cy-3-glucoside**, **3-(6-malonylglucoside)**, Dp and Pn-3-glucosides, pyranoanthocyanins
Passion fruit[c]	*Passiflora edulis*	**Pg-3-diglucoside**, **Dp-3-glucoside**
Peaches[c]	*Persica vulgaris*	**Cy-3-glucoside** and **3-rutinoside**
Pears (skin)[c]	*Prunus persica*	**Cy-3-galactoside**, **3-arabinoside**, 3-glucoside, 3-xyloside, Pe-3-galactoside and 3-rutinoside and acyl derivatives
Plums	*Prunus domestica*	**Cy-3-xyloside**, **3-rutinoside**, Pn-3-glucoside, 3-rutinoside
Pomegranate	*Punica granatum*	**Dp and Cy-3,5-diglucosides**, Pg-3,5-diglucoside, **Cy-3-glucoside**, Dp and Pg-3-glucoside
Raspberries	*Rubus idaeus*	**Cy-3-rutinoside**, **3-sophoroside**, **3-glucosylrutinosid**e, **3-glucoside**, Pg-3-glucosylrutinoside, 3-sophoroside, 3-glucoside, Mv-3-glucoside
Saskatoon berries	*Amelanchier alnifolia*	**Dp-3-glucoside**, **3-rutinoside**, **Mv-3-glucoside**, **Cy-3-glucoside**, 3-galactoside, 3-arabinoside, 3-xyloside
Sloeberries	*Prunus spinosa*	**Cy-3-rutinoside**, **3-glucoside**, **Pn-3-rutinoside**, 3-glucoside
Strawberries	*Fragaria* spp.	**Pg** and **Cy-3-glucosides**, their **succinates**, 3,5-diglucosides

[a]Cy = cyanidin, Pg = pelargonidin, Pn = peonidin, Dp = delphinidin, Pt = petunidin, Mv = malvidin.

Table 9.12 Main anthocyanins of selected vegetables, cereals and other crops.

Material	Latin name	Main anthocyanins[a,b]
Vegetables		
Cabbage (leaves)[c]	*Brassica oleracea var. capitata*	**Cy-3-sophoroside-5-glucoside** (malonyl, ***p*-coumaroyl**, di-*p*-coumaroyl, feruloyl, diferuloyl, **sinapoyl** and disinapoyl esters)
Carrot (black)		**Cy-3-xylosyl(sinapoylglucosyl)galactosides, 3-xylosyl(feruloylglucosyl)galactosides**, other 3-xylosylgalactosides, Pn-3-xylosylgalactosides
Eggplant (skin)	*Solanum melongena*	**Dp-3-[4-(*p*-coumaroyl)rutinoside]-5-glucopyranoside**[d] (nasunin), **3-glucoside**, 3-rutinoside-5-glucoside, 3-rutinoside, , 3-*p*-coumaroylrutinoside, 3,5-diglucoside
Lettuce (leaves)[c]		**Cy-3-(3-malonoyl)glucoside, 3-(3-acetoyl)glucoside**, 3-(6-malonoyl)glucoside, 3-glucoside
Onion[c]	*Allium cepa*	**Cy-3-(malonoyl)glucoside-5-glucoside, 3-(3-acetoyl)glucoside**, glucoside, 3-galactoside, 3-laminaribioside, Pn-3-glucoside
Radishes[c] (skin)	*Raphanus sativus*	**Pg-3-(*p*-coumaroyl)diglucoside-5-(malonoyl)glucoside, 3-(feruloyl)diglucoside-5-(malonoyl)glucoside**, 3-(caffeoyl)diglucoside-5-(malonoyl)glucoside
Cereals		
Maize[e]	*Zea mays*	**Cy**, Pg and **Pn-3-glucosides** (free and acylated by malonic acid)
Blue barley[e]	*Hordeum vulgare*	**Pt** and **Cy-3-glucoside**
Black rice[e]	*Oryza sativa*	**Cy** and **Pn-3-glucoside**, Cy-diglucoside
Sorghum	*Sorghum bicolor*	**Ap, Lt** and Mv **glycosides**
Other crops		
Kidney beans[c]	*Phaseolus vulgaris*	**Pg-3-sambubioside**, 3-glucoside, Cy-3-glucoside,
Potatoes[c]	*Solanum tuberosum*	Pg, Cy, Pn, Dp, Pt and Mv-5-(*p*-coumaroyl)glucoside-3-rutinoside, Pg, Cy, Dp and Pt-3-rhamnosylglucosides, Pg and Pn-3-(*p*-coumaroyl)rutinosides-5-glucosides, 3-(feruloyl)rutinoside-5-glucoside
Roselle	*Hibiscus sabdariffa*	**Dp-3-sambubioside, Cy-3-sambubioside**
Sweet potato[f]	*Ipomoea batatas*	**Cy and Pn-3-caffeoylsophoroside-5-glucoside, Cy and Pn-3-p-hydroxybenzoylsophoroside-5-glucoside, Pn-caffeoyl-feruloylsophoroside-5-glucoside**

[a] Cy = cyanidin, Pg = pelargonidin, Pn = peonidin, Dp = delphinidin, Pt = petunidin, Mv=malvidin, Ap = apigeninidin, Lt = luteolinidin.
[b] Components occurring in quantities higher than about 10% are highlighted in bold.
[c] Red varieties.
[d] (*E*)- and (*Z*)-isomers.
[e] Black, blue and purple grains produced for making specialty foods or for use in ornamentation.
[f] Purple-fleshed.

9.4.1.2.1 Grapes and wine

European grapevine (*Vitis vinifera*, Vitaceae) varieties contain only 3-*O*-monoglucosides of anthocyanidins. North American and other species, such as river bank grape (*V. riparia*) and rock (mountain) grape (*V. rupestris*), fox grape (*V. labrusca*) and their hybrids with *V. vinifera* also contain the corresponding 3,5-di-*O*-glucosides and their acyl derivatives. The total amount of anthocyanins can range from about 300 to more than 7000 mg/kg fresh weight.

Distribution of anthocyanins in red grapes (*V. vinifera*) is highly variable and differs according to species, variety and a number of other variables. Determination of the individual pigments is also used in the chemotaxonomic classification of red grape varieties. The most abundant pigments are the 3-*O*-glucosides of malvidin and peonidin, as well as their 6′′-acetylated and *p*-coumaroylated derivatives. The 3-*O*-glycosides of petunidin, delphinidin and cyanidin are also widespread. For example, Cabernet Sauvignon contains 42.6% malvidin-3-glucoside, 20.5% malvidin-3-acetylglucoside, 10.0% delphinidin-3-glucoside, 6.4% malvidin-3-*p*-coumaroylglucoside, 6.1% petunidin-3-glucoside, 5.3% peonidin-3-glucoside, 2.5% delphinidin-3-acetylglucoside, 2.2% petunidin-3-acetylglucoside, 1.3% cyanidin-3-glucoside, 0.9% peonidin-3-acetylglucoside, 0.6% peonidin-3-*p*-coumaroylglucoside, 0.5% delphinidin-3-*p*-coumaroylglucoside, 0.4% petunidin-3-*p*-coumaroylglucoside, 0.1% malvidin-3-caffeoylglucoside

and smaller amounts of cyanidin-3-acetylglucoside and cyanidin-3-*p*-coumaroylglucoside. The important pigment in non-European grape species is malvidin-3,5-diglucoside.

Essentially the same pigments that are found in the grape skins from which they were extracted during fermentation are responsible for the young red wine colour. During wine maturation and aging, the colour of wine significantly changes. The amount of the original anthocyanins decreases, as they react with colorless flavan-3-ols, such as catechin, epicatechin and condensed tannins, to form oligomeric pigments and undergo other multiple reactions to form a heterogeneous mixture of typical darker and more stable red pigments, which are less sensitive to changes in pH (nucleophilic attacks of water, which results in the formation of carbinol pseudo base and subsequent loss of colour) or discoloration by sulfur dioxide. This is why mature wines are darker than young wines. The reaction mechanisms of formation of pigments in aged red wines are described in Section 9.4.1.5.9.

Polymerisation reactions in old red wines lead to the gradual formation of insoluble, brownish-red, high molecular weight condensation products called **phlobaphens**, which form sediments in wine. Certain other wine components, such as proteins, ascorbic acid, reducing sugars and metal ions can apparently be involved in their formation.

9.4.1.2.2 Apples and pears

Anthocyanin pigments responsible for the red colour of apple and pear peels are derived from cyanidin. The main pigment is cyanidin-3-galactoside (idaein), which represents about 94% of pigments in the Jonathan and 85% of all anthocyanins in the Red Delicious cultivars. Other pigments of these apple cultivars are cyanidin-3-arabinoside (10 and 4%) and cyanidin-3-glucoside (5 and 3%). Cyanidin-3-xyloside and acyl derivatives of the above listed anthocyanins are found in traces. The total amount of anthocyanins is about 100–200 mg/kg fresh weight.

Colourless flavan-3-ols or catechins or pale yellow flavonoids (flavonols, dihydrochalcones) and phenolic acids also act as co-pigments of anthocyanins. The main flavan-3-ols are (+)-catechin, (−)-epicatechin, (+)-gallocatechin and (−)-epigallocatechin. The main dihydrochalcone (its glycoside) occurring in all parts of the apple tree except for the mature fruit is phloretin-6-glucoside, known as phlorizin (**9-105**). The main phenolic acids of apples are *p*-coumaric, caffeic, ferulic and sinapic acids that are present mainly as depsides (called chlorogenic acids, which are isomers of caffeoylquinic, *p*-coumaroylquinic and furuloylquinic acids), glucose esters or glucosides.

Compared with other red fruits, the concentration of anthocyanins in pear peels is distinctly lower, ranging from 50 to 100 mg/kg of fresh weight. Pigments of red varieties of pears are derived mainly from cyanidin (unlike in apples, anthocyanidins of pears are not acylated by phenolic acids). The main pigments are cyanidin-3-galactoside, cyanidin-3-arabinoside and 3-rutinoside, in some cultivars peonidin-3-galactoside is also found.

Pears are rich in other flavonoids, mainly flavonols, flavan-3-ols and phenolic acids. The flavonols are largely represented by the kaempherol derivatives quercetin and isorhamnetin. The main components are quercetin-3-glucoside, 3,5-diglucoside and 7-xyloside, isorhamnetin-3-rutinoside, 3-glucoside, 3-rhamnosylgalactoside and 3-galactoside. Other components are malonyl glucosides of kaempherol, quercetin and isorhamnetin. As in apples, these glycosides act as anthocyanin co-pigments, which results in yellow-to-brown opacities and sediments in pear juices. The main flavan-3-ols present are (−)-epicatechin and (+)-catechin at about 10 and 2 mg/kg, respectively. The total content of phenolic acids is about 280 mg/kg, of which chlorogenic acid represents about 25%.

9.4.1.2.3 Sour cherries

The main pigments of sour cherries are anthocyanins derived from cyanidin. Their mean total content ranges from 350 to 820 mg/kg fresh weight, but may be even higher. For example, in the popular Morello variety the levels are 69–77% of the anthocyanin pigments cyanidin-3-(2-glucosyl)rutinoside (mecocyanin), 11–16% cyanidin-3-rutinoside, 3–15% cyanidin-3-glucoside and 1–3% cyanidin-3-sophoroside. The sour cherry variety Montmorency contains as the main pigment cyanidin-3-rutinoside (27%), followed by cyanidin-3-(2-glucosyl)rutinoside (25%), cyanidin-3-glucoside (19%) and cyanidin-3-sophoroside (16%). Minor pigments include cyanidin-3-sambubioside and 3-glucoside and peonidin-3-rutinoside (3%). Glycosides are accompanied by free aglycones cyanidin (7%) and peonidin (3%).

The yellow flavonoid pigments of sour cherries include kaempherol-3-rutinoside and 3-glucoside, followed by phenolic acids depsides, mainly derivatives of caffeoylquinic and *p*-coumaroylquinic acids that are accompanied by free acids.

9.4.1.2.4 Olives

The immature olive is grey–green, and later green to yellow–green; the fruit darkens on ripening and becomes violet and almost black. The main pigment of immature green olives is chlorophyll. Ripe purple to almost black olives contain anthocyanin pigments at a concentration of about 5000 mg/kg fresh weight in practically all cultivars. Besides anthocyanins, the pulp contains numerous anthoxanthins, phenolic acids and other polyphenols.

The main anthocyanins of ripe olives, which are concentrated mainly in the skin, are cyanidin-3-glucoside, cyanidin-3-rutinoside and their acylated derivatives. Contents of monoglycosides and diglycosides are roughly in the ratio 1 : 1 to 1 : 4. For example, the Spanish olive variety Manzanilla contains about 15% cyanidin-3-glucoside and other cyanidin glycosides, traces of 3-rutinoside, but 60% 3-rutinoside acylated by caffeic acid, traces of 3-glucosylrutinoside, 25% 3-(2-glucosyl)rutinoside and traces of this anthocyanine acylated by caffeic acid. In numerous other varieties further pigments were also found, such as cyanidin-3-(2-xylosyl)rutinoside, 3-rhamnosyldiglucoside acylated by caffeic acid and 3-glucoside acylated by *p*-coumaric acid. Particular anthocyanins derived from peonidin may also be present. In Greek olives anthocyanins derived from delphinidin are also present. Pigments of pickled black olives are formed in the enzymatic browning reactions.

9.4.1.2.5 Potatoes

There are more than 5000 varieties of potatoes in the world. Some potato varieties are distinguished only by a deeply coloured skin caused by anthocyanins; their flesh is the usual white or cream, which is due to the presence of carotenoid pigments. Others have coloured flesh. In South America, there are potatoes with a diversity of colours: purple, pink, orange and yellow, often with a contrasting colour around the eyes. The colour of the flesh is often similar to the skins. The so-called purple potatoes (or blue potatoes), even if not commonly found in our habitual diet, are now available on the European market. They have purple skin and flesh, which becomes blue once cooked. The colour of potatoes is determined by genetics. There are genes for purple pigments and genes that cover particular parts of the plant: flowers, leaves, skin, eyes and flesh.

The concentration of anthocyanins in potatoes varies over a wide range. The level of anthocyanins in skin tissue is quite high. However, the skin is such a small volume of the whole tuber that generally red-skinned white-fleshed potatoes contain about 15 mg anthocyanins per fresh weight. However, potatoes with anthocyanin in the flesh range from 150 to about 400–500 mg/kg fresh weight. The red-flesh potatoes contain predominantly acylated glucosides of pelargonidin. Purple-flesh potatoes have a more complex content of acylated glucosides of pelargonidin, petunidin, cyanidin and malvidin. For example, the purple-flesh variety Vitelotte Noire with the total anthocyanin content 486 mg/kg (fresh weight) contains as the main anthocyanin pigments (*E*)-malvidin-3-*O*-[6-*O*-(4-*O*-*p*-coumaroyl-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-β-D-glucopyranoside (294 mg/kg) and (*E*)-petunidin-3-*O*-[6-*O*-(4-*O*-*p*-coumaroyl-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-β-D-glucopyranoside (125 mg/kg), known as petanin (**9-81**).

9.4.1.3 Use

Anthocyanins isolated from natural sources have been used as food colourings for more than 100 years, and for much longer in the form of various fruit juice concentrates. The disadvantage is that they only have the intense colour in solutions of pH < 3.5, so they are only suitable for acidic foods. Their importance as food colourings has increased in relation to consumers' growing interest in natural substances. Potential sources of these pigments are limited by the availability of the plant materials and overall economic conditions of their production, so only a few plant species may be used industrially.

The anthocyanin pigments most commonly used for food colouring are derived from grapes (skin or juice sediment), where the anthocyanin content ranges from 0.3 to 7.5 mg/kg. Historically, the oldest product of this type, produced in Italy since 1879, is called enocyanin (or enocianina). A rich source of anthocyanins is elderberries containing pigments at a concentration of of 2–10 g/kg fresh weight, or chokeberries (10 g/kg) that have similar composition of pigments. A very high content of anthocyanins is also found in blackberries (0.8–3.3 g/kg) that sometimes precipitate in juices. Other sources include red cabbage (containing 0.7–0.9 g/kg of anthocyanins), roselle calyces (15 g/kg dry matter), sometimes also sweet potatoes, red pulp oranges, leaves and seeds of red varieties of maize and locally also other products.

9.4.1.4 Biochemistry, physiology and nutrition

Flavonoids as well as stilbenes are synthesised from phenylalanine via cinnamic and *p*-coumaric acids. The extension of the chain by reaction with malonyl-CoA yields a tetraketide as an intermediate, the Claisen condensation of which produces chalcones. The basic flavonoids are naringenin chalcone (isosalipurpol) and isoliquiritigenin. Naringenin chalcone gives rise to flavanone (dihydroflavone) called naringenin (5,7,4′-trihydroxyflavanone). Hydroxylation and methylation of the skeleton creates additional hydroxyflavanones, which are, together with naringenin, precursors of all other flavonoids that arise by oxidation, reduction and dehydration reactions. Isoliquiritigenin is a precursor of isoflavonoids. Another chalcone (2,4,6,4′-tetrahydroxychalcone) is a precursor of quinochalcones.

The biological properties of anthocyanins have not yet been explored extensively. Their toxicity and mutagenicity were examined in relation to their use as food additives, but were not proved or were very low, so that anthocyanin pigments are generally allowed for food colouring, and in most countries there are no limits on their use. Very low toxicity was observed even in their metal complexes with Al(III) and Sn(II) ions. Apart from imparting colour to food raw materials and foods, anthocyanins also have an array of health-promoting benefits, as they can protect against a variety of oxidants through a number of mechanisms.

9.4.1.5 Properties and reactions

From the technological perspective, the most important property of anthocyanins is colour and its stability, which is usually relatively low. The main factors affecting the colour stability of anthocyanins are the structure of the molecule, presence of certain enzymes, pH, temperature, presence of oxygen and exposure to radiation. Anthocyanins may produce various coloured or colourless reaction products in reactions with other food components, such as, for example, ascorbic acid, sulfur dioxide, other phenols and metal ions.

9.4.1.5.1 Effect of pH

In aqueous solutions, anthocyanins are transformed into various products of different colour. Depending on pH, the following five different aglycone structures are in equilibrium (Figure 9.9):

- red flavylium cation
- colourless carbinol pseudo base
- purplish-red neutral quinoid base
- blue quinoid base
- yellow chalcones.

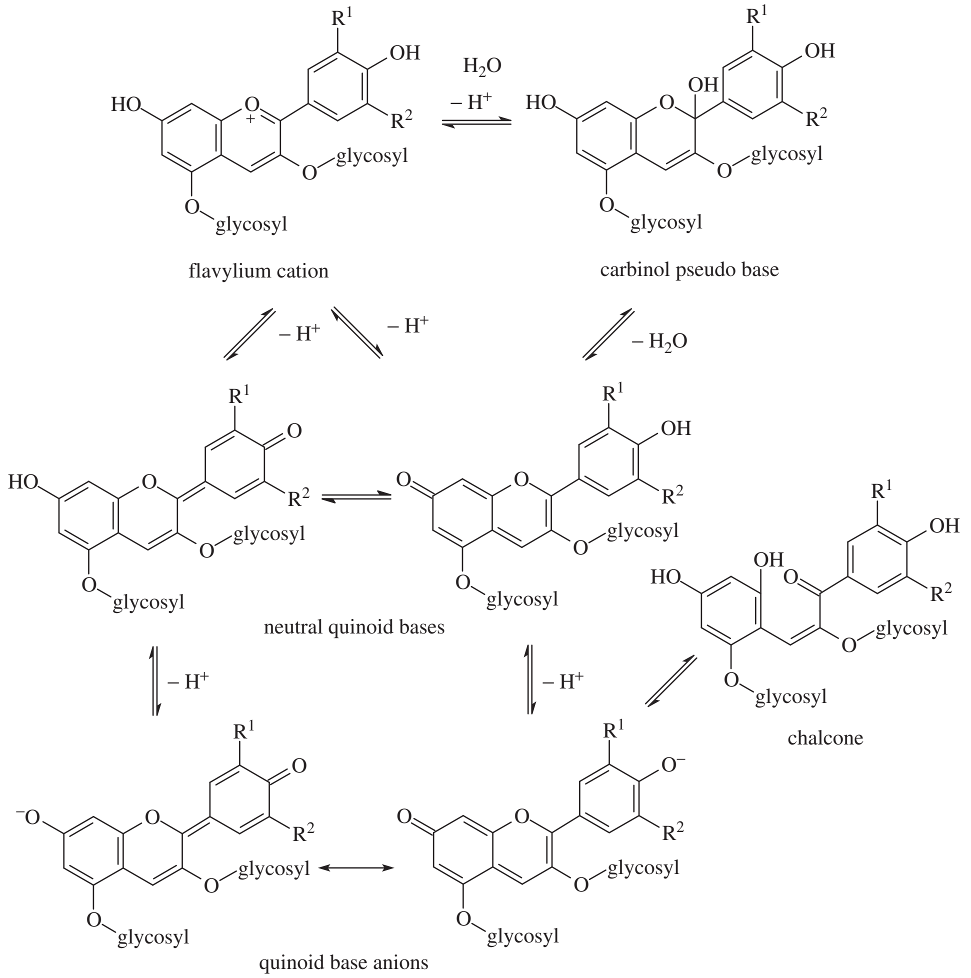

Figure 9.9 Transformations of anthocyanins according to pH (R^1 and R^2 = H, OH, OCH_3 or *O*-glycosyl).

In solutions of pH 1.0 and lower, anthocyanins exist solely as red-coloured flavylium salts. When increasing pH, the equilibrium shifts in favour of colourless carbinol pseudo base and the red colour fades. Around the range of pH values of 4.0 to 4.5, anthocyanins are completely colourless. Another increase in pH is manifested by the purplish-red colour, which is caused by formation of a neutral quinoid base that requires the presence of free hydroxyl groups on one of C-5, C-7 or C-4′ carbons. In solutions of pH 7 a blue coloured quinoid base is formed. After some time or following an increase in pH value, a gradual decrease of blue colour intensity occurs as a result of yellow chalcone formation. If the solution is acidified to around pH 1.0, the blue quinoid and colourless carbinol bases are converted back into red flavylium cations. The transformation of chalcones is slower and not quantitative.

In processed fruit and vegetables, the situation is more complex. Anthocyanins in plants (pH of from 2.5 to 7.5) occur as a purplish-red neutral quinoid base, but in food products they may be in media of different pH. However, they are mostly stabilised by inter co-pigmentation (interactions with other flavonoids) or intra co-pigmentation (acylated forms), or by interactions with other food components. Many products therefore retain their original colour or possess some discoloration. In products stored long-term (such as strawberry jams, olives) oligomers are then formed with colour similar to the original colour of the anthocyanins, while the original pigments may be absent altogether.

9.4.1.5.2 Effect of structure

The colour of non-acylated and monoacylated anthocyanins in acidic media is mainly dependent on the number and type of aglycone (anthocyanidin) substituents. Anthocyanidins with a higher number of hydroxyl groups tend to have a blue tint, and methoxyl derivatives have a red tint. Derivatives with a higher number of hydroxyl groups are less stable, and their stability increases with a growing number of methoxyl groups. Glycosides and their acyl derivatives (anthocyanins) generally have a red–blue colour and are more stable than the corresponding aglycones (anthocyanidins). During storage, heat treatment and exposure to light, diglycosides are more stable than monoglycosides. The type of bound sugar has some influence on the stability of the pigments.

The presence of one or more acyl groups stabilises anthocyanins (due to the so-called intramolecular co-pigmentation), and their

reaction with water in neutral or weakly acidic environments does not lead to the formation of a colourless quinoid base, but preferably to a blue quinoid base. These pigments are less sensitive to changes in pH, and colour is stable in weakly acidic and neutral media.

9.4.1.5.3 *Effect of temperature*

Like most chemical reactions, the stability of anthocyanins and the rate of their degradation are affected by temperature, and also depend on the pH value, their structure, the presence of oxygen and the possibility of entering into reactions with other components of the system.

Degradation of anthocyanins in the absence of oxygen, at pH ranging from 2.0 to 4.5, is virtually independent of pH and usually takes place under aerobic and anaerobic conditions as a first-order reaction. In the presence of oxygen, 3-glycosides of anthocyanidins show the highest stability at elevated temperatures in the pH range of 1.8 to 2.0, and 3,5-diglycosides are stable at pH 4.0–5.0. Most anthocyanins somewhat paradoxically exhibit increased stability at the elevated temperatures used in the processing of fruits and vegetables. This phenomenon is explained by the protective effect of various components of the system, and by condensation of monomers that leads to the formation of more stable oligomeric pigments, whose content increases with temperature and storage time. Oligomeric pigments are important colour carriers, especially of stored fruit juices and red wines.

The mechanism of anthocyanin degradation reactions depends not only on temperature, but also on the structure of substances. Decomposition reactions of 3-glycosides of anthocyanidins are shown in Figure 9.10. The major products are glycosides of the corresponding chalcones. Hydrolysis of glycosidic bonds in chalcones yields α-diketones (1,2-diketones). Subsequent reactions of the primary degradation products (most of them are colourless compounds) produce brown-coloured polymeric products. Somewhat different is the decomposition mechanism of 3,5-diglycosides of anthocyanidins, where diglycosides of coumarins arise as the main reaction products (Figure 9.11).

9.4.1.5.4 *Enzymes*

Loss of colour of anthocyanins may also be caused by enzymatic reactions catalysed by two groups of enzymes:

- glycosidases, which hydrolyse the glycosidic bond to form sugar and anthocyanin aglycone (anthocyanidin), which is unstable and spontaneously transformes into colourless products;
- polyphenol oxidases that also act in the enzymatic browning reactions.

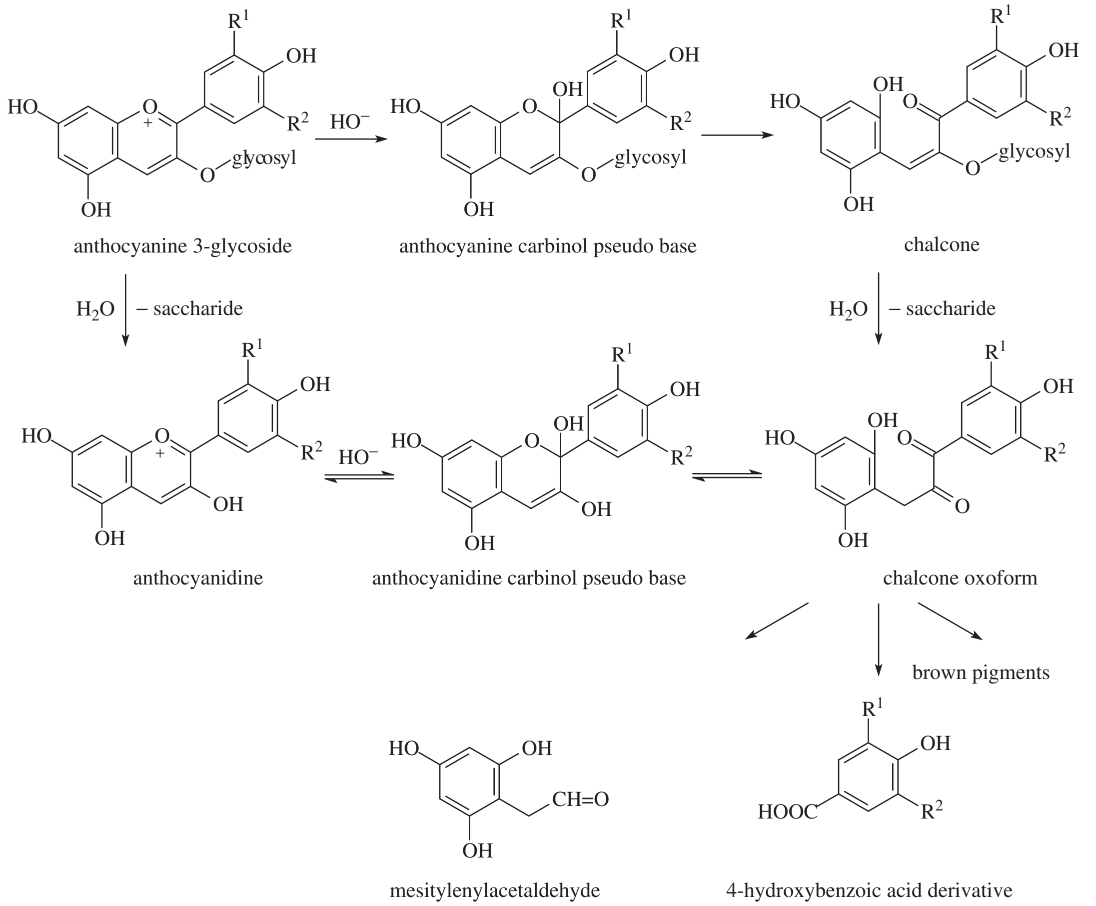

Figure 9.10 Degradation of 3-glycosides of anthocyanidins (R^1 and R^2 = H, OH, OCH_3 or *O*-glycosyl).

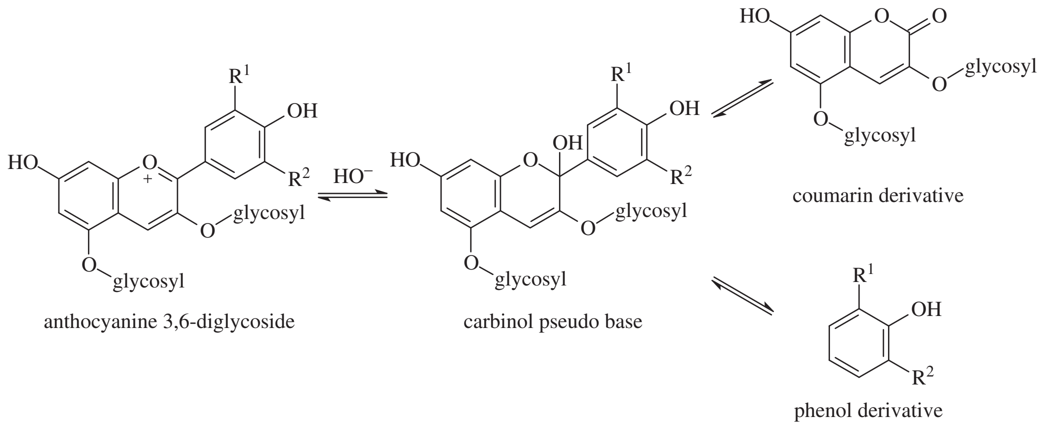

Figure 9.11 Degradation of 3,5-diglycosides of anthocyanidins (R^1 and R^2 = H, OH, OCH_3 or *O*-glycosyl).

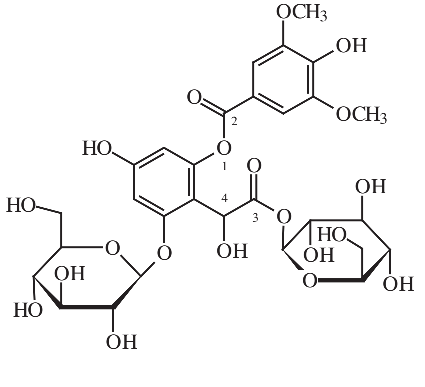
9.4.1.5.5 Oxygen and peroxides

Atmospheric oxygen oxidises anthocyanins to colourless or brown coloured products directly or through other labile compounds that are preferentially oxidised by oxygen (such as ascorbic acid). Degradation of anthocyanins that is induced by ascorbic acid proceeds indirectly via hydrogen peroxide, which arises by ascorbic acid oxidation. For example, the anthocyanin pigment malvin (malvidin-3,5-diglucoside), found in flowers of the mallow genus *Malva* (*M. sylvestris*, Malvaceae) and in a variety of fruits and flowers, is oxidised by hydrogen peroxide under the opening of the heterocyclic ring between C-2 and C-3, which yields a colourless substance malvone (**9-83**). A hydrogen atom may replace the hydroxyl group at C-4. On alkaline hydrolysis, malvone affords syringic acid. A similar degradation of anthocyanin hirsutin (hirsutidin-3,5-diglucoside) affords colourless hirsulone.



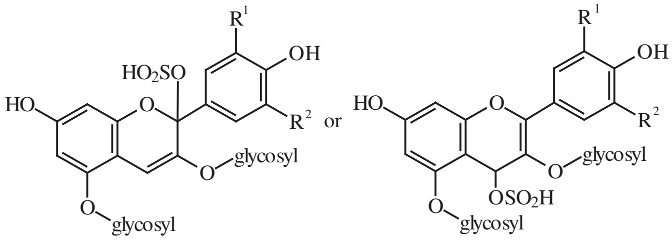
9-83, malvone

9.4.1.5.6 Radiation

Anthocyanins are unstable when exposed to visible, ultraviolet or ionising radiation. Decomposition takes place mainly as photooxidation. Anthocyanins substituted at C-5 hydroxyl group, which are fluorescent compounds, are more sensitive to photochemical degradation in comparison with C-5 unsubstituted anthocyanins.

9.4.1.5.7 Sulfur dioxide

The natural anthocyanin pigments form adducts with bisulfite ion. The bisulfite ion forms a bond to position C-2 or C-4 of the flavylium nucleus, which decolorises the pigment and simultaneously stabilises the glycosidic bond at position C-3 (**9-84**). The adducts are stable at pH about 3, but acidification to pH < 1 and heating leads to reversal of the reaction with quantitative recovery of the pigment. Such adducts are therefore likely to be likewise unstable under gastric conditions.



9-84, reaction products of anthocyanins with bisulfites

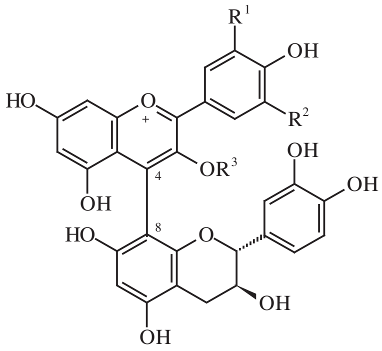
9.4.1.5.8 Sugars and their degradation products

Sugar concentrations higher than 20% (found in jams and similar products) have a stabilising effect on the colour of anthocyanins, mainly due to decreased water activity. Degradation of anthocyanins is accelerated in the presence of sugar degradation products, especially by furan-2-carbaldehyde and 5-hydroxymethylfuran-2-carbaldehyde that produce complex brown-coloured condensation products with anthocyanins.

9.4.1.5.9 Transformed pigments in red wines

Anthocyanins are relatively unstable and undergo numerous chemical reactions in beverages like red wines during fermentation processes, maturation and aging. The monomeric anthocyanins extracted from the grape skin are a crucial contribution to the colour of young red wine. Their intramolecular interactions and intermolecular interactions with other wine constituents and especially

phenolic compounds can further enhance the colour of wine. One of these reactions is based on the interaction (called co-pigmentation) of anthocyanin with flavan-3-ols (procyanidins, called co-pigments) through which a complex of these two compounds initially arises and subsequently the final pigments, which are dimers linked by covalent bonds. An example is a dimer of anthocyanin and (+)-catechin linked by a C4→C8 bond, which is formed in the nucleophilic attack of the phloroglucinol ring of catechin on the electron deficient C-4 position of anthocyanin (**9-85**). This dimer has a red colour similar to the colour of anthocyanin, even though the co-pigment is colourless flavan-3-ol. Another possibility for the formation of more stable pigments in red wines is the reaction of anthocyanins with colourless flavan-3-ols through their nucleophilic C-8 position (less likely through the C-6 position) mediated by aldehydes, such as the fermentation product acetaldehyde, which leads to coloured anthocyanin-alkylene-(epi)catechin conjugates (Figure 9.12). Acetaldehyde may also mediate analogous self-condensation of anthocyanins. The other aldehydes arising in wines as fermentation products and intermediates (such as propionaldehyde and isobutyraldehyde) or aldehydes extracted from oak wood during wine aging (such as benzaldehyde and cinnamaldehyde derivatives) may be involved in similar reactions leading to various anthocyanin-alkylene-(epi)catechin dimers. Some aldehydes, such



9-85, anthocyanin-catechin dimer

as methylglyoxal, furan-2-carbaldehyde, 5-hydroxymethylfuran-2-carbaldehyde may react directly with flavan-3-ols yielding alkylene-linked dimers. Their oxidation and dehydration yields xanthylium-type pigments (Figure 9.13). Cinnamic aldehydes, such as coniferaldehyde (R^1 = H, R^2 = OCH_3) and sinapaldehyde (R^1 = R^2 = OCH_3) produce, via alkylene-linked dimers, orange pigments called **oaklins** (Figure 9.13).

During maturation and aging, the concentration of monomeric anthocyanins decreases, while numerous more complex and stable anthocyanin-derived pigments are formed. One of the most

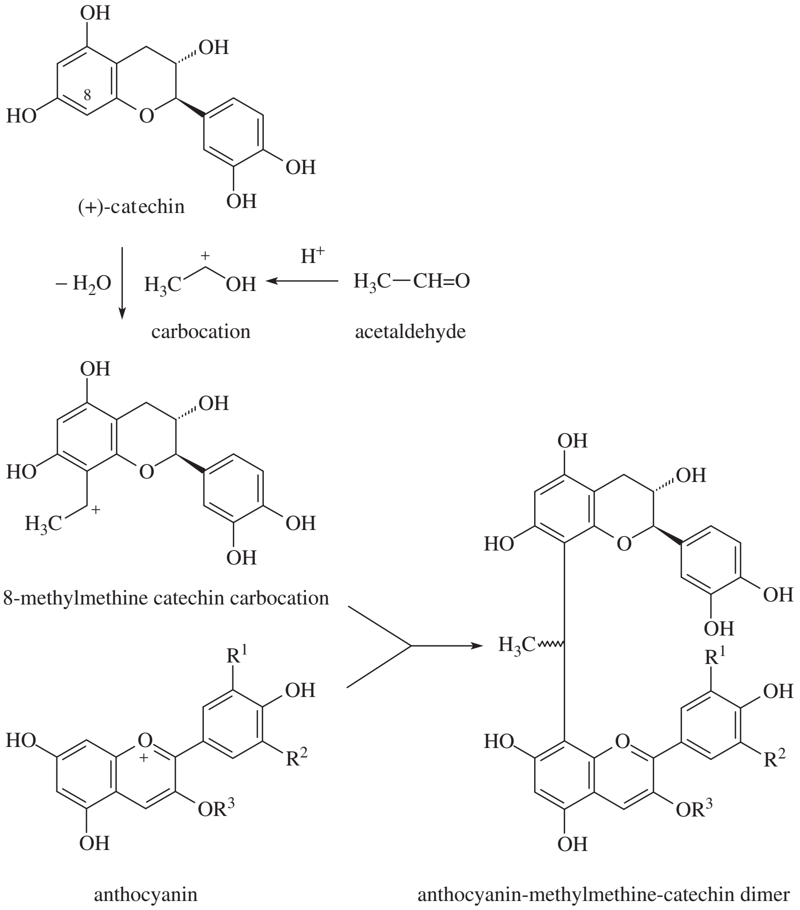


Figure 9.12 Reactions of anthocyanins with flavan-3-ols and aldehydes.

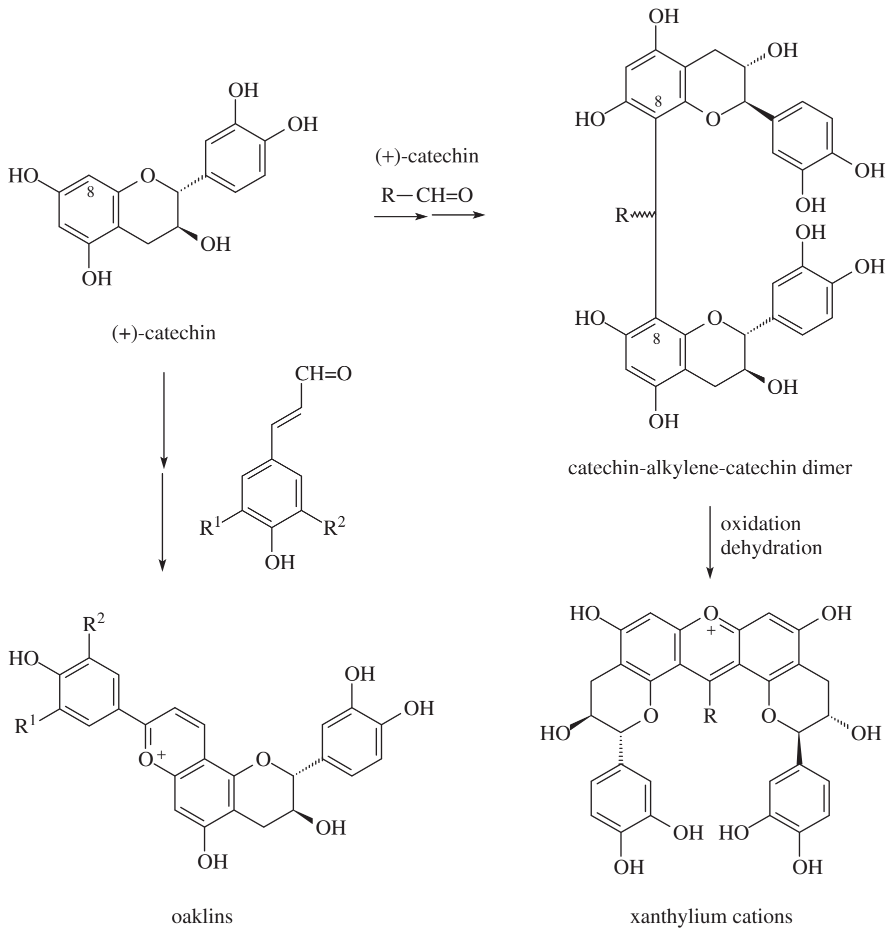

Figure 9.13 Reactions of aldehydes with flavan-3-ols.

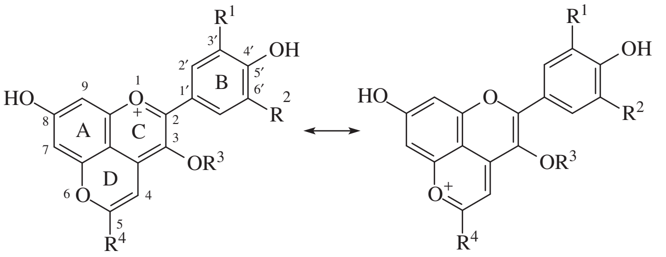

Figure 9.14 Basic structure of pyranoanthocyanins: (R^1, R^2 = H, OH or CH_3, R^3 = sugar residue).

interesting groups of anthocyanin reaction products in red wines is **pyranoanthocyanins** (Figure 9.14) possessing an additional pyran ring structure between C-4 and the hydroxyl group at C-5 of anthocyanin, which seems to be responsible for relatively higher stability of pyrananthocyanins (e.g. their resistance to pH changes and sulfur dioxide bleaching). The newly formed pyran ring is either unsubstituted or substituted at C-5 by COOH (in carboxypyranoanthocyanins), CH_3 (in methylpyranoanthocyanins), phenols (in pyranoanthocyanin-phenols) or flavanols (in pyranoanthocyanin-flavanols).

Among the pyranoanthocyanins bearing different moieties of fermentation products, the major and most important group occurring naturally in red wines is **vitisins**. The substituted carboxypyranoanthocyanins (A-type vitisins with carboxyl group at C-5) arise from the cycloaddition reaction of pyruvic acid to an anthocyanin moiety (Figure 9.15), while unsubstituted pyranoanthocyanins (B-type vitisins) are formed by reaction of anthocyanins with acetaldehyde as minor pigments. Vitisin A and vitisin B are derived from the main pigment of red wines malvidin-3-*O*-glucoside. Also identified in aged wines are yellow methylpyranoanthocyanins (with a methyl group at C-5) derived from malvidin-3-*O*-glucoside, which form by cycloaddition reaction of anthocyanins with acetoacetic acid followed by decarboxylation and isomerisation. For example, vitisin A derived from malvidin-3-*O*-glucoside and its acylated forms (acetyl and *p*-coumaroyl glucosides) have been identified in aged Port red wine.

More recently a group of neutral non-oxonium pyranoanthocyanins occurring in aged Porto red wine and named as **oxovitisins A** have been identified. Oxovitisins A arise by hydration of vitisins A, decarboxylation of the formed intermediate and isomerisation of the decarboxylation product (Figure 9.16).

In red wines, 4-hydroxycinnamic acids (such as *p*-coumaric, caffeic, ferulic and syringic acids) and their decarboxylation

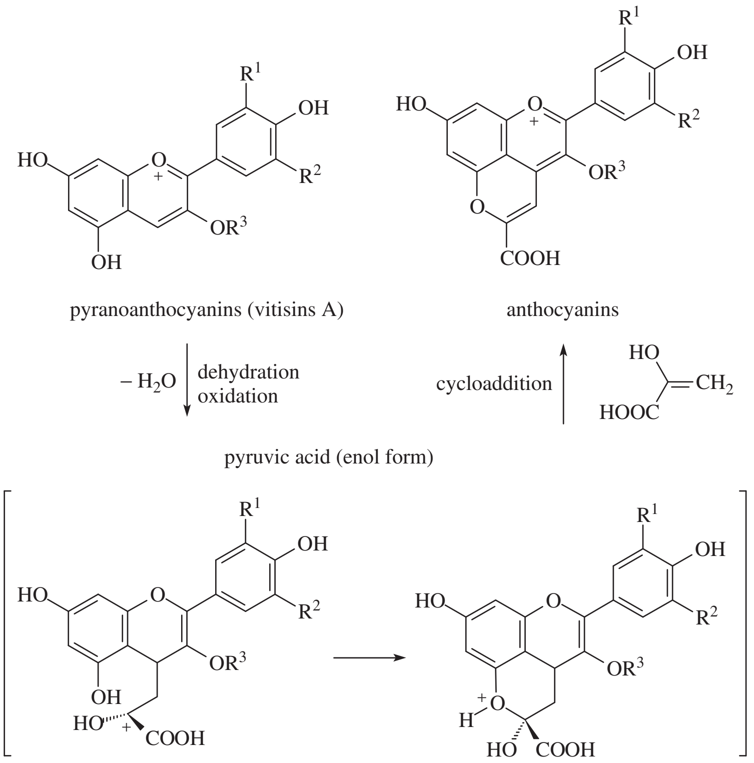

Figure 9.15 Reaction of anthocyanins with pyruvic acid and formation of A-type vitisins: (R^1, R^2 = H, OH or CH_3, R^3 = sugar residue).

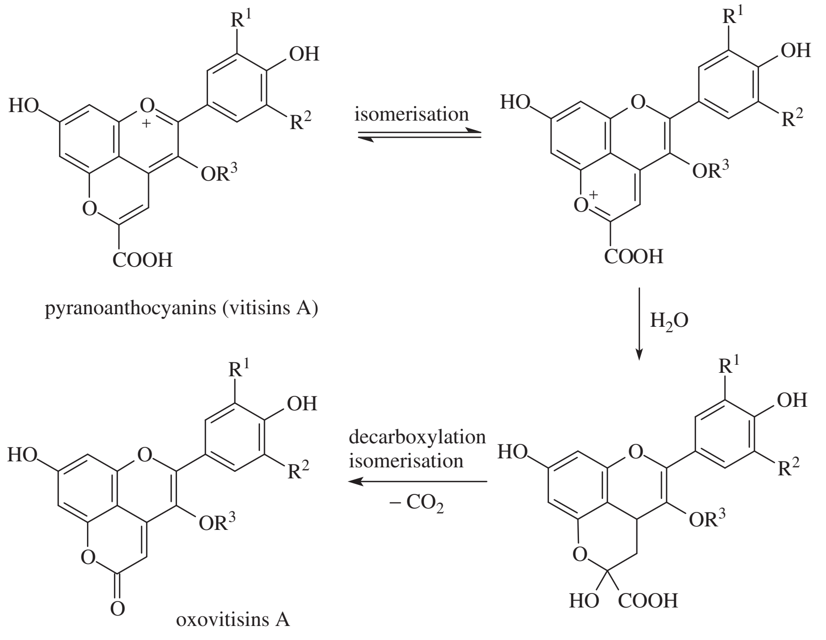

Figure 9.16 Formation of A-type oxovitisins from A-type vitisins: (R^1, R^2 = H, OH or CH_3, R^3 = sugar residue).

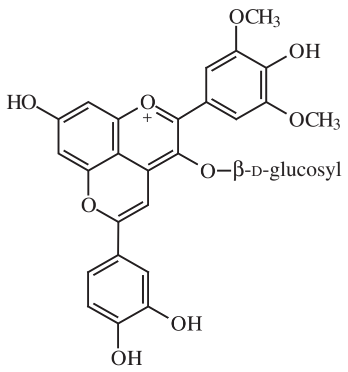
products 4-vinylphenols (such as 4-vinylphenol, 4-vinylcatechol, 4-vinylguaiacol and 4-vinylsyringol) can react with free anthocyanins to yield pyranoanthocyanin-phenols (also known as hydroxyphenyl-pyranoanthocyanins), some of which are named **pinotins**, since they were first isolated from *Vitis vinifera* cv. Pinotage wines. The formation of the best known representative of this family of pigments pinotin A (**9-86**) is analogous to the formation of A-type vitisins (Figure 9.15). The nucleophilic C-2-position of caffeic acid attacks the electrophilic C-4 position of malvidin-3-*O*-glucoside to form an intermediate carbonium ion, in which the reaction of C-5 hydroxyl of the anthocyanin moiety forms a pyran ring.

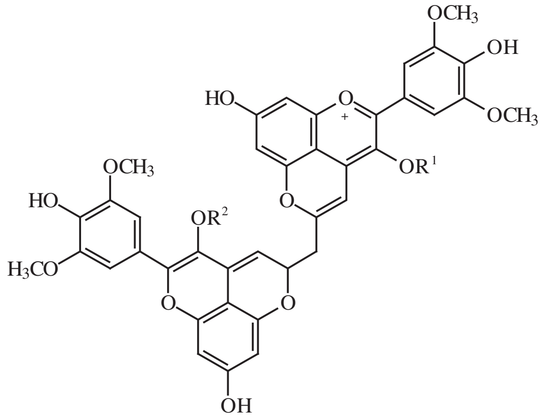


9-86, pinotin A

Orange pyranoanthocyanin-flavanols (also known as flavanyl-pyranoanthocyanins or vinylflavanol-pyranoanthocyanins) isolated from Port red wine contain a pyroanthocyanin moiety linked directly to flavan-3-ols or procyanidins. These pigments arise in wines from the reaction of anthocyanins with 8-vinylflavan-3-ols (such as 8-vinylcatechin) or 8-vinylprocyanidins (such as 8-vinylprocyanidin B_3) mediated by acetaldehyde as in the case of anthocyanin-alkylene-(epi)catechin conjugates (Figure 9.12). 8-Vinylflavanols are not present in grapes, but they have been proposed to result from the dehydration of the flavanol–ethanol adducts formed by reaction of flavanols with acetaldehyde. Examples of pyranoanthocyanin-flavanols generated from malvidin-3-*O*-glucoside and (+)-catechin and malvidin-3-*O*-glucoside and procyanidin B_3 are given in formulae **9-87**. In addition to pyranoanthocyanin-flavan-3-ol monomers and pyranoanthocyanin-procyanidin dimers more polymerised pyranoanthocyanin-flavanols (up to tetramers) have been found in some red table wines and Port red wine.

Related blue–violet vinylpyranoanthocyanins (also known as flavanyl/phenyl-vinylpyranoanthocyanins) named **portisins** are produced in Port red wine during aging. A-Type portisins arise from the reaction between 8-vinylflavanols and carboxypyranan-thocyanins (vitisins A), followed by the elimination of formic acid, which gives rise to the vinyl bridge (Figure 9.17). B-Type portisins arise from vitisins A and 4-hydroxycinnamic acids. The corresponding reaction mechanism is analogous to that of portisins A, but it involves further decarboxylation of the intermediate.

A relatively new class of turquoise coloured pyranoanthocyanin dimers derived from delphinidine glycosides was identified recently in aged Port wine and shown to be formed by reactions of carboxypyranoanthocyanin with methyl-pyranoanthocyanin. The structure of the identified pyranoanthocyanin methine dimer is given in formula **9-88**.



9-88, pyranoanthocyanin dimer

9.4.1.5.10 Transformed pigments in fruits and vegetables

Some of the pigments occurring in aged wines are similarly found in anthocyanin-rich fruits and vegetables. Three pyranoanthocyanins, the 3-glucosides of 5-carboxypyranodelphinidin,

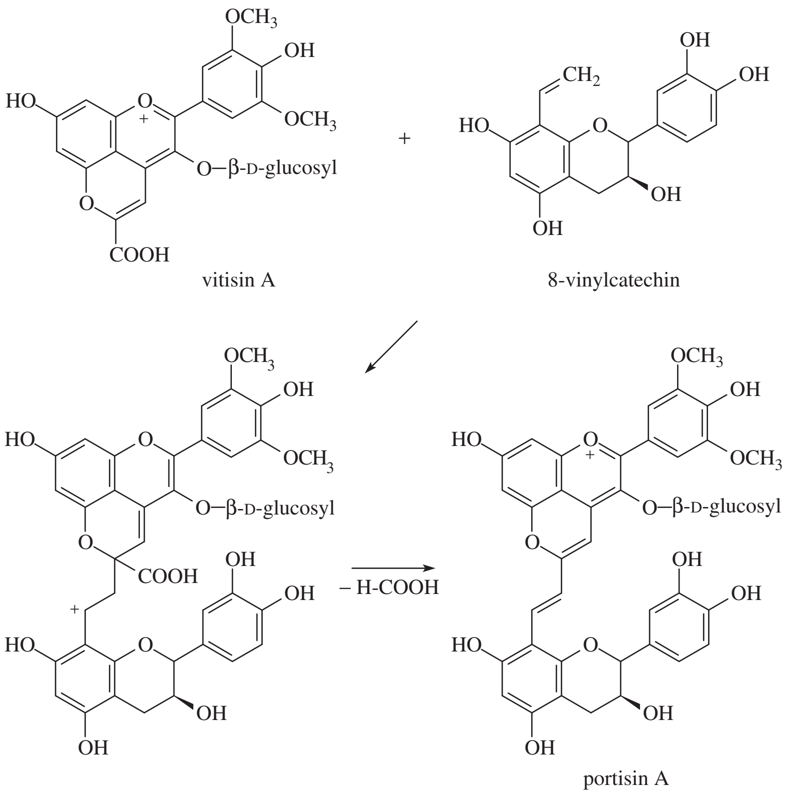

Figure 9.17 Formation of portisin A.

5-carboxypyranopetunidin and 5-carboxypyranomalvidin, were produced in an extract of black beans (*Phaseolus vulgaris*) fortified with pyruvic acid. Pyranoanthocyanin-phenols derived from cyanidin-3-*O*-glucoside and 4-vinylphenol, 4-vinylcatechol, 4-vinylguaiacol and 4-vinylsyringol were identified in blood orange juice. Anthocyanin-flavanol reaction products (derived from cyanidin and delphinidin) were also found in blackcurrants and strawberries. Vinylcatechol adducts of cyanidin (derived from 4-vinylphenol, 4-vinylcatechol and 4-vinylguaiacol) were isolated from black carrots.

9.4.1.5.11 Other reactions

Anthocyanin with the structure of *o*-diphenols form complexes with metals (such as Al, K, Fe, Cu, Ca and Sn) that can stabilise the colour of products, but also may cause unwanted discolorations. For example, complexes with tin formed in cans may change the red colour of fruits (such as strawberries) to purple.

9.4.2 Other flavonoids

Other flavonoids that are usually pale yellow-to-dark yellow pigments include flavanones, flavanonols, flavones, flavonols, chalcones, aurones and isoflavones. The most important food pigments are flavones and flavonols. However, with few exceptions, these flavonoid substances are not used as food colourings. Previously, some of these compounds were ranked among the so-called bioflavonoids (see Section 5.15) for their biological effects.

Flavonoids usually exist in the form of *O*-glycosides, which contain either free or acylated D-glucose, L-rhamnose, D-galactose, L-arabinose, D-xylose, D-apiose or D-glucuronic acid. Sugars are bound at positions C-7, C-5, C-4′, C-3′, but mostly through the hydroxyl group attached to the C-7 carbon. In addition to *O*-glycosides, flavonoids are quite often found as *C*-glycosides (mainly derived from flavones and flavonols), in which glucose is bound by the C–C bond in positions C-6 or C-8 of flavonoid molecules.

Hydrolysis of glycosides in the manufacturing of fruits and vegetables may in some cases (in acidic media and in particular at higher temperatures) lead to increased concentrations of aglycones. Most flavonoids in foods are involved in enzymatic browning reactions. The ability to bind heavy metals, along with the ability to terminate the radical oxidation reactions, gives flavonoids many antioxidant properties. However, metal complexes of flavonoids in foods sometimes cause unwanted discolorations.

9.4.2.1 Flavanones

Colourless to pale yellow flavanones are widespread in foods, but are not important as food pigments. At higher concentrations they are found only in citrus fruits. The main components are glycosides derived from (2*S*)-5,7-dihydroxyflavanones, which differ in substituents of the ring C (**9-89** and **9-90**).

The most important flavanone aglycones are hesperetin (5,7,3′-trihydroxy-4′-methoxyflavanone) and naringenin (5,7,4′-trihydroxyflavanone). Hesperetin is the major aglycone occurring

in oranges and lemons. Its contents in juices is about 1000 mg/l. Grapefruits contain naringenin as the main glycoside component.

Common glycosides of citrus and other plant materials are sakuranin (sakuranetin-5-glucoside), narirutin (naringenin-7-rutinoside, also known as neoponcirin), naringin (naringenin-7-neohesperidoside), eriodictin (eriodictyol-7-rhamnoside), ericitrin (eriodictyol-7-rutinoside), poncirin (isosakuranetin-7-neohesperidoside), hesperidin (hesperetin-7-rutinoside) and neohesperidin (hesperetin-7-neohesperidoside). In citrus fruits, flavanone glycosides are located mainly in the albedo. The main glycoside of oranges is hesperidin; the dominating glycoside (up to 90% of total glycosides) in grapefruits is naringin. Their contents in growing fruits increase till full ripeness and then remain constant at the level of 1–6 g per fruit.

Oranges contain only rutinosides (such as hesperidin and narirutin), and grapefruits contain rutinosides and neohesperidosides. The presence of naringin in orange juice therefore indicates the presence of grapefruit juice. Glycoside naringin (naringenin-7-neohesperidoside)occurring in grapefruits, neohesperidin (hesperitin-7-neohesperidoside) found in bitter bigarade oranges (*Citrus aurantium* var. *amara*, Rutaceae) and all other flavanone neohesperidosides are intensely bitter substance, unlike corresponding rutinosides and glucosides.

Liquiritin (liquiritigenin-4′-glucoside) occurs in licorice (*Glycyrrhiza glabra*, Fabaceae), sakuranin and prunin (naringenin-7-glucoside) in plums (*Prunus* spp., Rosaceae), pinocembrin glycosides occur in legumes, pyracanthoside (eriodictyol-7-glucoside) in firethorn (*Pyracantha coccinea*, Rosaceae). Butin and its 7,3′-diglucoside butrin are components of the tree *Butea monosperma* with orange–red flowers native to tropical and sub-tropical parts of the Indian Subcontinent and Southeast Asia that are used for colouring food, in medical products and to treat liver diseases. Prenylated flavanones (see Section 10.4) occur in hop cones.

9.4.2.2 Flavanonols

Flavanonols and their glycosides are not very significant flavonoids, because they do not occur at higher concentrations in food materials. An example of a flavonol is taxifolin (dihydroquercetin, **9-91**), which occurs in larger quantities in peanuts and as a components of pollen and along with other flavanonols is quite a common component of other plants.

9.4.2.3 Flavones

Flavones are, together with flavonols, the most widespread yellow pigments of plants. Typical compounds in foods are flavones substituted at C-5 and C-7, less often in the position C-6 of ring A and at C-4′ of ring B. If the substituent occurs in position C-4′, then the carbons C-3′ and C-5′ and rarely the carbon C-2′ are also often substituted. Common substituents are hydroxyl and methoxyl groups. Particularly frequent flavones are apigenin and luteolin (**9-92**), less often, tricetin and other flavones occur.

Examples of flavones with methylated hydroxyl groups in ring A are hispidulin, nepetin and cirsiliol, while acacetin, diosmetin and chrysoeriol have methoxyl groups in ring B. Methoxyl groups in both rings A and B have limocitrin, tangeretin, nobiletin and sinensetin (**9-93**), which occur in different types of citrus fruits, especially in peel, together with a number of other hydroxylated polymethoxyflavones and other flavonoids.

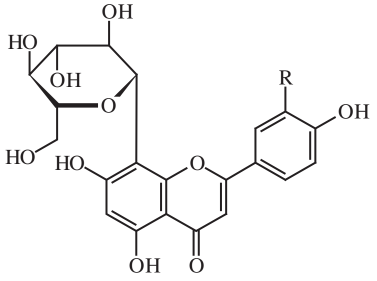
sinensetin, $R^4 = H$, $R^1 = R^2 = R^3 = R^5 = R^6 = OCH_3$

Sugars (mainly D-glucose, D-galactose and L-rhamnose) in *O*-glycosides of flavones are preferentially bound to the hydroxyl group in position C-7. Other *O*-glycosides and *C*-glycosides are rare. For example, curly mint (*Mentha crispa*, Lamiaceae) contains the glycoside known as diosmin (diosmetin-7-rutinoside). Unlike in anthocyanins, flavones do not occur as *O*-diglycosides.

The most common *C*-glycosides are vitexin (8-*C*-glucosylapigenin) and orientin (8-*C*-glucosylluteolin, **9-94**) that occur, for example, in rice bran and many fruits. Further common *C*-glycosides are isovitexin (6-*C*-glucosylapigenin) and isoorientin (6-*C*-glucosylluteolin). Orientin and isoorientin, the main components of fermented roiboos tea (*Aspalathus linearis*, Fabaceae), show antioxidant properties. Vitexin, isovitexin, flavone *C*-glycoside chafuroside A (with a potent anti-inflammatory activity) and its regioisomer chafuroside B (**9-95**) have been isolated from oolong tea. For example, *C*-glycoside, known as schaftoside (apigenin-6-*C*-β-D-glucopyranosyl-8-*C*-α-L-arabinopyranoside), is found in figs, and its presence may be used to detect fig juice in other fruit juices, for example, in grape juices.



9-94, flavone *C*-glucosides
vitexin, R = H
orientin, R = OH

A special separate group of about 60 pigments derived from flavones are **biflavonoids**. Biflavonoids are usually dimers of apigenin, with molecules linked by bonds C8→C8, C8→C3′ or C8-C4′ that have no importance as food pigments. Amentoflavone (**9-96**) and other biflavonyls, for example, occur in large quantities in the leaves of ginkgo, also known as the maidenhair tree (*Ginkgo biloba*, Gingoaceae). Leaf extracts containing flavonoids and terpenoids (so called ginkgolides and bilobalides) are used in pharmacy for problems with blood circulation in some parts of the body, and to strengthen the memory, improve concentration and to treat Alzheimer's disease.

9.4.2.4 Flavonols

Flavonols are, together with flavones, an important group of yellow plant pigments. All major flavonols occurring in foods have hydroxyl groups in positions C-3, C-5, C-7 and C-4 and mutually differ by substitutions at positions C-3′ and C-5′. Almost universal flavonols are kaempherol, quercetin and myricetin (**9-97**), which occur mainly as glycosides and as co-pigments accompanying anthocyanins. A particularly high content of quercetin (2.5–6.5%) is found in the dry outer skin of red onion cultivars.

An atypical flavonol is morin (**9-97**) occurring in the leaves of white mulberry (*Morus alba*, *Moraceae*). It is derived from kaempherol, but contains an additional hydroxyl group at position C-2′, as well as another flavonol datiscetin present in the leaves and roots of bastard hemp (*Datisca cannabina*, Datiscaceae), the

Asiatic herb looking like hemp, which is used for its yellow pigment and also as a laxative. In the roots, datiscetin is accompanied by galangin. Herbacetin and gosypetin have an additional hydroxyl group at C-8. Examples of flavonol methyl ethers are rhamnetein, isorhamnetin and other substances (**9-98**). Isorhamnetin occurs as 3-β-rutinoside (narcissin) in citrus and other fruits.

Free aglycones are found in relatively small quantities, and the main forms are flavonol glycosides. Flavonol glycosides are mainly 3-glycosides and less often the 7-glycosides. The most widespread compounds are glycosides derived from quercetin and kaempherol; glycosides of myricetin are less common. Trivial names of common glycosides derived from quercetin are given in Table 9.13. Normally, however, the systematic names of flavonoids are favoured.

A generally widespread glycoside of many plants is rutin. Avicularin and isoquercitrin occur, for example, in blueberries (*Vaccinium myrtillus*, *Ericaceae*); spiraein, together with rutin, is a constituent of onion (onions are a primary source of dietary quercetin glycosides in the Western diet), chestnuts (seeds of horse chestnut, *Aesculus hippocastanum*, Sapindaceae) and the flowers of some plants (such as elm meadowsweet, *Filipendula ulmaria*, Rosaceae). A relatively common glycoside is myricitrin (myricetin-3-rhamnoside), while in cotton plants (*Gossypium* spp., Malvaceae) occur populnin (kaempherol-7-glucoside), quercimeritrin, herbacitrin (herbacetin-7-glucosidea) and gosypitrin (gosypetin-7-glucoside). For example, apples contain, as major glycosides, quercetin-3-glucoside and 3-galactoside (depending on the variety and other factors, they are found in levels of about 0.01– 0.95 g/kg), 3-rhamnoside (0.01–0.37 g/kg), 3-arabinoside (0.02–0.78 g/kg), 3-xyloside (0.03–0.25 g/kg) and 3-rutinoside (0.01–0.12 g/kg). In smaller amounts, apples contain 3-glucosides of kaempherol and myricetin. Elderberries (*Sambucus nigra*, Adoxaceae) contain quercetin-3-rutinoside that is missing in strawberries, quercetin-3-glycoside (trisaccharide containing two molecules of L-rhamnose and one molecule of D-glucose) occurs in blackcurrants, but not in redcurrants. The presence of these flavonoids in fruit juices can be used to detect of adulteration, such as the replacement of individual types of berries in fruit juices and addition of low-cost fruits in fruit spreads produced from strawberries, raspberries and blackcurrants.

Flavonols and their glycosides are found in tea (*Camellia sinensis*, Theaceae) in larger quantities than they are in fruits. The main components of all teas are 3-glucosides, 3-galactosides and 3-rutinosides of flavonols, 3-rhamnoside of quercetin and 3-rhamnodiglucosides and 3-glucorhamnogalactosides of quercetin and kaempherol), which significantly contribute to the bitter taste of tea infusions. Black teas usually contain 0.4–1.7% glycosides, green tea 1.5–1.7% glycosides and instant teas from 2.6 to 3.1% glycosides in dry matter.

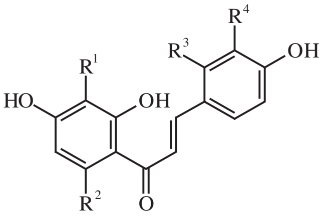
Table 9.13 Trivial and systematic names of selected quercetin glycosides.

Trivial name	Systematic name	Trivial name	Systematic name
Avicularin	quercetin-3-α-L-arabinofuranoside	Spiraein (spiraeoside)	quercetin-4′-β-D-glucopyranoside
Reinoutrin	quercetin-3-β-D-xylopyranoside	Hyperin (hyperoside)	quercetin-3-β-D-galactopyranoside
Isoquercitrin	quercetin-3-β-D-glucopyranoside	Quercitrin	quercetin-3-α-L-rhamnopyranoside
Quercimeritrin	quercetin-7-β-D-glucopyranoside	Rutin	quercetin-3-β-rutinoside

Rutin and several other flavonoid glycosides exhibit antioxidant properties and affect the flexibility and permeability of blood capillaries. Rutin (formerly vitamin P) is thus used in pharmaceutical preparations and food supplements. Together with other substances called bioflavonoids (see Section 5.15), rutin increases levels of ascorbic acid in various animal organs, either by protection against oxidation catalysed by metal ions, or by increased ascorbic acid utilisation in the body. Natural sources of ascorbic acid containing flavonoids (such as rosehips with a considerable amount of rutin) are thus more effective than synthetic vitamin C. A complex of rutin with iron causes dark discoloration of asparagus in tins, and the stannous complex of rutin is yellow.

9.4.2.5 Chalcones

Chalcones, dihydrochalcones and aurones are not particularly important components of plant food materials, but they occur as notable pigments of flowers of many ornamental plants, such as the common snapdragon (*Antirrhinum* spp., Scrophulariaceae) (Asteraceae), cosmos (*Cosmos* spp.) and dahlia (*Dahlia* spp.) from the Asteraceae family. Chalcones are also pigments of legume seeds (**9-99**) and woods. Prenylated chalcones are found in hop cones (**10-98**).



9-99, chalcones
isoliquiritigenin, $R^1 = R^2 = R^3 = R^4 = H$
butein, $R^1 = R^2 = R^3 = H$, $R^4 = OH$
marein, $R^1 = R^4 = OH$, $R^2 = R^3 = H$
okanin, $R^1 = R^3 = R^4 = OH$, $R^2 = H$
chalconaringenin, $R^1 = R^3 = R^4 = H$, $R^2 = OH$

Isoliquiritigenin, for example, occurs in soybeans as 4′-*O*-β-D-glucopyranoside. The most common chalcone is butein. Its 4-glucoside is called coreopsin and 4,3′-diglucoside is isobutrin. These glycosides are found as pigments of tropical flowers of the legume plant *Butea monosperma* (Fabaceae), which are used locally for food colouring (see Section 9.4.2.1). Marein and okanin are pigments in the central part of the flowers of tickseed, also known as calliopsis (*Coreopsis* spp., Asteraceae). The pigment absorbs UV radiation (unlike the carotenoid pigments in the other parts of the flowers) and is an attractant for bees and other insects that pollinate the flowers. Chalconaringenin is the predominant compound in tomatoes. Its concentration is 9–182 mg/kg, which comprises 35 to 71% of the total flavonoid content.

Chalcones always contain a hydroxyl group at C-2, which comes from the pyrane ring C of flavanones, which produce chalcones in alkaline medium (Figure 9.18). Under acidic conditions, especially with heating, the opposite reaction proceeds – conversion of chalcones into flavanones. For example, naringenin chalcone gives rise to naringenin; hesperidin arises from hesperidin chalcone and isobutrin from butrin. These reactions are related to the enzymatic reactions of chalcone biosynthesis, which catalyses chalcone-flavanone isomerase.

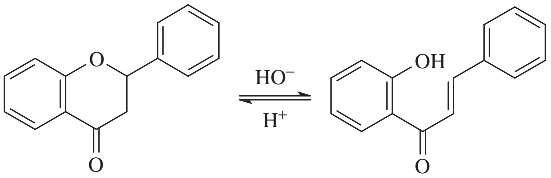


Figure 9.18 Interconversion of flavanones and chalcones.

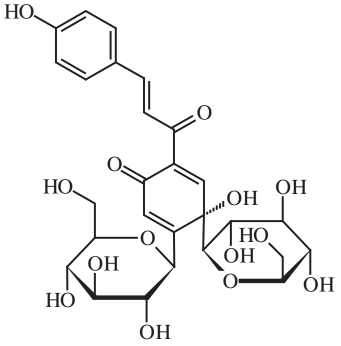
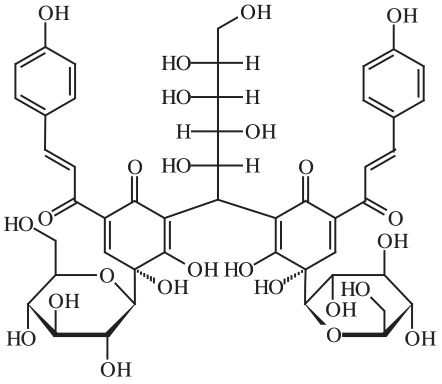
9.4.2.5.1 Quinochalcones

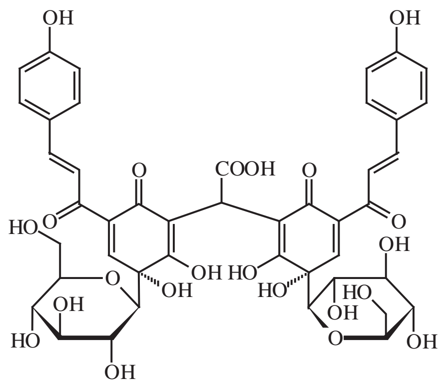
Carthamin (carthemon) is a yellow-to-red, water-soluble pigment derived from safflower flowers (*Carthamus tinctorius*, Asteraceae). Safflower seeds are used for making edible oil, which is used in cooking. The pigment is a mixture of three coloured compounds, red carthamin, safflor yellow A, safflor yellow B and also contains small amounts of their precursors. The precursor of carthamin in flowers is 2,4,6,4′-tetrahydroxychalcone, which is glycosylated at first to safflor yellow A (**9-100**) and then further to safflor yellow B (**9-101**), which gives on oxidation yellow precarthamin (**9-102**), decarboxylation and further oxidation of which yields carthamin (**9-103**). Isomerisation of carthamin in an acidic environment yields yellow isocarthamin (**9-104**). Hydrolysis of carthamin gives glucose and two aglycones – flavanones carthamidin and isocarthamidin.



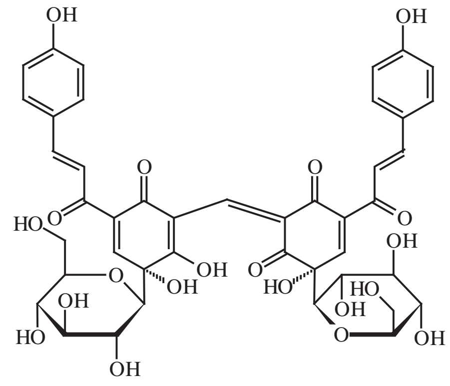
9-100, safflor yellow A



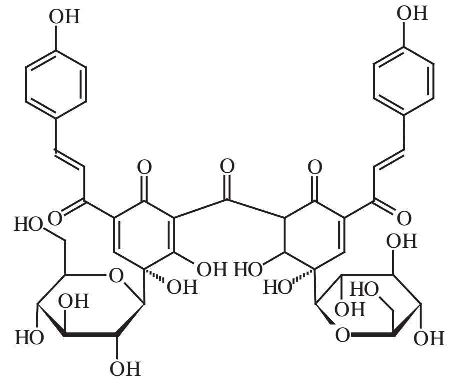
9-101, safflor yellow B



9-102, precarthamin



9-103, carthamin

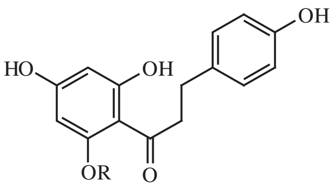


9-104, isocarthamin

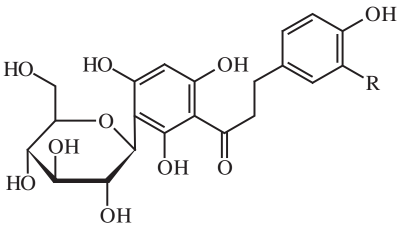
Carthamin was used as a wool dye in ancient times and is now the only chalcone type pigment recommended in some countries for food colouring. As a food additive, carthamin is known as Natural Red 26. Its properties are not yet well known, but it may become a promising food colouring, for example for yoghurt and other dairy products.

9.4.2.6 Dihydrochalcones

An example of natural dihydrochalcones is phloretin (**9-105**). The most famous glycoside of phloretin, phloretin-6-*O*-β-D-glucoside, is called phlorizin. Its occurrence is practically limited to the botanical genus *Malus* (apple), where phlorizin functions as an inhibitor of seed germination. In mammals, phlorizin causes glycosuria (glucose excretion in the urine). It has a bitter taste, like naringin. In small quantities, phlorizin is also found in apples and apple products (at a level of 0.1–22 mg/kg dry matter in the skin, from 0.03 to 0.3 mg/kg in the flesh and from 0.01 to 0.4 mg/kg in the juices), where it is accompanied by a small amount of 6-*O*-xyloglucoside. The presence of these characteristic flavonoids of apples may be used to detect the addition of apple juice to other fruit juices. Phloretin-3′5′-di-*C*-β-D-glucopyranoside is the first *C*-glycoside identified in tomatoes and also the first dihydrochalcone from *Solanum* species. In tomatoes, its amount ranges from 2 to 15 mg/kg. High levels of the dihydrochalcone *C*-glucosides aspalathin and nothofagin (**9-106**) with antioxidant activities are present in the rooibos plant (*Aspalathus linearis*, Fabaceae). Aqueous spray-dried extracts of fermented rooibos usually contain up to 0.5% aspalathin. Fermented rooibos is the most common form used by the food industry as a herbal tea or in products such iced teas and yoghurt. The fermentation process, necessary for development of the characteristic rooibos flavour and colour, however, greatly reduces the aspalathin content of the plant material and leads to the formation of flavones isoorientin and orientin as major products.



9-105, dihydrochalcones
phloretin, R = H
phlorizin, R = *β*-D-glucosyl



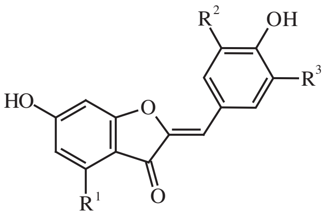
9-106, nothofagin, R = H
aspalathin, R = OH

Enzymatic and acid hydrolysis of phlorizin releases the aglycone phloretin, alkaline hydrolysis yields 4-hydroxyphenylpropionic acid and β-D-glucopyranosideside of phloroglucinol (1,3,5-trihydroxybenzene), which is called phlorin. It has been shown that phlorin is present in peel of citrus fruits. In species and varieties of oranges, phlorin was found in juices and peel extracts with a mean of 22 and 492 mg/l, respectively, while for grapefruits, means were 108 mg/l in juices and 982 mg/l for peel extracts. In contrast, phlorin was not found in mandarin and clementine juices except for a few mandarin varieties (30–33 mg/l).

Dihydrochalcones prepared semi-synthetically by reduction of flavanones neohesperidin and naringin have an intensely sweet taste. Neohesperidin dihydrochalcone is used as a sweetener (see Section 11.3.2.1.2).

9.4.2.7 Aurones

Just as with chalcones and dihydrochalcones, aurones, 2-benzylidenebenzo-2*H*-furan-3-ones, are likewise not very important pigments of food raw materials. For example, hispidol has been found in soybeans as 6-*O*-β-D-glucoside. Aurones, however, are widespread in various flowers where they play a significant role in their pigmentation. Sulfuretin (**9-107**) is a pigment of dahlia (*Dahlia* spp., Asteraceae) flowers, aureusidin occurs in flowers of the common snapdragon (*Antirrhinum majus*, Plantaginaceae), where it occurs as 6-*O*-β-D-glucoside (called aureusin) together with 4-*O*-β-D-glucoside of aureusidin (cernuoside) and 6-*O*-β-D-glucoside of bracteatin.



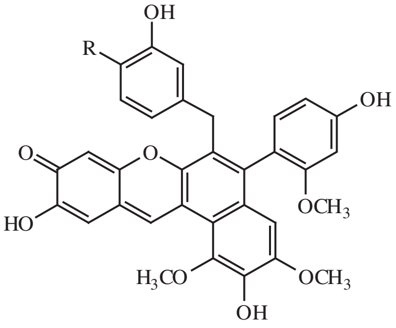
9-107, aurones
hispidol, $R^1 = H$, $R^2 = H$, $R^3 = H$
sulfuretin, $R^1 = H$, $R^2 = OH$, $R^3 = H$
aureusidin, $R^1 = OH$, $R^2 = OH$, $R^3 = H$
bracteatin, $R^1 = OH$, $R^2 = OH$, $R^3 = OH$

9.4.2.8 Isoflavones

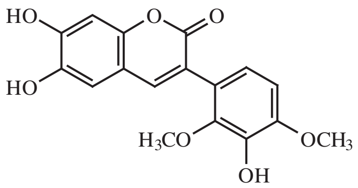
Isoflavones have been found in higher concentrations only in the legume family of plants (Fabaceae) and occur in significant amounts only in soybeans and soya bean products. Isoflavones exhibit oestrogenic activity, but also further toxic effects, and are often classified, together with other active compounds, as phytoestrogens (see Section 10.4).

9.4.2.9 Santalins

The lipophilic red pigments santalins, santalin A and santalin B (**9-108**), are (along with some other related compounds, such as the coumarin derivative santalin AC (**9-109**) and yellow isoflavone 3′,4′,5-trihydroxy-7-methoxyisoflavone) components of the slightly fragrant red sandalwood (red sanders) and red sandalwood extracts obtained from *Pterocarpus santalinus* (Fabaceae), which is grown mainly in India. Biosynthesis of santalins is based on anthocyanins and lignans. Their main use has previously been in dyeing wool and in folk medicine for antiseptic properties. Currently, red sandalwood is used for colouring tea infusions, acid pickled vegetables and even some sausages. The so-called white sandalwood obtained from the trees *Santalum album* (Santalaceae), unlike red sandalwood, is used to flavour foods and other materials, for its high essential oil content (about 2.5%).



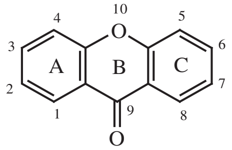
9-108, santalin A, R = OH
santalin B, $R = OCH_3$



9-109, santalin AC

9.5 Xanthones

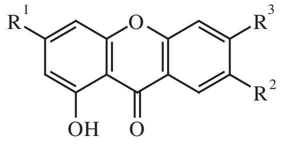
Xanthones are a group of about 70 yellow pigments of basic structure $C_6–C_1–C_6$. They are derived from xanthone (xanthen-9-one, **9-110**) and are biogenetically related to flavonoids. Their occurrence is limited to a few families of higher plants, Clusiaceae (syn. Guttiferae), Gentianaceae, Anacardiaceae, Moraceae and Polygalaceae, some fungi and lichens. From time immemorial, some xanthones have been used as textile dyes and food colorants. Xanthones also exhibit different pharmacological effects and find use, for example, as cardiovascular protectants.



9-110, xanthone

Some important xanthones are the yellow pigments gentisin (1,3,7-trihydroxyxanthone) and gentisein (1,3,6-trihydroxyxanthone, **9-111**) occurring along with other xanthones as glycosides in the yellow gentian root (*Gentiana lutea*, Gentianaceae), which is used for its bitter taste and specific aroma in the production of bitter liqueurs. Gentisein also occurs in centaury (*Centaurium erythraea*), belonging to the same plant family.

A representative of other important xanthones is norathyriol (1,3,6,7-tetrahydroxyxanthone), which occurs as 2-*C*-glucoside



9-111, substituted xanthones

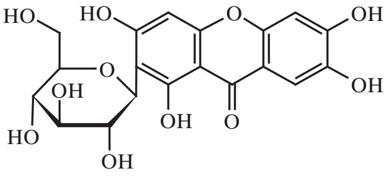
gentisin, R^1 = OH, R^2 = OH, R^3 = H
norathyriol, R^1 = OH, R^2 = OH, R^3 = OH



9-112, mangiferin

called mangiferin (**9-112**) in a variety of plants and also in the leaves, peels and immature mango fruits. Mangiferin is accompanied by a minor 4-*C*-glucoside known as isomangiferin. The occurrence of mangiferin-6′-*O*-gallate has been described in mango leaves. Mangiferin has anti-inflammatory, antiviral and antioxidant effects. In India, mango tree leaves (*Mangifera indica*, Anacardiaceae) were fed in a limited amount to cattle, whose urine was used as a yellow dye for fabrics and carpets. Biosynthesis of norathyriol starts from phenylalanine and proceeds via cinnamic and benzoic acids, and condensation of this with malonic acid yields 2,4,6-trihydroxybenzofenone. Its oxidation gives 2,3′,4,6-tetrahydroxybenzofenone and its cyclisation provides gentisin and its oxidation norathyriol.

The major secondary metabolites of the tropical tree *Garcinia mangostana* (Clusiaceae) originating in Sunda Islands and the Moluccas, known as mangosteen, are prenylated xanthone derivatives, some of which possess antifungal, antimicrobial, antioxidant and cytotoxic activities. The mangosteen dark purple to red–purple edible fruits have a soft and juicy white aril with a sweet, slightly acid taste and a pleasant aroma. The pericarp of mangosteen fruits has been used in Thai indigenous medicine for the treatment of skin infections, wounds, and diarrhea. The main constituent of the fruit pericarp is yellow xanthone with isoprenoid substituents at positions C-2 and C-8, called α-mangostin, which is accompanied by a number of related pigments, such as γ-mangostin, garcinone E, endraxanthone G, 8-deoxygartanin and gartanin (**9-113**). Another yellow pigment in the mangosteen family is the polyisoprenylated benzophenone derivative garcinol (**9-114**). It occurs at a level of 2–3% in culinary fruits of *G. indica* (and other species), commonly known as kokum. The dried rind of the fruit is used as a garnish for curry and in traditional medicine in India.

The European mushrooms of the genus *Cortinarius* (Cortinariaceae) characteristically contain the xanthone dermoxanthone (**9-115**) and its methyl ester that were found in the stem of the surprise webcap *C. semisanguineus*. These xanthones are responsible for the bright yellow fluorescence of the mushroom under UV light.

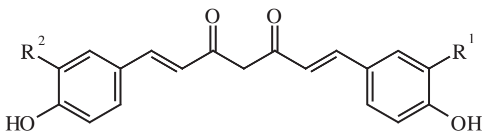
9.6 Curcuminoids

A group of phenolic compounds related to lignans are curcuminoids that are classified as **diarylheptanoids** (C_6–C_7–C_6 compounds). Curcuminoids include the yellow pigments of turmeric (*Curcuma longa*) and other species (about 30 are known) of the genus *Curcuma*. Turmeric, also known as yellow ginger, is a rhizomatous plant from the ginger family (Zingiberaceae), native to India and tropical South Asia. The yellow dried and ground rhizome is used as a spice in curries and to impart colour to various dishes and condiments.

Turmeric contains the diketone curcumin, which is accompanied by demethoxycurcumin and bisdemethoxycurcumin (**9-116**). The predominant pigment is mostly curcumin, (1*E*,6*E*)-1,7-bis(4-hydroxy-3-methoxyphenyl)hepta-1,6-dien-3,5-dione. Its content in the dry rhizome is about 2%; the content of two other pigments is <0.6%. Representation of the pigments may vary according to species, origin and maturity of rhizomes. For example, rhizomes of *C. aromatica* contain only traces of bisdemethoxycurcumin and the main pigment in some species may be demethoxycurcumin.



9-116, turmeric pigments (keto forms)
curcumin, $R^1 = R^2 = OCH_3$
demethoxycurcumin, $R^1 = OCH_3$, $R^2 = H$
bisdemethoxycurcumin, $R^1 = R^2 = H$

Experimental studies demonstrated that curcumin prevents and may even be a cure for Alzheimer's disease and can be a prevention agent and a chemotherapeutic agent for colon cancer. In addition, curcumin shows potent anti-inflammatory and antioxidant activity (the most favoured antioxidant is the enol form). Recombination of curcumin radicals formed in foods yields dimers as radical termination products (Figure 9.19), in addition to the coupling products of curcumin with lipid hydroperoxides.

Turmeric is insoluble in water but dissolves well in alcohol and oils. Water-soluble complexes of turmeric are formed by reaction with chlorides of some metals, such as tin and zinc. These complexes have an intense orange colour. The colour of turmeric is virtually stable at typical processing temperatures, but in the light, in the presence of atmospheric oxygen and in alkaline media (the lemon yellow colour at pH = 3 turns to orange–red at pH = 10), turmeric breaks down into colourless products.

Turmeric is mainly used for colouring dairy and bakery products (e.g. ice cream, confectionery and dry mixtures). Oleoresins containing aromatic substances of turmeric are used as a spice. Many species of the genus *Curcuma* (turmeric) and the related genus *Zingiber* (ginger) are locally used as a spice and in traditional medicines.

Biosynthesis of curcuminoids is similar to the biosynthesis of phenylpropanoids, such as flavonoids. Intermediates, such as 4-coumaroyl-CoA, condense with malonyl-CoA (via diketide as an intermediate) to form bisdemethoxycurcumin. Curcumin arises by subsequent oxidation and methylation of bisdemethoxycurcumin.

9.7 Isochromenes

Monascus or monascus red has a certain importance as a food colorant, being a mixture of yellow, orange and red pigments derived from 1*H*-isochromene (**9-117**). In this mixture of lipophilic substances, the yellow pigments monascin and ancaflavin (**9-118**) and their orange oxidised forms rubropunctatin and monascorubin (**9-119**) predominate. These intracellular pigments produce different types of fungi of the genus *Monascus*, especially *M. purpureus*, in solid cultures, for example on cooked rice or bread. Red rice (in China *ankak* or *anka* or *ang khak*, in Japan Beni-Koji or Anka-Koji) dried and crushed to a powder is traditionally used in China, Japan

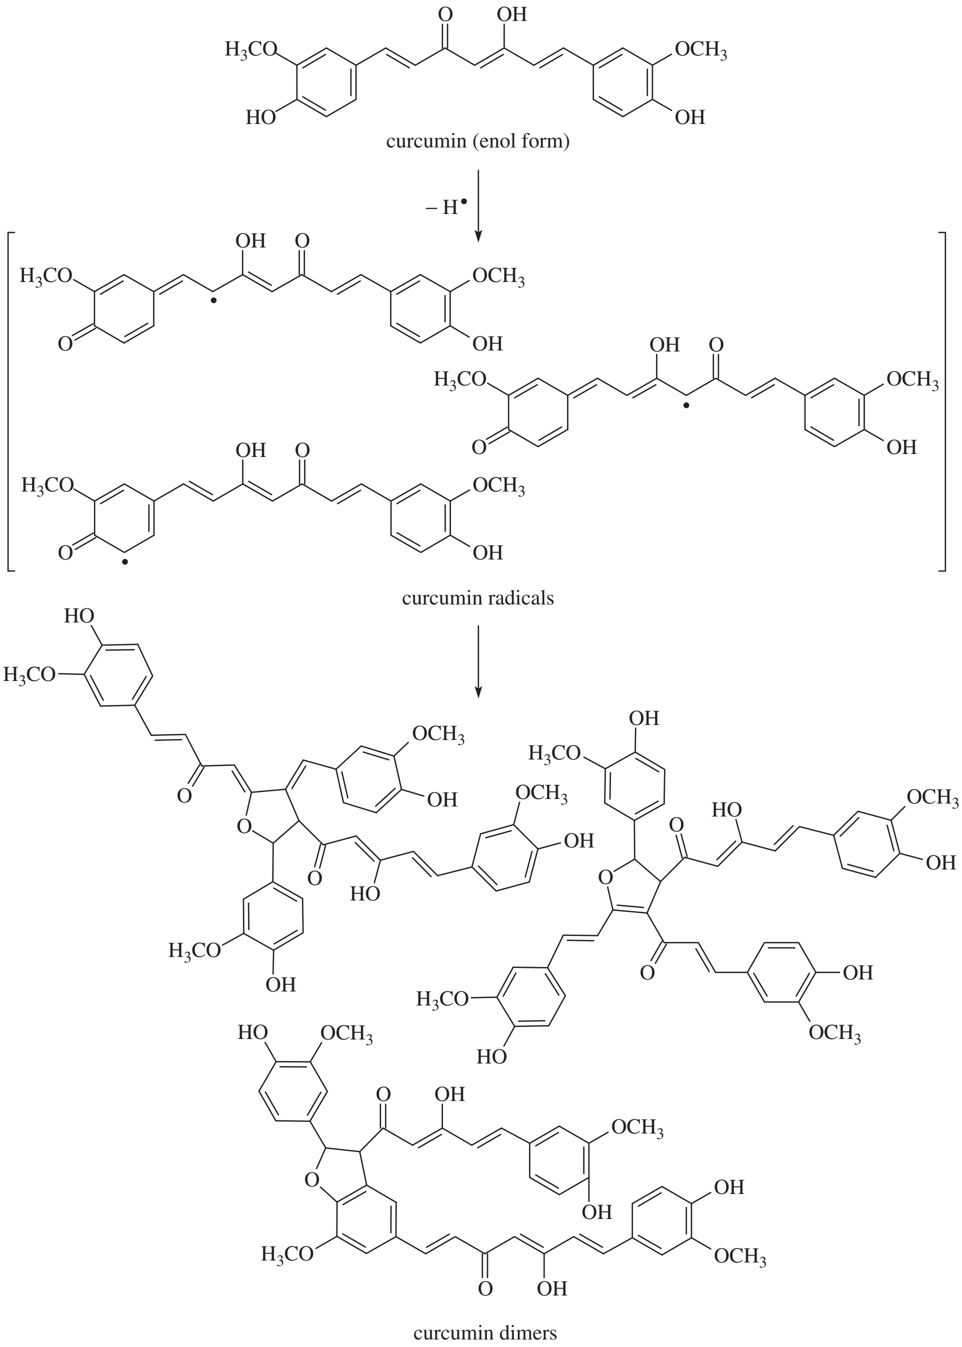

Figure 9.19 Formation of curcumin dimers via radical-radical coupling reaction.

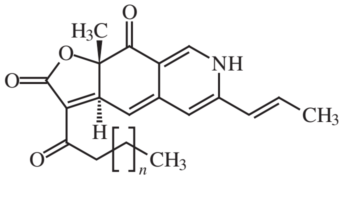
and other countries as a colorant to impart colour to meat, fish, soybean curd (tofu), rice wine (sake), beans, candy and other foods.

Native pigments react easily with amino compounds (amino acids, amino alcohols, amino sugars and proteins) to form extracellular, water-soluble nitrogen analogues of native pigments, which are collectively called **azaphilones**. Red to purple pigments rubropunctamine and monascorubramine (**9-120**) are the nitrogen analogues of yellow pigments, which are formed by reaction with amino compounds.



9-120, rubropunctamine, $n = 3$
monascorubramine, $n = 5$

Many related azafilones produce different Ascomycetes as toxins. Monascus red may even contain mycotoxin citrinin (see Section 12.3.1), which was originally mistakenly regarded as a non-toxic yellow pigment called monascidin A.

The main chromophore of isochromenes arises as a hexaketide from activated forms of acetic and malonic acids and the side chain of pigments is derived from 2-oxohexanic and 2-oxooctanoic acids that are synthesised analogously to other fatty acids.

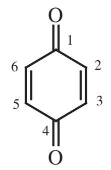
9.8 Quinoid pigments

Plant materials contain a large number of various phenolic substances that give rise to coloured quinones and other pigments formed from phenols by biochemical and chemical reactions. Many of these pigments are also found in foods.

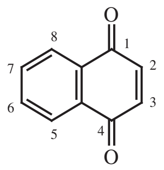
9.8.1 Quinones

Quinones represent a group of about 200 yellow, red, brown and almost black pigments with variable structure. They include simple quinones, dimers, trimers and condensation products that mutually differ in the number of hydroxyl groups and other substituents. The naturally occurring quinoid pigments are mostly derived from:

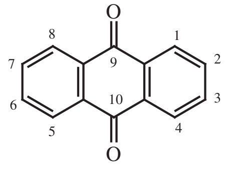
- benzo-1,4-quinone (also known as *p*-benzoquinone or 1,4-dioxobenzene, **9-121**)
- naphtho-1,4-quinone (1,4-dioxonaphthalene, **9-122**)
- anthra-9,10-quinone (9,10-dioxoanthracene, **9-123**).



9-121, benzo-1,4-quinone

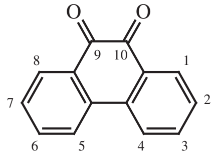


9-122, naphtho-1,4-quinone



9-123, anthra-9,10-quinone

There are also other groups of quinones, common substances are benzo-1,2-quinones (*o*-benzoquinones), which mainly arise in enzymatic browning reactions, and toxic naphtho-1,2-quinone is generated by burning diesel fuel in diesel engines. Related quinones are derived from phenanthra-9,10-quinone (9,10-dioxophenanthrene, **9-124**). Examples of phenanthra-9,10-quinones are furanophenathraquinones occurring in red (Chinese) sage *Salvia miltiorrhiza* root used in traditional medicine (see Section 11.2.2.3.5). Many quinones have more complex structures. For example, a group of terpenoid quinones have been identified that include biologically active plastoquinones, ubiquinones (coenzymes Q), tocopherols and tocotrienols with vitamin E activity, phylloquinone and its derivatives posses vitamin K activity (see Chapter 5).



9-124, phenanthra-9,10-quinone

Quinoid pigments occur in different parts of higher plants, algae, lichens, higher fungi and microorganisms and can also be found in some insects. Quinoid pigments are usually present as differently coloured precursors or in the form of colourless substances, which are mostly reduced forms (leucoforms) of quinones (commonly hydroxy derivatives and their glycosides and esters).

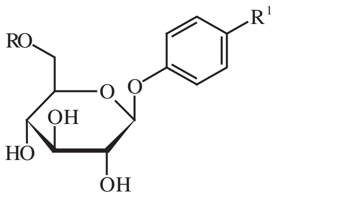
In the past, some quinoid pigments were used as textile and leather dyes (that were later replaced by synthetic dyes) and many plants were specially grown for this function. Some quinoid pigments are now used for cosmetic and pharmaceutical purposes and also as food additives. Compared with other pigments, natural quinoid pigments are of less importance.

9.8.1.1 Benzoquinones

Benzo-1,4-quinoid structures occur in nature as the final oxidation products of various mono- and polycyclic compounds. Most simple benzo-1,4-quinones occur in microorganisms (moulds), higher fungi and lichens, and less frequently in higher plants and some insects. Common substances are glycosides occurring in colourless reduced forms (such as derivatives of hydroquinone known by the systematic name of benzene-1,4-diol). Coloured quinones are formed from these precursors by hydrolysis catalysed by saccharases and by enzymatic oxidation or autoxidation of aglycones.

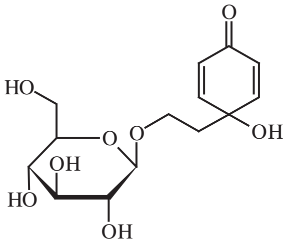
The basic compound is a pale yellow benzo-1,4-quinone, which occurs in plants as a colourless hydroquinone β-D-glucoside called arbutin (**9-125**). This compound is an active component of leaves of the lingonberry (cowberry, *Vaccinium vitis-idaea*) and the related bearberry (*Arctostaphylos uva-ursi*, Ericaceae) native to the northern areas of the Northern Hemisphere. The drug is mainly used as a disinfectant and urinary antiseptic agent. Arbutin is found in the leaves of cowberry in quantities of 3.3 to 5.4% and in bearberry leaves in the amount of 4.2–7.7%. The aglycone hydroquinone is also present at a low level (0.1–0.2% and 0.3%, respectively), which arises via hydrolysis of arbutin by arbutase. Other related glycosides are methylarbutin (1.3%) and pyroside (hydroquinone 6′-acetyl-β-D-glucoside, **9-125**), hydroquinone β-gentiobioside and salidroside (tyrosol β-D-glucoside).

Arbutin is also found in small quantities in cereals (e.g. in wheat and rice) and also in some fruits (especially in pears), and its

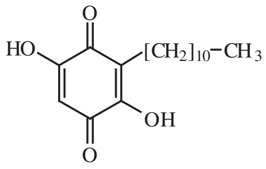


9-125, hydroquinone glucosides
arbutin, R = H, R^1= OH
methylarbutin, R = H, R^1 = OCH_3
pyroside, R = $COCH_3$, R^1 = OH

incidence in fruit juices is an indicator of the presence of pear juice. The arbutin derivative 6′-*O*-(4-hydroxybenzyl)arbutin occurs in marjoram (*Origanum majorana*, Lamiaceae). Also widespread in plants (e.g. in wheat grains) are 2-methoxy and 2,6-dimethoxy derivatives of arbutin, which may cause a pink discoloration in flour. In olives (*Olea europaea*, Oleaceae) a different type of quinoid glycoside occurs, called cornoside (**9-126**). Cornoside is related to oleuropein, which is a bitter substance in olives (see **8-223**). Fruits of *Embelia ribes* (Myrsinaceae), native to India and traditionally used in folk medicine as an anthelmintic drug and to reduce appetite and body weight, and fruits of *Ardisia japonica* of the same plant family, contain yellow–orange 2,5-dihydroxy-3-undecylbenzo-1,4-quinone known as embelin (**9-127**), which is an example of alkyl substituted benzo-1,4-quinones.



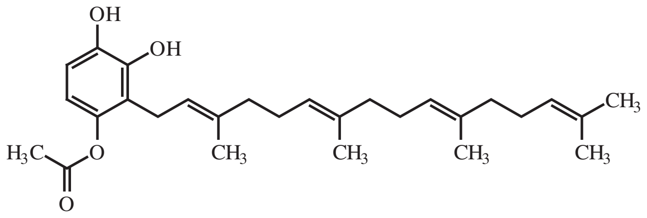
9-126, cornoside



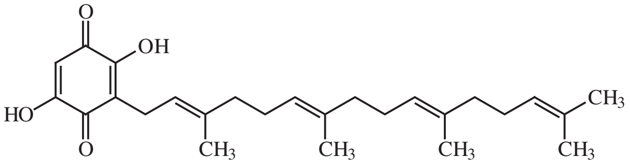
9-127, embelin

Prenylated benzoquinones also occur, albeit rarely, in Boletales mushrooms. Suillin (**9-128**) occurring in weeping (granulated) bolete (*Suillus granulatus*, Suillaceae) is an example of acetylated and prenylated 1,2,4-trihydroxybenzenes. Its oxidation products are responsible for the brown colour of mushroom caps. Prenylated benzoquinones mostly appear as meroterpenoids named boviquinones. Boviquinone-4 (2,5-dihydroxy-3-geranylgeranyl-1,4-benzoquinone, **9-129**) is an example of prenylated benzoquinones found in Jersey cow mushroom (*S. bovines*). The red pigment tridentoquinone (**9-130**) is the main pigment of *S. tridenticus*.

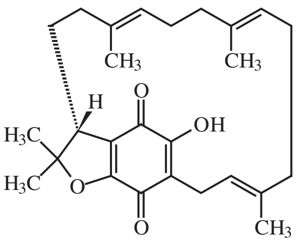
The analogue of agaritine (see Section 10.4) found, for example, in mushrooms of the genus *Agaricus*, which is derived from 4-aminophenol, known as γ-glutamyl-4-hydroxybenzene (**9-131**) readily oxidisese to the corresponding quinone via γ-glutamyl-3,4-dihydroxybenzene. This quinone decomposes to 2-hydroxy-4-iminocyclohexa-2,5-dienone (**9-131**), which imparts a pink–red colour to some agarics (such as common mushroom *A. bisporus*). The yellow nitrogen-containing pigment characteristic of the



9-128, suillin



9-129, boviquinone-4



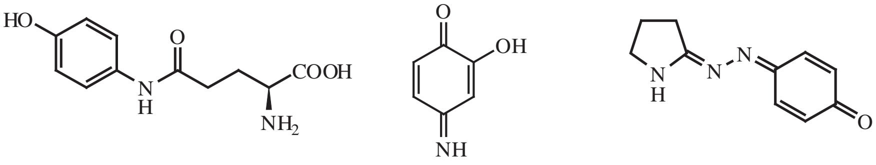
9-130, tridentoquinone

yellow-staining mushroom (*Agaricus xanthodermus*, Agaricaceae) and of some other *Agaricus* species is caused by the metabolite of glutamic acid derived hydrazine agaritine, known as agaricone (**9-131**) that forms by oxidation of the corresponding leucophenol in the damaged tissue.

Benzoquinone carbon atoms can be derived from acetic acid (acetyl-CoA in polyketide quinones) or from glucose (via shikimic acid in microorganisms and fungi). Terpenoid side chains are biosynthesised in the mevalonate (terpenoid) pathway.

9.8.1.1.1 Terphenylquinones

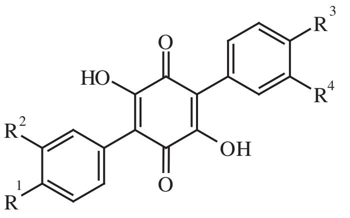
Terphenylquinones (benzo-1,4-quinones substituted at positions C-2 and C-5 by phenyl groups), and their alkyl derivatives are red, violet to brown pigments of many species of lichens, moulds and higher fungi. They often occur in various leuco forms (as dihydroxy derivatives or their acetates). Terphenylquinones, exemplified by the dark red polyporic acid and bronze–brown atromentin (**9-132**), are mainly produced by wood-rotting higher fungi of the order Polyporales growing on various deciduous trees, but in other higher fungi, such as in the Boletales fungi, they appear only sporadically. For example, polyporic acid, the parent compound of numerous terphenylquinones and related compounds, is the major component of *Hapalopilus nidulans* amounting up to 43% of its dry weight. The orange tooth (*Hydnellum aurantiacum*) colour is derived from atromentin and 3,6-dibenzoylatromentin, known as aurantiacin. Atromentin



γ-glutamyl-4-hydroxybenzene 2-hydroxy-4-iminocyclohexa-2,5-dienone agaricone

9-131, precursors and pigments in mushrooms of the genus *Agaricus*

occurs in the intact fruit bodies in the form of colourless precursors, such as dihydroaurantiacin in *Hydnellum aurantiacum* and as leucomentins in a number of other fungi. An example of leuco derivatives of atromentin is leucomentin-2 (**9-133**) esterified with (2*Z*,4*S*,5*S*)-4,5-epoxyhex-2-enoic acid. Atromentin is the key intermediate for many conversions leading to more hydroxylated terphenylquinones (such as variegatin, **9-132**) and other pigments. Mushrooms of the genus *Tapinella* (Tapinellaceae), for example, produce orange–yellow flavomentins and violet spiromentins derived from atromentin. Flavomentins constitute diesters and monoesters of atromentin with (2*Z*,4*S*,5*S*)-4,5-epoxyhex-2-enoic and (2*Z*,4*E*)-hexa-2,4-dienoic acids. Spiromentins possess unique spiro structures in which 4,5-dihydroxybenzo-1,2-quinone is linked to a lactone acetal unit. These metabolites are exemplified by flavomentin A (**9-134**) and spiromentin A (**9-135**).



9-132, polyporic acid, $R^1 = R^2 = R^3 = R^4 = H$
atromentin, $R^1 = R^3 = OH$, $R^2 = R^4 = H$

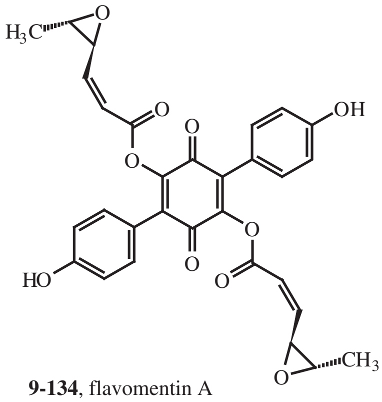
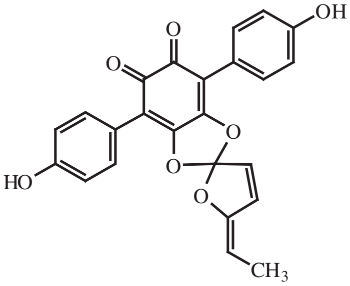
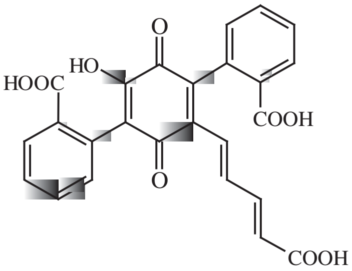
9-133, leucomentin-2



9-134, flavomentin A

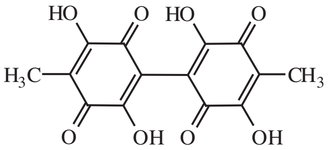


9-135, spiromentin A



9-136, muscarufin

The yellow pigment (2*E*,4*E*)-5-[3,6-dioxo-2,5-di(2-carboxyphenyl)-4-hydroxy-1,4-cyclohexadien-1-yl]-2,4-pentadienoic acid, known as muscarufin (**9-136**), a putative derivative of terphenylquinones, is one of the main pigments of the fly agaric (*Amanita muscaria*) hat. In dimeric forms, terphenylquinones contribute to the yellow colour of some lichens and chocolate brown hats of mushrooms of the order Boletales that are characterised by a diversity of colours. The widespread yellow fungal dimeric metabolite oosporein (**9-137**) shows antifungal, antibiotic and antiviral activities, in addition to being the major secondary metabolite of some fungal biological control agents. For example, it shows growth-inhibitory effect on the phytopathogenic fungus *Phytophthora infestans* (Pythiaceae) that causes a serious disease called late blight in solanaceous crops.



9-137, oosporein

Polyporic acid is biosynthesised by condensation of two molecules of phenylpyruvic acid in the shikimate pathway via the intermediate 2,5-diphenyl-3-hydroxy-4-oxohex-2-enoic acid and by oxidation of the resulting hydroquinone. Terphenylquinones are transformed by enzymatic reactions into pulvinic acids and many other products, some of which are also characteristic pigments of lichens and fungi.

9.8.1.1.2 Pulvinic acids

Yellow pigments of lichens, moulds and higher fungi called pulvinic (pulvic) acids (**9-138**) are formed, along with other products, from the corresponding terphenylquinones (**9-132**) through lactone formation, after the terphenylquinone ring has been oxidised and opened. The unsubstituted parent compound, called pulvinic acid, only occurs in the form of its methyl ester, named vulpinic acid. Xerocomic and variegatic acids play the most important role, being responsible for the blue colours acquired in many boletes after their fruiting bodies are injured, which results in the oxidation of these acids to the corresponding blue quinonmethide anions (**9-139**). Pulvinic acids are especially widespread in mushrooms belonging to the genera *Gomphidius* (Gomphidiaceae) and *Suillus* (Suillaceae). The yellow pigment gomphidic acid was found for the first time in the slimy spike-cap (*G. glutinosus*). The yellow–brown cap and stem of the larch bolete (*Suillus grevillei*) contains at least 11 yellow, orange and red pigments derived from decarboxylated pulvinic acids, of which 3′,4′,4-trihydroxypulvinone (**9-140**), derived from variegatic acid (**9-138**), is the major pigment. Simple oxidation products of terphenylquinones under the preservation of the central quinone ring are cycloleucomelone and cyclovariegatin (**9-141**). Cycloleucomelone occurs in the fruiting bodies of *Boletopsis leucomelaena* (Suillaceae) accompanied by a series of colourless analogues containing five, four and three acetyl residues. Cyclovariegatin is a minor pigment of larch bolete and a precursor of violet thelephoric acid (**9-142**). Many other enzymatically catalysed and spontaneous reactions lead to a vast number of other mushroom metabolites. Variegatorubin and xerocomorubin (**9-143**) exemplify red pigments formed from pulvinic acids by the second lactone ring formation. Examples of complex structures derived from pulvinic acids are badione A and norbadione A that are responsible for the chocolate brown and golden yellow colours of the cap skin of bay bolete *Boletus badius* (Boletacaee) (see Section 6.7.4). Oxidative coupling of two molecules of xerocomic acid (**9-138**) yields bright yellow sclerocitrin (**9-144**) found in the fruiting bodies of the common earth ball *Scleroderma citrinum* (Sclerodermataceae), together with norbadione A as the main pigments, which are accompanied by xerocomic acid and badione A. It also occurs as the main pigment of the lemon–yellow coloured stalk base of peppery bolete (*Chalciporus piperatus*, Boletaceae), accompanied by the second main pigment chalcitrin (**9-145**), norbadione A, variegatic acid and variegatorubin.

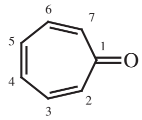
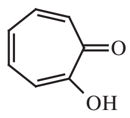
9.8.1.1.3 Troponoids

Another group of phenolic compounds are troponoids, compounds derived from tropone (cyclohepta-2,4,6-trien-1-one), which contains as a basic skeleton a seven-membered ring having three conjugated double bonds and a carbonyl group (**9-146**). Troponoids arise by transformation of phenolic compounds and are synthesised mainly by fungi and higher plants, but arise also in non-enzymatic browning reactions. The basic compound with the enol hydroxyl group is 2-hydroxytropone (2-hydroxycyclohepta-2,4,6-trien-1-one), which is called tropolone (**9-147**). Possible pathways leading from quinone methide to tropolone skeleton are outlined in Figure 9.20. Chinone methide arises either from a 2-methylphenyl radical and oxygen or from a benzyl radical and hydroperoxyl (perhydroxyl) radical.

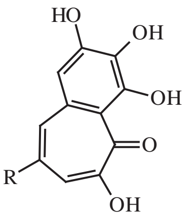


9-146, tropone

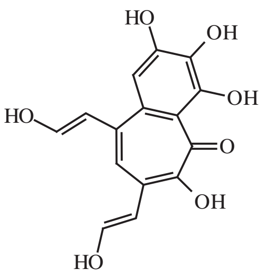


9-147, tropolone

Natural tropone analogues are represented by the brownish-red pigment purpurogallin (**9-148**), occurring, for example, in oak apples, where it arises as a product of gallic acid (gallotannines) oxidation and decarboxylation. Enzymatic oxidation of gallic acid and elimination of carbon dioxide produces its dimer 8-carboxypurpurogallin (**9-148**). A purpurogallin derivative, fomentariol (**9-149**) is produced by the plant pathogen known as the tinder fungus (*Fomes fomentarius*, Polyporaceae). Most troponoids are antibacterial and antifungal agents. Pigments of black tea with a tropone ring (theaflavins and epitheaflavinic acids) are produced from catechins in enzymatic browning reactions (see Section 9.12.4.1).



9-148, purpurogallin, R = H
8-carboxypurpurogallin, R = COOH

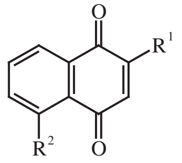


9-149, fomentariol

9.8.1.2 Naphthoquinones

Most naphthoquinones occur in higher plants in the form of glycosides of non-coloured reduced forms. Coloured naphthoquinones are released by glycosidases and enzymatic oxidation or autoxidation of aglycones.

A representative of simple naphthoquinones is yellow–orange lawsone (2-hydroxynaphtho-1,4-quinone, **9-150**), which occurs as a mixture of several naphthoquinones in henna (*Lawsonia inermis*, Lythraceae) growing in the Middle East and India, but also located in many other plants. The pigment, which exhibits antimicrobial effects, is obtained from the leaves of henna bushes, used for centuries for decorating hands, feet, nails and skin, as well as hair dye.



9-150, lawsone, R^1 = OH, R^2 = H
juglone, R^1 = H, R^2 = OH
plumbagin, R^1 = CH_3, R^2 = OH

Red–brown juglone (5-hydroxynaphtho-1,4-quinone, **9-150**) is present in the leaves and immature fruits of walnuts (*Juglans regia*, Juglandaceae) and other species as colourless 4-β-D-glucopyranoside of 1,4,5-trihydroxynaphthalene (1,5-dihydroxy-4-naphthalenyl-β-D-glucopyranoside), which is known as hydrojuglone. Juglone arises either by hydrolysis of the glycoside and oxidation of aglycone or by glycoside oxidation and its subsequent hydrolysis. Juglone is an allelopatic substance, which inhibits the growth of many other plants and is responsible for the skin colouring changing to yellow–brown when handling unripe walnuts. Its homologue is a yellow pigment plumbagine (5-hydroxy-2-methylnaphtho-1,4-quinone, **9-150**), which occurs in different parts of the European common leadwort (*Plumbago europaea*, Plumbaginaceae). Plumbagine is also found in the common sundew (*Drosera rotundifolia*, Droseraceae) and other plants. Juglone and plumbagine may produce dermatitis in susceptible people, and juglone has a laxative effect in the same way as some anthraquinones.

The roots of alkanet, also known as common bugloss (*Alkanna tinctoria*, syn. *Anchusa tinctoria*, Boraginaceae) growing in the south of Europe, contain the reddish pigment alkannin (alkannet, **9-151**) that was used as a textile dye. The (*S*)-isomer of alkannin is used today as a food colouring E103 to impart colour to ice creams, sweets and other products. The red (*R*)-isomer called shikonin was isolated from the roots of the medicinal plant *Lithospermum erythrorhizon* of the same family, which is native to China.

Naphthoquinone derivatives are also common secondary metabolites of slime molds of the class Myxogastria (formely known as Myxomycota). Examples are the red pigments trichione and homotrichione (**9-152**) of the sporophores of *Trichia floriformis*. Naphthalene and naphthoquinone structures are also widespread as red, purple, brown and black pigments in higher

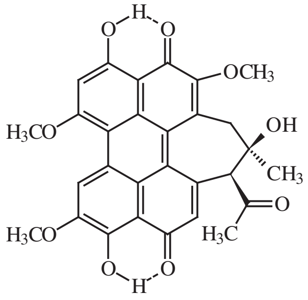
1,8-dihydroxy-1′,8′-dimethoxy-4,4′-binaphthyl, R = CH_3



9-154, hypocrellin

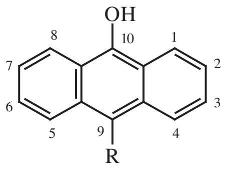
fungi of the phylum Ascomycota. For example, xylariaceous wood fungi of the genus *Daldinia* (Xylariaceae) are dominated by metabolites produced by oxidative coupling of colourless naphthalene-1,8-diol. Examples of these structures are 4,4′-binaphthyl derivatives 1,1′,8,8′-tetrahydroxybinaphthyl and its ether 1,8-dihydroxy-1′,8′-dimethoxybinaphthyl (**9-153**) and more condensed brown-to-black pigments called perylenequinones. A simpler perilenequinone known as hypocrellin (**9-154**), isolated from the bamboo fungus *Hypocrella bambusae* (Hypocreaceae), is a photodynamic pigment.

Biosynthesis of naphthoquinones lawsone and juglone starts, similarly to phylloquinone biosynthesis, from the shikimic acid metabolite chorismic acid, and proceeds via the intermediate 1,4-dihydroxy-2-naphthoic acid. The precursor of alkannin is 4-hydroxybenzoic acid, which is another metabolite of

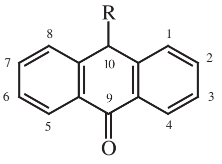
shikimic acid. Isoprenoid substituents are derived from geranyl diphosphate in the mevalonate pathway. Naphthoquinone plumbagin and naphthoquinones of fungi are examples of naphthoquinones arising exclusively by the acetate–polymalonate pathway via corresponding ketides.

9.8.1.3 Anthraquinones

Anthraquinones are the most widespread group of natural quinones. They occur in higher plants, fungi, lichens and some insects. Anthraquinones are accompanied by derivatives of anthranol, anthrahydroquinone (**9-155**) and their oxo forms anthrone and oxanthrone (**9-156**), which are, as glycosides, precursors of anthraquinone pigments.

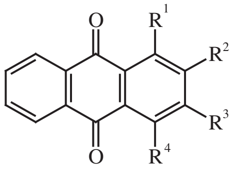


9-155, anthranol, R = H
anthrahydroquinone, R = OH



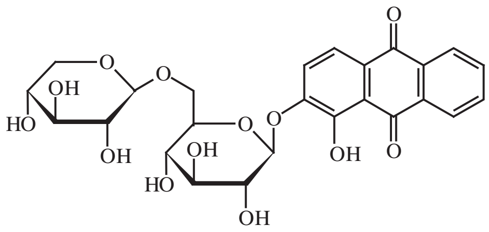
9-156, anthrone, R = H
oxanthrone, R = OH

The most familiar single anthraquinone substituted with hydroxyl groups on only one benzene ring is yellow–orange 1,2-dihydroxyanthraquinone, called alizarin (or Turkish Red or Mordant Red 11), and red pigment 1,2,4-trihydroxyalizarin, known as purpurin (**9-157**) that occura in roots of the common madder (*Rubia tinctorum*, Rubiaceae). Other anthraquinone aglycones in madder are lucidin and quinizarin (**9-157**). Alizarin occurs as a glycoside known as ruberythric acid (**9-158**), the sugar moiety of which is primeverose (6-*O*-β-D-xylopyranosyl-β-D-glucopyranose) bound to the C-2 alizarin hydroxyl group. Another main glycoside is lucidin-3-*O*-primeveroside. The pigments arise from glycosides by fermentation or acid hydrolysis. Related anthraquinone anthragallol (**9-157**) occurs with its hydroxy derivatives, methyl ethers, glycosides and other derivatives in a number of plants.

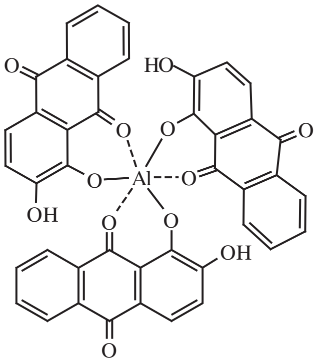


9-157, alizarin, R^1 = OH, R^2 = OH, R^3 = H, R^4 = H
purpurin, R^1 = OH, R^2 = OH, R^3 = H, R^4 =OH
lucidin, R^1 = OH, R^2 = CH_2OH, R^3 = OH, R^4 = H
quinizarin, R^1 = OH, R^2 = H, R^3 = H, R^4 = OH
anthragallol, R^1 = OH, R^2 = OH, R^3 = OH, R^4 = OH

Alizarin is used as a dye mostly for textile purposes, but also for food colouring. Purpurin is normally not coloured, but is red when dissolved in alkaline solutions. Mixed with clay and treated with alum and ammonia, it gives a brilliant red colorant madder lake (**9-159**).



9-158, ruberythric acid

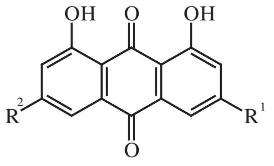


9-159, madder lake

Anthraquinone pigments in madder are biosynthesised by the shikimate (chorismate) pathway, which provides only anthra-9,10-quinones. The starting compound is naphtho-1,4-quinone-2-carboxylic acid.

9.8.1.3.1 Emodins

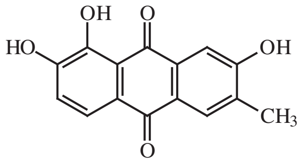
A very important group of polyhydroxysubstituted anthraquinones substituted at both aromatic rings are emodins (**9-160**). A common feature of these anthraquinones is the presence of at least two OH groups (at C-1 and C-8) and a methyl group (at C-3) or its oxidised forms (hydroxymethyl or carboxyl group).



9-160, chrysophanol, R^1 = CH_3, R^2 = H
emodin, R^1 = CH_3, R^2 = OH
aloe-emodin, R^1 = CH_2OH, R^2 = H
rhein, R^1 = COOH, R^2 = H
parietin, R^1 = CH_3, R^2 = OCH_3

Emodin (formerly also known as frangula-emodin) is widespread in fungi, lichens and higher plants, some of which are used in medicine. It occurs, for example, in the bark and fruits of common shrubs of the genus *Frangula* (such as alder buckthorn, *F. alnus*) and *Rhamnus* (such as buckthorn, *R. cathartica*) of the Rhamnaceae family and in the leaves and pods of Egyptian senna (*Senna alexandrina*, syn. *Cassia angustifolia*, Fabaceae). The aqueous extract of

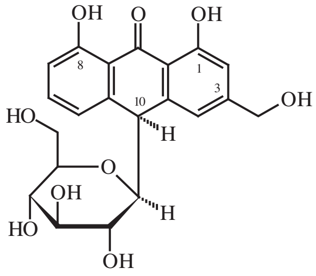
Egyptian senna is allowed as a dye for cigarette paper. Chrysophanol, emodin, rhein and parietin (also known as physcion) and chrysarone (**9-161**) are found in the red crisp stalks and especially in the roots of various species of rhubarbs (*Rheum* spp., Polygonaceae). Aloe-emodin is found in some aloe species (*Aloe* spp., Xanthorrhoeaceae) and is also synthesised by the mold *Aspergillus wentti*, which is used for the production of pectolytic enzymes. Parietin occurs in lichens of the genus *Xanthoria*.



9-161, chrysarone

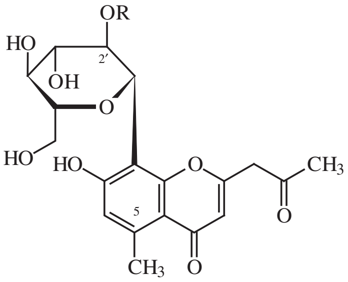
Like other quinones, emodins occur in plants as glycosides. For example, in rhubarb (*R. rhabarbarum*, syn. *R. undulatum*, and false rhubarb *R. rhaponticum*), chrysophanol is present as 1-*O*-β-ᴅ-glucopyranoside, called chrysophanein or chrysophaniin, and parietin occurs as 1-*O*-glucoside, known as physcionin. The same glycosides and chrysophanol-8-*O*-glucoside, called pulmatin, occur in *R. pulmatum*. In young leaves glycosides derived from anthranols are prevalent, while in older leaves anthraquinone glycosides prevail.

Plants of the genus *Aloe* contain a reduced form of aloe-emodin as the *C*-glucoside of the corresponding anthrone, which is called aloin. Lemon yellow aloin is a mixture of two isomers. The major product (*S*)-aloin or (*S*)-β-ᴅ-glucopyranoside-aloe-emodin is referred to as aloin A (or barbaloin, **9-162**), the (*R*)-isomer is aloin B (isobarbaloin). Related glycosides called aloinosides *a* and *b* contain α-ʟ-rhamnopyranose bound by an *O*-glycosidic bond to the hydroxymethyl group at C-3.



9-162, aloin A

Some emodins have a laxative effect and relevant purgative drugs (containing about 10% of aloin) were used for centuries in medicine. Aloin also shows retching and mutagenic effects. *Aloe* spp. are largely used in foods and beverages as flavoring agents. Because of the averse pharmacological effects of aloe constituents on consumers, the EEC listed aloin as a marker of *Aloe* occurrence in food and limited the amount of aloin to levels of 0.1 mg/kg in foods, 0.1 mg/l in beverages and 50 mg/l in alcoholic beverages. The choice of aloin as a marker of aloe in beverages is inadequate since aloin is unstable in aqueous and alcoholic solutions. The degradation products include aloin dimers and trimers and aloe-emodin, therefore more stable 5-methylchromones aloesin and aloeresin A (**9-163**) were suggested as alternative markers for the presence of aloe in alcoholic beverages.



aloesin, R = H
aloeresin A, R = *p*-coumaroyl

9-163, 5-methylchromones of *Aloe* spp.

Fungi contain a range of anthraquinones of octaketide origin with both rings substituted. In many cases, anthraquinones are found in fungi as the corresponding colourless reduced forms that may occur as glycosides. Many natural anthraquinones are oligomers formed by the coupling of two or more anthraquinone molecules. These oligomers further differ in the points through which monomers are attached and may have more than one polymorphic form. For example, the major dark orange pigment of the European toadstool *Cortinarius cinnabarinus* (Cortinariaceae) is fallacinol (6-*O*-methoxycitreorosein, **9-164**). Several species of the genera *Cortinarius*, *Dermocybe* and *Tricholoma*, such as *C. cinnamomeoluteus*, trivially known as man on horseback, produce a bright yellow dimeric anthraquinone flavomannin-6,6′-di-*O*-methyl ether (**9-165**). This pigment is biosynthesised by 7,7′-coupling of the corresponding green dihydroanthracenone (*R*)-torosachrysone (**9-166**). In its homochiral form it also occurs in the European *C. citrinus* and *C. croceus*, while in Australian fungi it forms a mixture of (3*R*,3*R*′,*M*)- (**9-165**) and (3*R*,3*R*′,*P*)-atropoisomers. The green (*R*)-atrochrysone (**9-166**) occurs in *C. atrovirens* and *C. odoratus*, (*S*)-torosachrysone-8-*O*-methyl ether is a constituent of *C. fulmineus*, *C. citrinus*, *C. splendens*, *T. equestre* and the sulfur knight *T. sulfureum*.

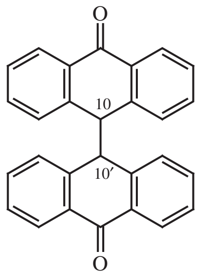
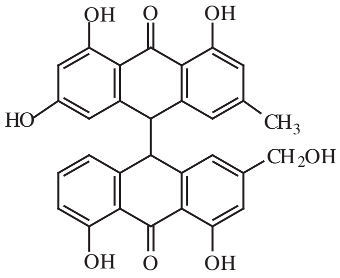
9-166, (*R*)-atrochrysone, R = H
(*R*)-torosachrysone, R = CH_3

9.8.1.3.2 Bianthrones and related compounds

In addition to emodins, rhubarb root also contains dimeric reduced forms of emodins derived from 10,10′-bianthronyl (**9-167**), which are called bianthrones (dianthraquinones). They can occur as homobianthrones, such as emodin bianthrone and parietin bianthrone, or as heterobianthrones (mixed dimers), such as palmidin A (**9-168**), which is bianthrone of emodin and aloe-emodin.



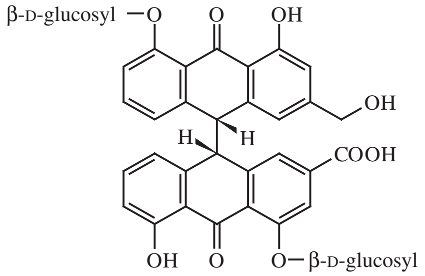
9-167, 10,10′-bianthronyl



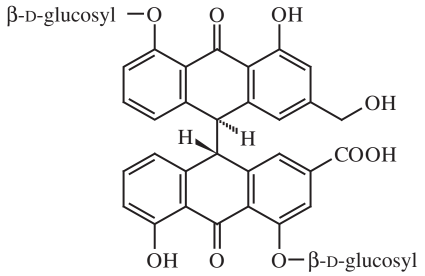
9-168, palmidin A

The related sennosides, glycosides A, B, C and D, occur in amounts of 1.5–3% in the leaves of Egyptian senna shrubs that are cultivated primarily in India. Senna leaves were previously used by Arab physicians as a laxative drug and digestive stimulant. Heterobianthrones sennosides A (*meso*-derivative, **9-169**) and B (*trans*-derivative, **9-170**) are bianthrone glycosides derived from aloe-emodin and rhein, homobianthrones sennosides C (*meso*-derivative) and D (*trans*-derivative) are derived only from rhein.

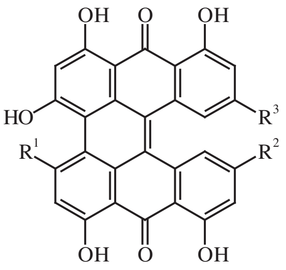
An even more condensed derivative of emodin bianthrone is the purple photodynamic pigment hypericin, 1,3,4,6,8,13-hexahydroxy-10,11-dimethylphenanthro[1,10,9,8-*opqra*]perylen-7,14-dione (**9-171**). Hypericin is a pigment of the flowers of St. John's wort (*Hypericum perforatum*, Hypericaceae), a yellow-flowering perennial herb indigenous to Europe, and other



9-169, sennoside A



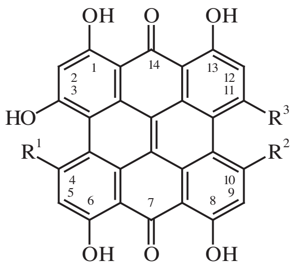
9-170, sennoside B



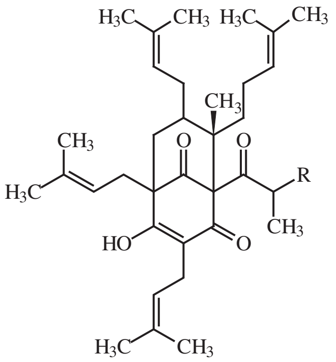
9-171, protohypericin, $R^1 = OH$, $R^2 = CH_3$, $R^3 = CH_3$
protopseudohypericin, $R^1 = OH$, $R^2 = CH_3$, $R^3 = CH_2OH$

Hypericum species, which is accompanied by related pigments pseudohypericin and isohypericin and (**9-172**) and their precursors protohypericin and protopseudohypericin, phloroglucinols (hyperforin and adhyperforin, **9-173**), flavonol glycosides and biflavones. Hyperflorin and its derivative adhyperflorin inhibit different receptor neurotransmissions (act as inhibitors of hormones catecholamines, such as serotonin, and of GABA and glutamate) and have antidepressant effects for which the plant is widely known as a herbal treatment for depression. A pigment structurally related to hypericin is the dark red pigment phagopyrin (**9-174**), 1,3,4,6,8,13-hexahydroxy-10,11-dimethyl-2,5-di-2-piperidinylphenanthro[1,10,9,8-*opqra*]perylen-7,14-dione that is found mainly in flowers and herbs of common buckwheat (*Fagopyrum esculentum*) of the family Polygonaceae. Hydrolysis of phagopyrin provides hypericin and other products. Consumption of phagopyrin and hypericin and subsequent irradiation by sunlight leads to phagopyrism, which was observed in white and white-spotted animals (sheep, pigs, cattle and horses) that were fed buckwheat leaves. The presence of hypericin in food is consequently regulated by legislation. According to Regulation (EC) No. 1334/2008,

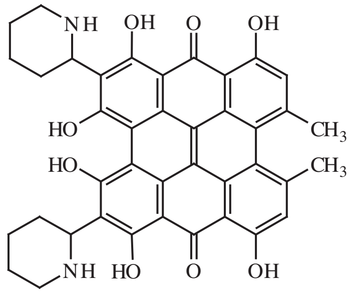
flavourings and food ingredients with flavouring properties produced from *Hypericum perforatum* may only be used for the production of alcoholic beverages.



9-172, hypericin, R^1 = OH, R^2 = CH_3, R^3 = CH_3
pseudohypericin, R^1 = OH, R^2 = CH_3, R^3 = CH_2OH
isohypericin, R^1 = CH_3, R^2 = OH, R^3 = CH_3



9-173, hyperflorin, R = CH_3
adhyperflorin, R = CH_2CH_3

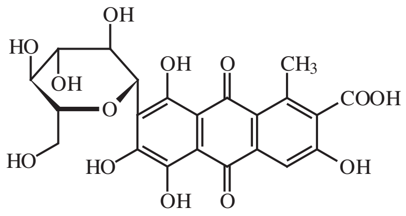


9-174, phagopyrin

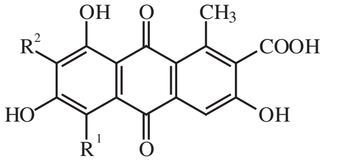
Emodins with both aromatic rings hydroxylated are synthesised exclusively by the polyketide pathway as octaketides. Biosynthesis of bianthrones and other condensed emodin derivatives occurs by one-electron oxidation of anthrone derivatives (anthranols) to radicals, which are joined to form bianthrones.

9.8.1.3.3 Carmine pigments

Carmine pigments are anthraquinone derivatives, which, unlike other anthraquinones, are of animal origin. **Carmine** (also known as Natural Red 4) is the term that describes the aluminium chelate of anthraquinone derivative carminic acid. The term **cochineal** is used to describe both the fertilised females of the coccid insect *Dactylopius coccus* (*Coccus cacti*, Dactilopiidae), from which carmine is derived, and also the pigments obtained. The insects live as a parasites on cacti of genera *Opuntia* and *Nopalea* (Cactaceae) and especially on *N. coccinellifera*, which was originally grown in Mexico. Dry and milled insect bodies are used as the pigment, and the pigment can constitute up to 22% of solids. The main component of cochineal is carminic acid (**9-175**), which is present as *C*-glucoside, 7-α-D-glucopyranosyl-9,10-dihydro-3,5,6,8-tetrahydroxy-1-methyl-9,10-dioxo-2-anthracenecarboxylic acid, the aglycone of which is the anthraquinone derivative 9,10-dihydro-3,5,6,8-tetrahydroxy-1-methyl-9,10-dioxo-2-anthracenecarboxylic acid, which is called kermesic acid (**9-176**).



9-175, carminic acid

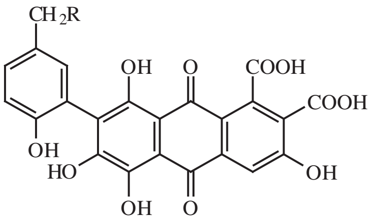


9-176, kermesic acid, R^1 = OH, R^2 = H
ceroalbolinic acid, R^1 = H, R^2 = OH

Carminic acid is a water-soluble and stable substance. The shade of colour in solution depends on pH and is orange at pH 3, red at pH 5.5 and purple at pH 7. The colour intensity is relatively low, therefore carminic acid is used mainly as the red aluminium salt called carmine lake or crimson lake (containing about 50% of carminic acid), which is prepared from powdered insect bodies hydrolysed in diluted ammonia (or sodium carbonate) and by addition of alum. It is used as an intense red pigment for colouring some aperitifs (vermouths), meat products, specialty bakery and confectionery products, jams and dairy products.

A similar pigment to carmine is **kermes** that was mainly used in the Middle Ages in the Mediterranean region. Kermes is derived from European species of insects, mainly of *Kermes vermilio and K. illicis* (Kermesidae) living on the kermes oak (*Quercus coccifera*, Fabaceae). The main pigment of kermes is kermesic acid, the same aglycone as in carminic acid. Along with kermesic acid, isomeric ceroalbolinic acid (**9-176**) also occurs.

Lac is the scarlet secretion of a number of species of insects of several genera, of which the most commonly cultivated species is *Kerria lacca* (syn. *Laccifer lacca*, Kerriidae). The main producers of lac are India and Malaysia. Lac pigment is a complex mixture of laccaic acids (**9-177** and **9-178**), erythrolaccin and deoxyerythrolaccin (**9-179**).



9-177, laccaic acid A, R = $CH_2NHCOCH_3$

9.9 Carotenoids

Carotenoids are widespread yellow and orange (rarely yellow–green and red) lipophilic pigments of plants, fungi, algae, microorganisms and some animals (crustaceans, fish, birds and mammals). Their annual production in nature is estimated at 1×10^8 tons. In plants, carotenoids are principally associated with chlorophylls in plastids called chromoplasts and chloroplasts. Today, about 700 naturally occurring carotenoid pigments are known. Of this number, about 50 compounds may act as provitamins A.

9.9.1 Structure and nomenclature

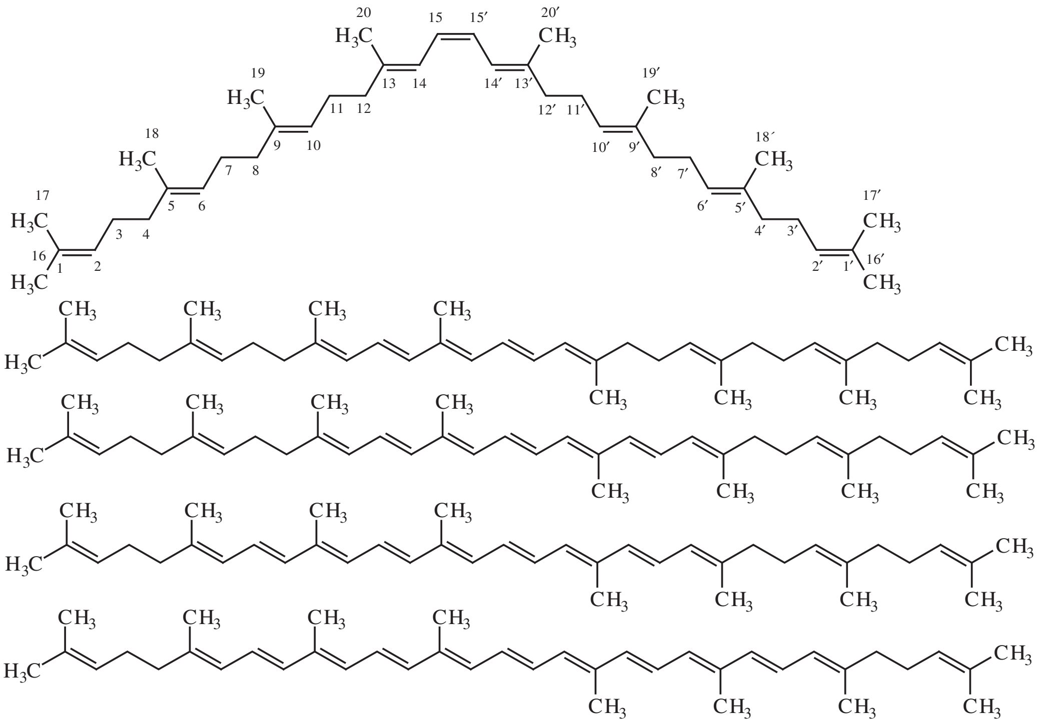
Most carotenoid compounds are tetraterpenoids formally containing eight isoprene units. They owe their colour to the chain of conjugated double bonds, which occurs in several basic structures and their combinations.

Carotenoids are divided into two main groups:

- hydrocarbons called **carotenes**
- oxygen-containing compounds (alcohols, aldehydes, ketones, epoxides and other compounds) derived from carotenes, which are known as **xanthophylls**.

9.9.1.1 Carotenes

The simplest prototype of carotenes, called **ψ-carotenes**, is the polyunsaturated acyclic hydrocarbon (15*Z*)-7,8,11,12,7′,8′,11′,12′-octahydro-ψ,ψ-carotene, known as phytoene, which is synthesised from two molecules of geranylgeranyl diphosphate. Isomerisation of phytoene yields the *trans*-isomer phytofluene (7,8,11,12,7′,8′-hexahydro-ψ,ψ-carotene). Oxidation of phytofluene gradually gives ζ-carotene (7,8,7′,8′-tetrahydro-ψ,ψ-carotene), neurosporene (7,8-dihydro-ψ,ψ-carotene) and lycopene(ψ,ψ-carotene), which is the final product of the biosynthesis (**9-180**) and the main pigment of tomatoes (30–200 mg/kg), watermelons (33–121 mg/kg) and rose hips (101–834 mg/kg



9-180, acyclic carotenes

fresh weight). Acyclic carotenes, with the exception of lycopene, are found in food materials in small quantities. They accompany alicyclic carotenes and xanthophylls, which are the main carotenoids.

Alicyclic carotenes are formed by enzymatically catalysed cyclisation at one or both ends of the acyclic ψ-carotenes, which leads to formation of a β-ionone structure in **β-carotene**s or α-ionone structure in **ε-carotene**s (Figure 9.21). Examples of hydrocarbons with a β-ionone ring at only one end of the molecule are β-zeacarotene and γ-carotene (β,ψ-carotene). Cyclisation at both ends of the molecule produces structures that are present, for example, in β-carotene, α-carotene or α-zeacarotene. β-Carotene with two β-ionone rings is therefore systematically called β,β-carotene, α-carotene is β,ε-carotene, because it has only one β-ionone ring and one α-ionone ring. Carotene with two α-ionone rings (ε-rings) is ε-carotene or ε,ε-carotene. Carotenes with a β-ionone ring, such as α-carotene, β-carotene and γ-carotene, are precursors of retinol and are, therefore, provitamins A. β-Zeacarotene is not provitamin A, because it has a partially reduced side chain (**9-181**).

9.9.1.2 Xanthophylls

Xanthophylls are the main carotenoids of plants. They primarily arise as products of biochemical oxidation (hydroxylation and epoxidation) of carotenes. Xanthophylls derived from acyclic carotenes occur in foods in small quantities. For example, tomatoes contain as minor pigments 1,2-epoxylycopene, 5,6-epoxylycopene, 1,2-epoxyphytoene and some other compounds. Much more common are monohydroxysubstituted alicyclic derivatives of carotenes called **cryptoxanthins**. Most plant materials contain small amounts of α-cryptoxanthin also called zeinoxanthin, derived from α-carotene (**9-182**) and β-cryptoxanthin, derived from

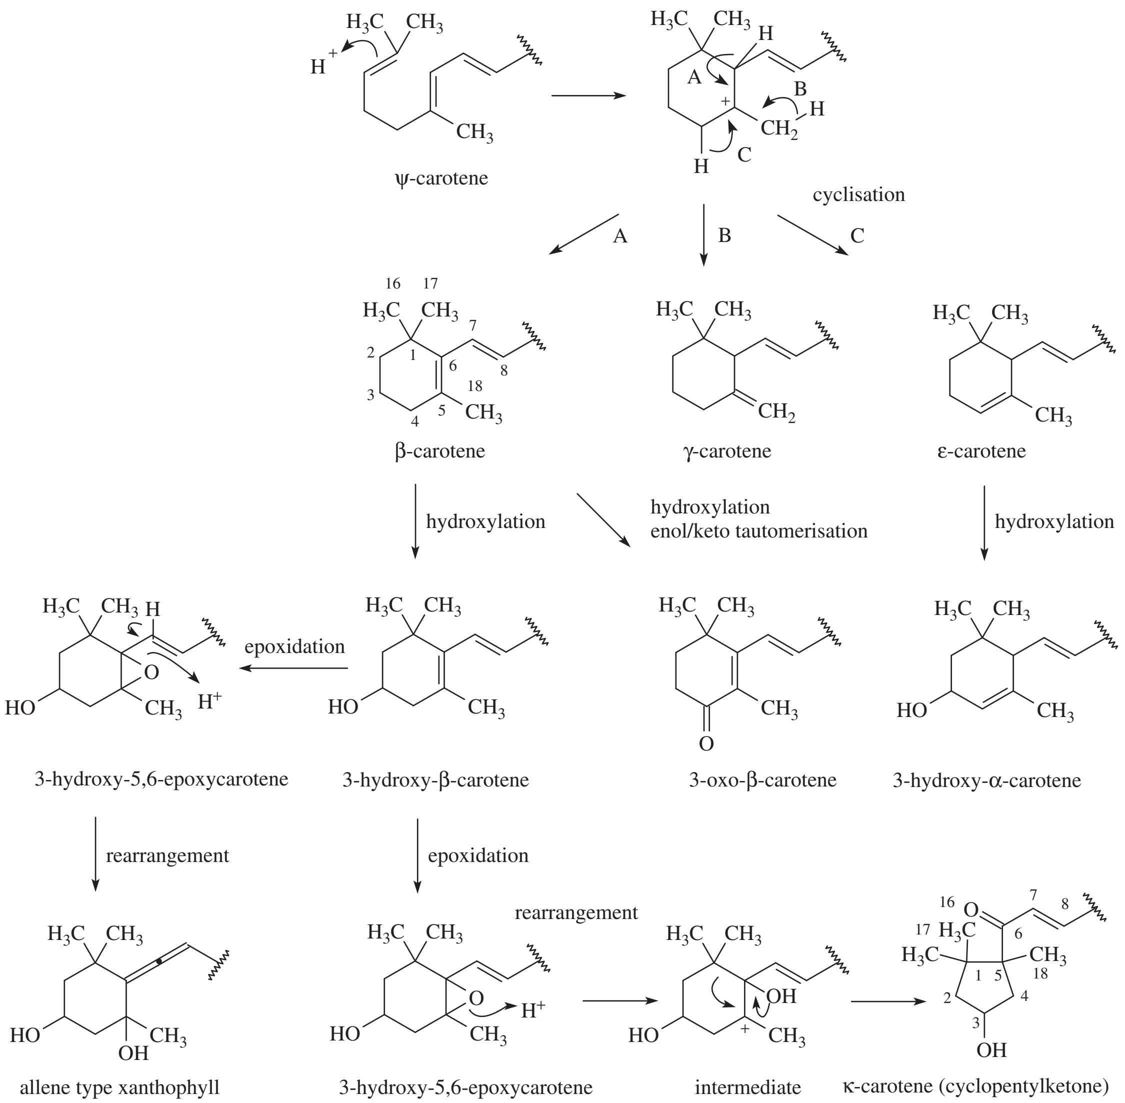


Figure 9.21 Formation of alicyclic carotenes and xanthofylls.

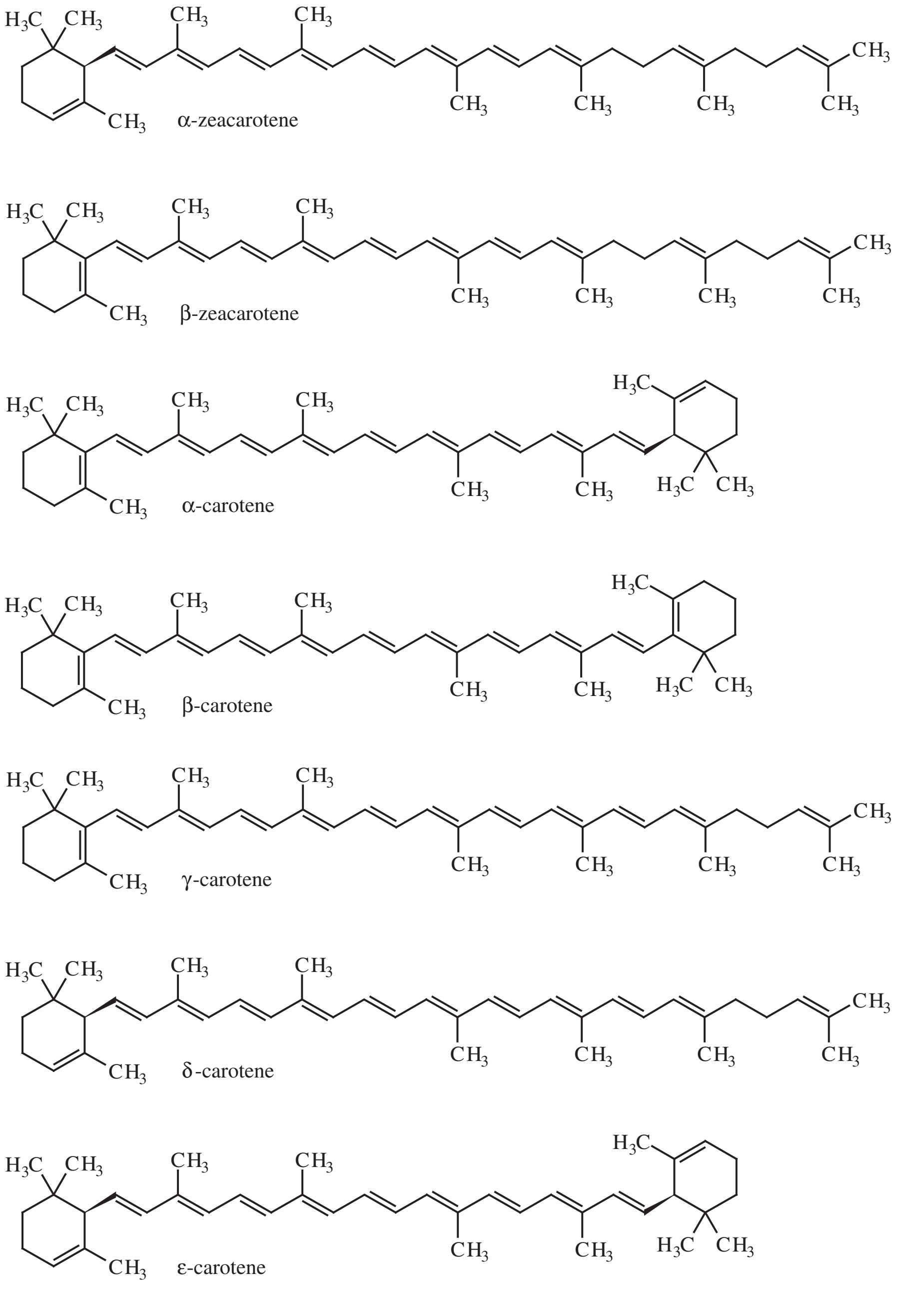
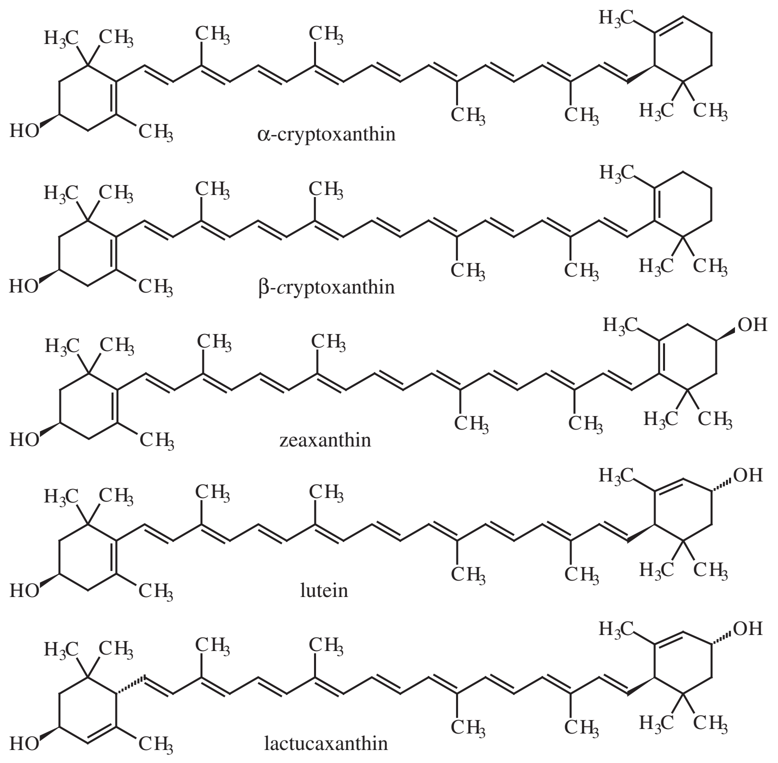


9-181, alicyclic carotenes

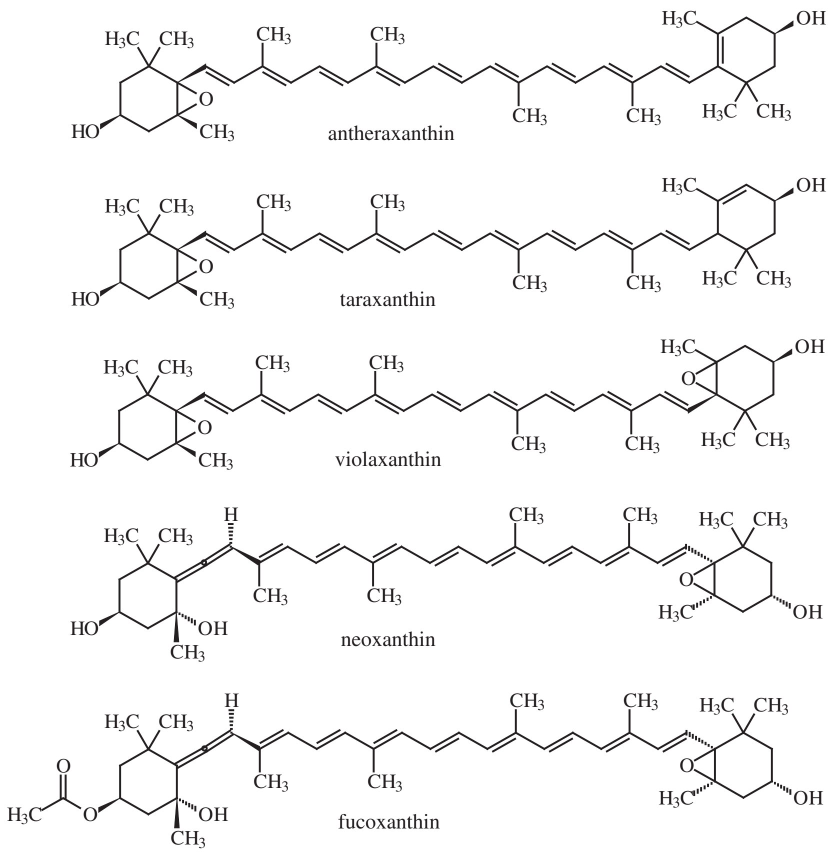
β-carotene, which are precursors of xanthophylls containing two hydroxyl groups in the molecule. The xanthophyll β-cryptoxanthin is provitamin A. Examples of dihydroxysubstituted pigments are zeaxanthin (arising from β-cryptoxanthin and β-carotene, respectively) and lutein (the precursor of which is α-cryptoxanthin and α-carotene, respectively), the precursor of lactucaxanthin is ε-carotene.[4]

Oxidation of these compounds subsequently gives rise to 5,6-epoxides, such as antheraxanthin (**9-183**) derived from β-carotene or taraxanthin (lutein epoxide) derived from α-carotene. Oxidation

[4]The systematic name of zeaxanthin is (3*R*,3′*R*)-7,8-didehydro-β,β-carotene-3,3′-diol or 3,3′-dihydroxy-β-carotene, lutein is (3*R*,3′*S*,6′*R*)-β,ε-carotene-3,3′-diol or 3,3′-α-carotene. Antheraxanthin is 5,6-epoxy-5,6-dihydro-β,β-carotene-3,3′-diol, taraxanthin is (3*S*,5*R*,6*S*,3′*S*,6′*R*)-5,6-epoxy-5,6-dihydro-β,ε-carotene-3,3′-diol, violaxanthin is (3*S*,5*R*,6*S*,3′*S*,5′*R*,6′*S*)-5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene-3,3′-diol or zeaxanthin diepoxide. Neoxanthin is (3*S*,5*R*,6*R*,3′*S*,5′*R*,6′*S*)-5′,6′-diepoxy-6,7-didehydro-5,6,5′,6′-tetrahydro-β,β-carotene-3,5,3′-triol. Mutatochrom (also known as citroxanthin) is 5,8-epoxy-5,8-dihydro-β,β-carotene, mutatoxanthin is 5,8-epoxy-5,8-dihydro-β,β-carotene-3,3′-diol, luteoxanthin is 5,6,5′,8′-diepoxy-5,6,5′,8′-tetrahydro-β,β-carotene-3,3′-diol, auroxanthin is 5,8,5′,8′-diepoxy-5,8,5′,8′-tetrahydro-β,β-carotene-3,3′-diol. Capsanthin is (3*R*,3′*S*,5′*R*)-3,3′-dihydroxy-β,κ-caroten-6′-one, capsorubin is (3*S*,5*R*,3′*S*,5′*R*)-3,3′-dihydroxy-κ,κ-caroten-6,6′-dione, cryptocapsin is (3′*S*,5′*R*)-3′-hydroxy-β,κ-caroten-6′-one.



9-182, hydroxy and dihydroxy carotenes



9-183, 5,6-epoxides and allenes

at both ends of the molecule gives 5,6,5′,6′-diepoxides, such as violaxanthin. Neoxanthin, formerly also called foliaxanthin, which is found in higher plants, and fucoxanthin, occurring in algae, are examples of rarely occurring compounds called **allenes** (dienes with cumulated double bonds).

Isomerisation of 5,6-epoxides yields both isomers of the corresponding 5,8-epoxides. Examples are mutatochrom (derived from β-cryptoxanthin, **9-184**) and mutatoxanthin (derived from zeaxanthin). Luteoxanthin and auroxanthin are both 5,6- and 5,8-diepoxides. By rearrangement of the 5,6-epoxy group, an additional group of xanthophylls arises that are also called cyclopentylketones or κ-carotenes (**9-185**). The most important κ-carotenes are capsanthin and capsorubin. Smaller amounts of cryptocapsin, capsanthon, capsochrom and capsanthin epoxides also can be found. The reaction mechanisms of biosynthesis of most xanthophylls are shown schematically in Figure 9.21.

9.9.1.3 Apocarotenoids

A relatively small, but very important group of xanthophylls are compounds containing less than 40 carbon atoms in the molecule. These compounds, resulting from the breakdown of carotenoids, are called **degraded carotenoids** or **apocarotenoids**. Apocarotenoids exhibit different biological functions. The most important apocarotenoid is vitamin A_1 (all-*trans*-retinol).

An important and quite widespread product of the catabolism of carotenoids is apocarotenal β-citraurin, (*R*)-3-hydroxy-8′-apo-β-carotene-8′-al with 30 carbon atoms in the molecule (**9-186**). Other important apocarotenals are bixin (*cis*-bixin) with 22 carbon atoms and crocetin with 20 carbon atoms.

9.9.2 Occurrence

Carotenoids are important and are the most widespread lipophilic pigments of many fruits and vegetables. They occur in all photosynthetic plant tissues, where they are found as photochemically active components of plastids called chromoplasts. Carotenoids are often accompanied by other pigments, for example by anthocyanins in peaches and apricots. The presence of carotenoids in the green parts of plants is often masked by chlorophyll pigments.

Qualitative and quantitative composition of carotenoids depends on many factors, such as the species and varieties of plants, season, maturity stage, method of processing and other factors. In some fruits and also in potatoes, carotenoids occur in units of mg/kg, but in most fruits and vegetables they are present in dozens of mg/kg, and in carrots, tomatoes and peppers there are hundreds of mg/kg of carotenoids.

A certain proportion of carotenoids in plants is associated with proteins, as is the case of chlorophyll pigments. These associates are generally known as **carotenoproteins**. Xanthophylls are also present as fatty acids esters or as glycosides. For example, the main yellow pigment of sunflower (*Helianthus annuus*, Asteraceae) flowering head is lutein dipalmitate.

All-*trans*-isomers of carotenoids in fresh and thermally processed materials are accompanied by small amounts of *cis*-isomers, called **neocarotenoids**. β-Carotene is accompanied mainly by geometric isomers 9-*cis*, 13-*cis*- and 15,15′-*cis*-β-carotene. Lutein is accompanied mainly by 9-*cis*- and 9′-*cis*, 13-*cis*- and 13′-cis isomers; less common are 15-*cis* and 15′-*cis* isomers. Neoxanthin is accompanied by 9-*cis*-, 9′-*cis*-, 13-*cis*- and 13′-*cis* isomers. Thermal processing can induce carotenoid *trans* to *cis* isomerisation.

9-186, β-citraurin

9.9.2.1 Fruits

A particular type of fruit usually contains a number of carotenoids (see Table 9.14), of which some may be the dominating pigments. Rarely – for example in apricots and mango – the main pigment is β-carotene. Other pigments are various other carotenes and xanthophylls that are present in very small quantities. Peaches contain higher amounts of xanthophylls in comparison with apricots, and these partly occur in the form of fatty acid monoesters and diesters. The main fatty acids bound in xanthophylls are palmitic and myristic acids. Oranges contain relatively small amounts of carotenes, but highly variable amounts of cryptoxanthin, lutein, antheraxanthin and violaxanthin as the main pigments that are accompanied by other xanthophylls. β-Cryptoxanthin and zeaxanthin are the most abundant pigments of persimmon flesh (*Diopyros kaki*, Ebenaceae), and the total amount of these two components accounts for 38–85% of the total carotenoids.

9.9.2.2 Vegetables

9.9.2.2.1 Carrots

The predominant pigment of carrots is β-carotene (Table 9.14). Its content is generally 60 to 120 mg/kg, but the amount of β-carotene in some varieties may reach 300 mg/kg. These pigments are partly associated with proteins.

Table 9.14 Composition and content of main carotenoids of fruits and vegetables.

Carotenoids	Content (mg/kg fresh weight)

9.9.2.2.2 Leafy vegetables

In leafy vegetables, β-carotene usually amounts to 10–20% of total carotenoid content. As in carrots, other carotenoid pigments are various xanthophylls. Lutein, violaxanthin and neoxanthin usually occur in large amounts, while cryptoxanthin, zeaxanthin (the main carotenoid of maize), antheraxanthin and other xanthophylls are found in smaller amounts (Table 9.14). The presence of carotenoids is masked by chlorophylls. Lettuce (*Lactuca sativa*, Asteraceae) is an example of a vegetable accumulating a higher amount of lactucaxanthin.

9.9.2.2.3 Tomatoes

The main pigment in tomato, lycopene, typically represents 85% of the tomato's total carotenoids. The content of β-carotene is relatively low, about 6 mg/kg, and about 1 mg/kg represents γ-carotene (see Table 9.14). Some orange hybrid tomatoes contain lower amounts of lycopene and higher amounts of β-carotene (up to about 80 mg/kg) and γ-carotene (about 7 mg/kg).

Lycopene content increases during tomato ripening and the final content is in the range of 30–200 mg/kg (about 95% represents the all-*trans* isomer). Tomato products are mostly prepared by

evaporation of tomato juice, therefore tomato products, such as concentrated juice (62 mg/kg), puree (133 mg/kg) or ketchup (102 mg/kg), contain higher concentrations of lycopene than the starting material (30 mg/kg), but also contain less stable *cis*-isomers, the content of which increases with temperature and time of heating. Up to 20% of the initially present *trans*-isomer may isomerise.

9.9.2.2.4 Bell peppers

Some carotenoids are found only in a limited number of plant species. An example is capsanthin and other cyclopentylketones in red bell peppers (*Capsicum* spp., Solanaceae) (Table 9.14).

The main pigments in green peppers, in addition to chlorophylls, are lutein (8–14 mg/kg), violaxanthin (8–10 mg/kg), neoxanthin (8–9 mg/kg) and β-carotene (6–8 mg/kg). During maturation, the minority yellow xanthophylls present in green fruits (β-cryptoxanthin and zeaxanthin) are enzymatically oxidised via 5,6-epoxides (e.g. via 5,6-epoxycryptoxanthin, antheraxanthin and violaxanthin) to several red κ-carotenes (Figure 9.21). The principal red pigment is always capsanthin, which constitutes 32–38% of carotenoid pigments of peppers. Present in amounts of 1–4% are capsanthin 5,6-epoxide, capsorubin (6–10%) and a small number of other substances, such as capsolutein, cryptocapsin and other pigments. The relative content of major carotenoids formed during ripening of pepper pods is given in Table 9.15.

Biosynthesis of κ-carotenes proceeds simultaneously with esterification of pigments by fatty acids. The majority of pigments of mature peppers (about 80%) are totally or partially esterified with fatty acids. The main fatty acids of yellow xanthophylls are linoleic, myristic and palmitic acids, in red xanthophylls they are mainly bound lauric, myristic and palmitic acids.

9.9.2.2.5 Rose hips

The total amount of carotenoids in rose hips from different species of the genus *Rosa* (Rosaceae) ranges from 101 to 834 mg/kg in flesh of fresh rose hips or from 42.3 to 1024 mg/kg (dry matter), of which 18.7–516 mg/kg represent carotenes, and 23.6–38.9 xanthophylls. The main pigment is lycopene (12.1–296 mg/kg), which is followed by other carotenes, (7*Z*,9*Z*,7′*Z*,9′*Z*)-lycopene, also known as (9*Z*,9′*Z*)-ζ-carotene or prolycopene (1.2–21.3 mg/kg), γ-carotene (0–15.2 mg/kg) and ζ-carotene (0–14.6 mg/kg). The main xanthophyls are lutein and zeaxanthin (7.2–25.8 mg/kg), neochrome (6.6–9.8), neoxanthin (0–8.8 mg/kg) and violaxanthin (0–8.1 mg/kg).

Table 9.15 Changes of main carotenoids during pepper pods ripening (% of total carotenoids).

	Degree of ripeness					
Carotenoids	**Green**	**Light yellow**	**Yellow**	**Orange**	**Red**	**Dark red**
α-Carotene	0.3	0.7	0.4	0.5	0.2	0.2
β-Carotene	11.3	12.2	7.1	5.9	9.2	8.9

[a]Mixture of two isomers.

9.9.2.3 Other plant materials

9.9.2.3.1 Cereals

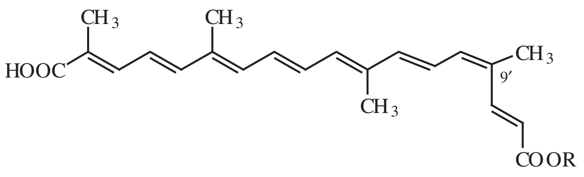
The common wheat varieties (*Triticum aestivum*, Poaceae) contain as the main carotenoid lutein (about 2 mg/kg), which is accompanied by small amounts of β-carotene (about 1% of total carotenoids) and traces of zeaxanthin. The total carotenoid content in *T. durum* is about three times higher than that in common wheat, with lutein (1.5 to 4 mg/kg) as the main component. Lutein is similarly the main carotenoid component in oats and barley.

Maize is exceptionally high in lutein at a concentration of about 20 mg/kg. In addition to the high content of lutein, maize also has high concentration of zeaxanthin (6–10 mg/kg), β-cryptoxanthin (2 mg/kg), β-carotene (1 mg/kg) and small concentrations of 15-*cis*-lutein, 13-*cis*-lutein, 13′-*cis*-lutein, 9-*cis*-lutein, 9′-*cis*-lutein and 9-*cis*-zeaxanthin.

The major brown rice carotenoids are β-carotene and lutein (both about 0.1 mg/kg), while zeaxanthin levels are lower (about 0.030 mg/kg).

9.9.2.3.2 Annatto

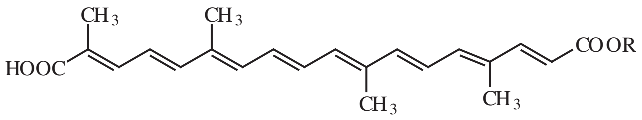
Annatto (also known as achiote) is the pigment from fruits (red seeds and pulp) of the achiote tree (*Bixa orellana*, Bixaceae), which is indigenous to Central and South America, where it is used as a dye, as medicine, and as an ingredient in many foods. The seeds can be ground into a powder, turned into a paste or infused into oil. The main natural component of annatto is apocarotenoid bixin, also known as (9′*Z*)-bixin (9′-*cis*-bixin, **9-187**) that arises as a product of lutein catabolism. The amount of bixin in seeds is about 2%. Bixin is orange, relatively unstable and slightly fat-soluble (it dissolves to give about 5% solutions).



9-187, (*Z*)-bixin, R = CH_3
(*Z*)-norbixin, R = H

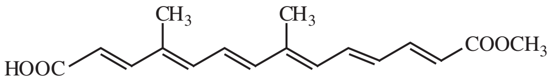
Commercially, the seeds and flesh are processed by extraction with vegetable oils at reduced pressure, and at temperatures lower than 130 °C. Under these conditions, 9′-*cis*-bixin undergoes partial isomerisation to the all-*trans* isomer called (*E*)-bixin (*trans*-bixin, **9-188**). Extracts contain from about 0.2 to 0.5% of a mixture of these two pigments in different proportions according to the conditions of extraction. The resulting *trans*-bixin is a red, relatively stable and fairly fat-soluble pigment.

The extraction of annatto seeds with aqueous alkaline solutions (at temperatures up to 70 °C) produces orange dicarboxylic acid called norbixin or 9′-*cis*-norbixin (**9-187**), which is soluble in a polar media. Isomerisation of norbixin yields red all-*trans*-norbixin (**9-188**), which is slightly soluble in fats.



9-188, (*E*)-bixin, R = CH_3
(*E*)-norbixin, R = H

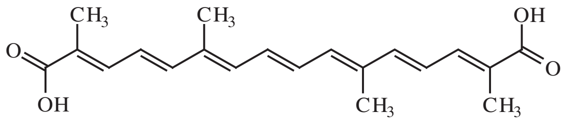
During extraction, 9′-*cis*-bixin is also partly decomposed to orange and pale yellow products. The main product is 14-methyl-hydrogen-4,8-dimethyltetradeca-2,4,6,8,10,12-hexaene-1,14-dioic acid (**9-189**). This compound exists in various stereoisomers such as the *all-trans* isomer, 15-*cis*, 13-*cis* and 9-*cis* isomer. Related compounds with 18 and 13 carbon atoms per molecule, *m*-xylene, toluene and other products also arise. Coloured degradation products of 9′-*cis*-bixin may constitute up to 40% of pigments in commercial products.



9-189, 14-methyl-hydrogen-4,8-dimethyltetradeca-2,4,6,8,10,12-hexaene-1, 14-dioic acid

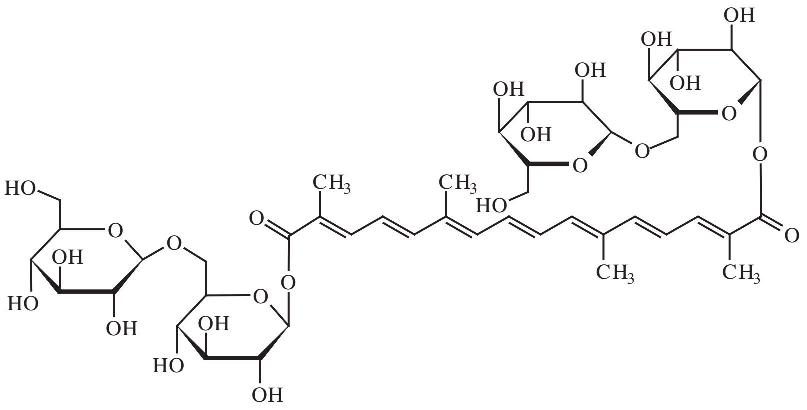
9.9.2.3.3 Saffron

Each flower of the saffron crocus (*Crocus sativus*, Iridaceae) has three filiform (20–30 mm long), purplish brown stigmas, which are dried and used as a culinary spice for its pungent, characteristic spice odour (the carrier is mainly aldehyde safranal, see Section 9.9.5.2.3), bitter taste (caused by picrocrocin, see Section 8.3.5.1.3) and colour. Saffron contains water-soluble yellow–orange apocarotenoid pigments, the chromophore of which is water-insoluble brick red aglycone crocetin, also known as α-crocetin (8,8′-diapocarotene-8,8′-dicarboxylic acid, **9-190**) formed by cleavage of zeaxanthin. Crocetin in saffron occurs as a water soluble yellow–orange ester of crocetin with disaccharide gentiobiose (di-β-gentiobiosylcrocetin), which is called α-crocin or just crocin (**9-191**). Crocin is accompanied by some minor pigments: di-β-gentiobiosyl-, β-gentiobiosyl-β-D-glucosyl-, di-β-D-glucosyl-, mono-β-gentiobiosyl- and mono-β-D-glucosylesters and also by esters derived from trisaccharide neapolitanose, such as β-gentiobiosyl-β-neapolitanosylcrocetin and di-β-neapolitanosylcrocetin.



9-190, crocetin

The disadvantage of saffron is its high price, so it is often falsified. Dry orange marigold petals (*Calendula officinalis*, Asteraceae) are mostly used for falsification, or alternatively the petals of safflower (*Carthamus tinctorius*, Asteraceae). The pigment of yellow marigold petals is 5,6-epoxylutein, also known as flavoxanthin, and the pigment of orange petals is lycopene. The pigment of safflower



9-191, crocin

petals is carthamin (see Section 9.4.2.5.1). Crocin is also found in fruits of the gardenia (*Gardenia augusta*, syn. *G. jasminoides*, Rubiaceae).

9.9.2.3.4 Vegetable oils

The concentration of carotenoids in crude vegetable oils is about 0.03–0.25%. Their content in refined oils is lower and depends on the conditions during refining. Pigments that are found in refined oils differ in their structure from natural pigments as they contain products of isomerisation and degradation of natural pigments.

A relatively high content of carotenoids (0.05–0.2%) is found in palm oil obtained from mesocarp of oil palm seeds (*Elaeis guineensis*, Arecaceae). It has a light orange colour as its main components are α- and β-carotene, occurring in a ratio of about 2 : 3.

9.9.2.4 Foods of animal origin

Carotenoids are similarly present in foods of animal origin. However, animals are unable to synthesise carotenoids *de novo*, and only convert plant pigments occurring in food into substances of different structure or store them as such.

9.9.2.4.1 Depot fats of mammals and birds

The main pigments of depot fats of birds (poultry) and mammals are xanthophylls lutein and zeaxanthin. Also present are small amounts of β-carotene and other pigments.

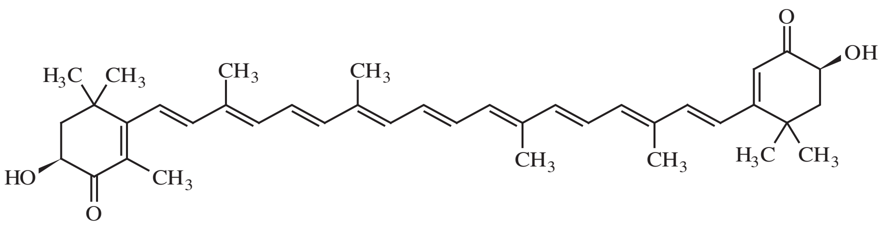
9.9.2.4.2 Eggs

Egg yolk and shell colours are important aspects of egg quality in many countries. Egg yolk pigmentation is a complex process influenced by many factors, such as nutrition, carotenoid source, health, egg handling and storage. Egg yolk contains as the main pigments the same xanthophylls and carotenes that occur in the depot fat of hens. The most abundant pigment is lutein/zeaxanthin, followed by β-cryptoxanthin and β-carotene and other carotenes occurring in the feed (such as canthaxanthin and β-apo-8′-carotenal). The amount of β-carotene is low (0.3–1% of total carotenoids), as this carotene is quickly metabolised.

Brown-shelled eggs presently dominate markets in the United Kingdom, France, Ireland and Portugal, whereas white eggs are preferred in Germany, Austria, Switzerland, Spain, the United States and Australia. The pigments of brown eggs are mixtures of protoporphyrin IX, biliverdin IX and its zinc chelate, with traces of other haemoglobin derived pigments in various proportions.

9.9.2.4.3 Fish and crustaceans

The red pigment of salmonid fish and many crustaceans (shrimps, crabs, crayfish and others) is xanthophyll astaxanthin, (3*S*,3*S*′)-astaxanthin, which is (3*S*,3*S*′)-β,β-carotene-3,3′-dihydroxy-4,4′-dione (**9-192**). Astaxanthin in crustaceans is bound to proteins in dark blue–red and green–red carotenoproteins. During cooking, proteins denature and the typical red colour of free astaxanthin becomes more vibrant. For example, the light blue crab *Homarus gammarus* (Nephropidae), known as European lobster



9-192, astaxanthin

or common lobster, contains the blue carotenoprotein known as α-crustacyanin. The protein (320 kDa) is composed of 16 apoprotein units, each of which contains one molecule of astaxanthin.

9.9.3 Use

Some carotenoid pigments are used as fresh or dried plant parts or extracts (so-called oleoresins) to impart colour to food (e.g. carrots, orange peels, tomatoes, saffron, annatto and paprika, which is made from dried and ground fruits of various *Capsicum* species and cultivars). Palm oil containing carotenoid pigments is also used for the same purpose.

Natural and synthetic carotenoids have found use as lipophilic and hydrophilic food dyes and also, relatively recently, as antioxidants. In amounts of 1–10 mg/kg, carotenoids are used to impart colour to many foods, such as margarines, cheeses, yoghurt, ice creams, fruit juices, dressings, flour, pasta products and cakes. The most common carotenoids are β-carotene (E160a), annato (E160b), paprika extract (E160c), lycopene (E160d), degradation product of β-carotene β-apo-8′-carotenal (E160), orange–red ethyl ester of the corresponding acid, which is ethyl β-apo-8′-carotenoate (Food Orange 7, E160f), lutein (E161b) and red canthaxanthin (E161g, **9-193**).

Canthaxanthin (β,β-carotene-3,3-dione) is also found in some beetle species and occurs as the major pigment in flamingo feathers, along with astaxanthin and other minor xanthophylls, such as phoenicoxanthin, (3-hydroxy-β,β-carotene-3,3-dione), phoenicopterone (β,ε-carotene-4-one) and echinenone.

The above listed carotenoids are also added to the feed of dairy cows and poultry to ensure desirable pigmentation of milk, dairy products, eggs and meat. All these carotenoids are added to feed for laying hens and broilers (to provide pigmentation of eggs and meat), with the exception of β-carotene, and also synthetic citranaxanthin (E161i, **9-194**) and carotenoids obtained from different plant materials. The reason why the feed for laying hens and broilers does not contain added β-carotene is its quick conversion into retinol, which has almost no effect on the yolk and meat colours. β-Carotene in beef cattle is stored in adipose tissue and also passes partly into milk.

9.9.4 Biochemistry, physiology and nutrition

Some carotenoids are precursors (provitamins) of vitamin A. Other carotenoids, such as cryptoxanthin, zeaxanthin and lutein, exhibit, by contrast, about half of the activity of provitamins A. Some carotenoids, such as lycopene, astaxanthin and canthaxanthin, are more effective in quenching singlet oxygen than β-carotene. Carotenoids also react with free radicals such as β-carotene. Because of their antioxidative properties, they are used in the prevention of degenerative processes and as anticancer agents.

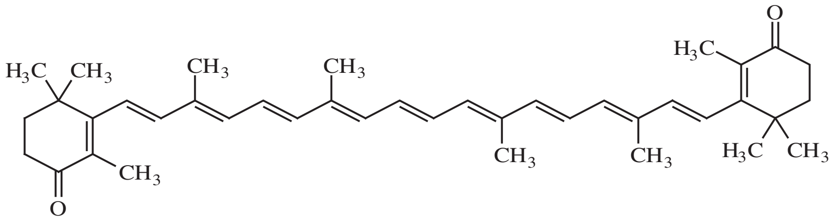
9.9.5 Reactions and changes

The combined effect of oxidoreductases, light, heat, oxygen, hydronium ions and other factors can lead to isomerisation, oxidation and degradation of carotenoids and xanthophylls (see Section 5.2.6.2). Carotenoids present in the form of carotenoproteins are more stable than free substances. Xanthophylls, especially epoxides of carotenoids, are more susceptible to changes under the conditions used during food processing. Apocarotenoids, which contain a carboxyl group, form soluble salts in alkaline media.

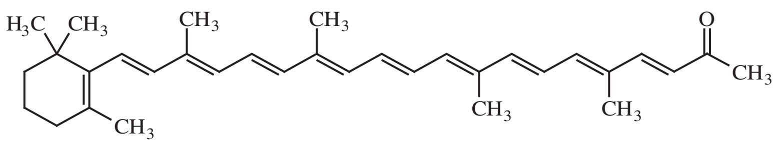
9.9.5.1 Carotenoids and colour

Food products, which undergo undesirable colour changes in the presence of enzymes and oxygen, are sterilised to achieve the inactivation of enzymes, and stored in an inert atmosphere or in the presence of antioxidants. In cases where it is impossible to prevent the degradation of carotenoids (e.g. during the storage of flour or the manufacture of pasta, losses of carotenoids can reach 30–60%), the material can be coloured using synthetic carotenoids.

In acidic citrus juices, spontaneous conversion of 5,6- and 5′,6′-epoxides to 5,8- and 5′,8′-epoxides occurs. Relatively rapid



9-193, canthaxanthin



9-194, citranaxanthin

enzymatic degradation of carotenoids (about 50% of pigments are degraded within 20 min) occurs in stored raw spinach puree. Lipoxygenases are indirectly involved in the degradation of carotenoids, as a result of their reaction with free hydroperoxide radicals. Therefore, it is necessary to inhibit oxidoreductases of spinach leaves by blanching them in hot water before freezing. During storage of frozen blanched spinach puree, changes in the content of carotenes and xanthophylls are minimal.

Thermal processing of vegetables using mild processes, such as steaming, results in relatively low losses in the content of carotenes (up to 10%) and in somewhat higher losses in the content of xanthophylls. Epoxy xanthophylls, such as violaxanthin and taraxanthin, however, undergo significant losses. When cooking spinach, broccoli or green beans by steaming or boiling in water for 3–10 min, the loss of taraxanthin can reach 35–100%, and the loss of violaxanthin may be 35–65% depending on the type and method of processing. Cooking beans in water for 10 min results in a loss of about 60% and cooking for 1 hour leads to complete degradation of both epoxy carotenoids.

The pigment content during drying and grinding of pepper pods is reduced to about half. Most losses are caused by dilution of the product by non-coloured parts of fruits, such as seeds, but some degradation of carotenoids also occurs. The least stable are the yellow pigments, especially β-carotene, while the red pigments (capsanthin and its derivatives) only decompose to a small extent. In paprika stored in the presence of oxygen, the hydroxyl groups of cyclopentane ring of capsanthin are readily oxidised with the formation of the corresponding diketone capsanthone, also known as capsanthinone, which is (3*R*,5′*R*)-3-hydroxy-β,κ-carotene-3′,6′-dione. Capsanthone decomposes further to β-citraurin, β-citraurin yields 3-oxo-β-apo-8′-carotene, which is degraded to low molecular weight products. Products containing a carbonyl group in the molecule enter the non-enzymatic browning reactions, which results in a change of the red colour of paprika to brown.

Similar reactions also occur in dried and concentrated tomato products (such as dried soups, juice concentrates, pickles and ketchup). From 5,6-epoxylycopene (5,6-epoxy-5,6-dihydrolycopene) present in fresh fruits arises, through epoxide ring opening under acidic conditions, 5,6-dihydroxy-5,6-dihydrolycopen.

In stored foods containing natural bixin (9′-*cis* isomer), in the presence of light, all-*trans*-bixin may result and, by its hydrolysis, all-*trans*-norbixin. In cheeses containing bixin, these substances bind to phosphoproteins (e.g. to some caseins), causing pink discoloration of products. In addition to *trans*-isomers, some degradation products of bixin may also arise, such as methyl ester of all-*trans*-4,8-dimethyltetradeca-2,4,6,8,10,12-hexaenoic acid and aromatic hydrocarbons (e.g. *m*-xylene).

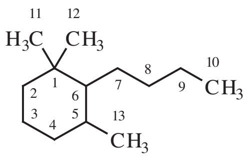
9.9.5.2 Carotenoids and aroma

Carotenoids are precursors of many important compounds, which are formed as products of their catabolism or oxidation, for example, during fruit ripening or processing. Oxidation of carotenoids into fragments called **apocarotenoids** or **diapocarotenoids** is provided by a group of enzymes known as dioxygenases, which catalyse the transfer of molecular oxygen to the substrate. Cleavage of carotenoids in the central double bond (so called symmetric fission) results in the formation of two C_{20} molecules of apocarotenoids. In this way, for example, the visual signalling molecules of retinal and retinoic acid is produced (see Section 5.2.2). Asymmetric (eccentric) cleavage of carotenoids yields apocarotenoid molecules with different carbon chain lengths. The most important degradation products are C_{15}, C_{13}, C_{11}, C_{10} and C_9 compounds. The biologically important C_{15} compound is phytohormone abscisic acid, which is regarded as the major player in mediating the adaptation of plants to stress and preparing plants for a period of dormancy (loss of leaves and other phenomena). Degradation products of carotenoids responsible for the smell and taste of food (mainly fruits and vegetables) and the smell of many flowers are mainly C_{13}, C_{11}, C_{10} and C_9 compounds, but C_{14}, C_8 and other apocarotenoids may also arise. The most important apocarotenoids are C_{13} compounds. Degraded carotenoids with more original carbons (C_{39}, C_{38} or C_{37}), called **norcarotenoids**, are not precursors of aromatic compounds. One to three carbon atoms are formally removed by other reactions (such as oxidation and decarboxylation) than is the case of apocarotenoids.

9.9.5.2.1 Apokarotenoids C_{13}

Apokarotenoids C_{13} result from the cleavage of C-9/C-10 and C-9′/C-10′ bonds. In the latter case, another fission product is a C_{14} diapocarotenoid. The main pigment of red varieties of tomatoes is lycopene (ψ,ψ-carotene), which is accompanied by other acyclic carotenes. Fission of the C-9/C-10 (C-9′/C-10′) bond in lycopene yields the odorous compound of tomatoes (3*E*,5*E*)-6,10-dimethylundeca-3,5,9-trien-2-one (pseudoionone) and, obviously, C_{14} diapocarotene 4,9-dimethyldodeca-2,4,6,8,10-pentaenedial. Acyclic carotene phytoene gives rise to C_{13} methylketone (*E*)-6,10-dimethylundeca-5,9-dien-2-one (known as geranylacetone or dihydropseudoionone) and diapocarotenoid 4,9-dimethyldodeca-4,6,8-trienedial (Figure 9.22). One molecule of geranylacetone may arise from ζ-carotene.

The C-9/C-10 (or C-9′/C-10′) double bond cleavage in alicyclic carotenes and xanthophylls yields products with a structure derived from the hydrocarbon megastigmane (**9-195**). Common carotenes may produce eight C_{13} methylketones (**9-196**). For example, the cleavage of β,β-carotene (β-carotene), β,ε-carotene (α-carotene) and (*R*)-β,β-carotene-3-ol (β-cryptoxanthin) produces β-ionone, which is a fragrant component of raspberries, blueberries, passion fruit, apricot, carambola, cherry, mango, plums, black tea, tomatoes, carrots, bell peppers and tobacco. α-Carotene is a precursor of (*R*)-ionone, also known as (+)-α-ionone. This compound, with a fruity and floral aroma reminiscent of violets and raspberries, is a fragrant component of blackcurrants, blueberries, raspberries,



9-195, megastigmane

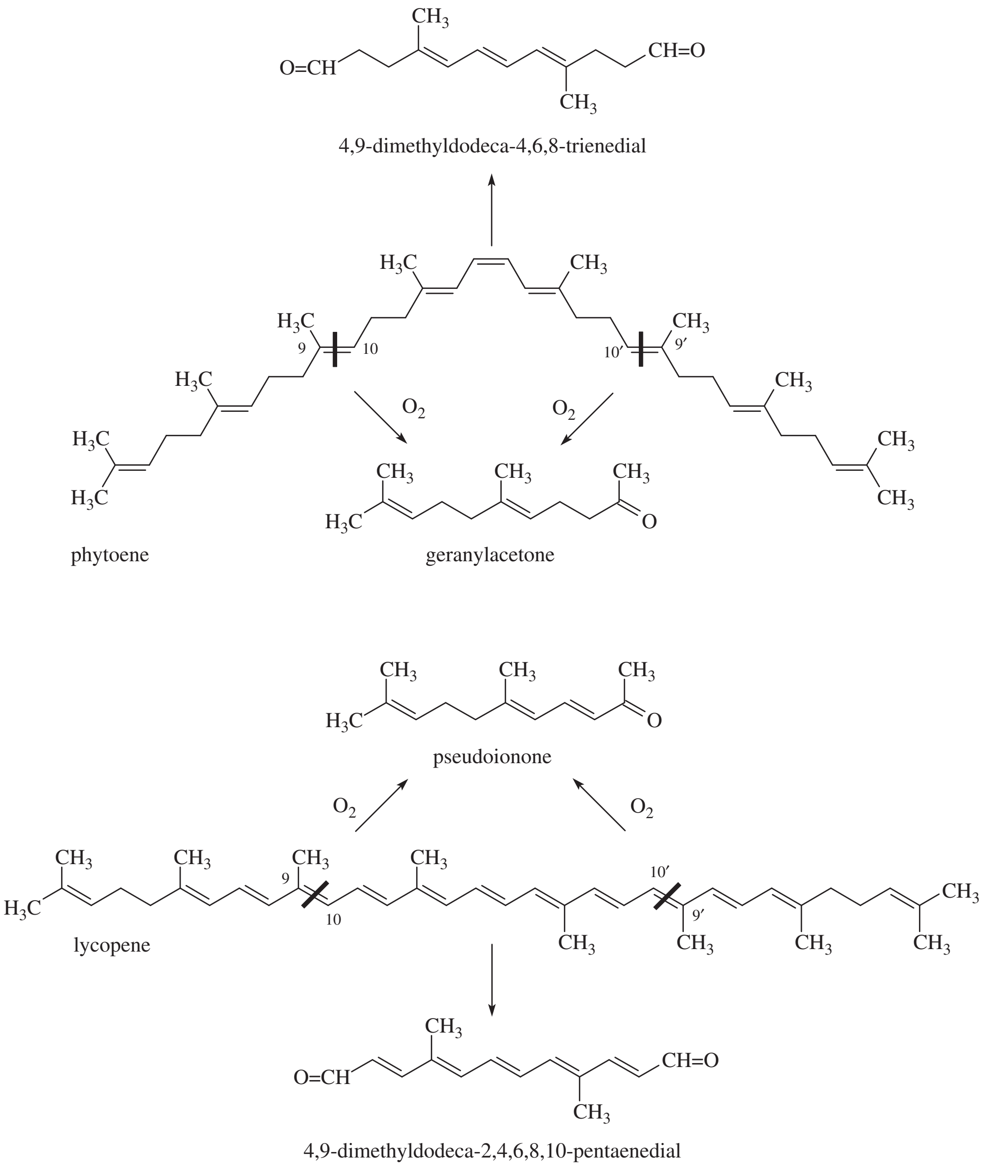


Figure 9.22 Fission of acyclic carotenes.

bananas, cherries, plums, peaches, vanilla, tomatoes, carrots, celery, black tea, tobacco and other products.

Hydroxy ionones and epoxy ionones arise by fission of various xanthophylls. For example, (*S*)-3-hydroxy-β-ionone arises from β-cryptoxanthin, (3*R*,3′*R*)-β,β-carotene-3,3′diol (zeaxanthin) and (3*R*, 3*R*′,6′*R*)-β,ε-carotene-3,3′diol (lutein). 5,6-Epoxy-β-ionone arises, for example, from (3*R*,5*S*,6*S*,3′*R*)-5,6-epoxy-5,6-dihydro-β,β-carotene-3,3′-diol (antheraxanthin) and (3*S*,5*R*,6*S*,3′*S*,5′*R*,6′*S*)-5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-caroten-3,3′-diol (violaxanthin). (3*R*,6*R*)-3-Hydroxy-α-ionone may arise from lutein, (3*S*,6*S*)-3-hydroxy-α-ionone from (3*S*,3′*S*,6*S*,6′*S*)-ε,ε-carotene-3,3′-diol (lactucaxanthin) and (3*S*,6*R*)-3-hydroxy-α-ionone from (3*R*,3*S*′,6′*R*)-β,ε-carotene-3,3′-diol (3′-epilutein).

The special ketone known as grasshopper ketone arises from (3*S*,5*R*,6*R*,3′*S*,5′*R*,6′*R*)-5′,6′-epoxy-6,7-didehydro-5,6,5′,6′-tetrahydro-β,β-carotene-3,5,3′-triol (neoxanthin). While maintaining the stereochemistry at carbon C-3, hydroxy ionones and grasshopper ketone can be glycosylated and become precursors of many other compounds. About 50 products formed by oxidation, reduction, dehydration and cyclisation have been identified; some of them being formed by more complex mechanisms. Some of these reactions are shown in Figure 9.23, which illustrates the conversion of (*S*)-3-hydroxy-β-ionone into 1,2-dihydro-1,1,6-trimethylnaphthalene. In small amounts, this compound is a fragrant component of peaches, strawberries, tomatoes and wine. It has a low threshold (20 μg/l in wine) and in older vintages of Riesling wines may be responsible for the kerosene-like smell, while in passion fruit juices it causes an off-flavour described as aroma flattening during pasteurisation.

Figure 9.24 illustrates the mechanism of transformation of (3*S*,6*R*)-3-hydroxy-α-ionone into several very important

odour-active compounds, 3-oxo-α-ionone and 3,4-dihydro-3-oxoedulanes (components of wine aroma), a decalin derivative (a component of passion fruit aroma) and megastigmatrienones considered essential fragrances of tobacco.

Several important C_{13} compounds are derived from epoxy apocarotenoids. These epoxides yield, by epoxy group protonation and C-4 deprotonation, C-6 alcohols (epoxy apocarotenoids with hydroxyl group in the side chain give rise to diols), which may be glycosylated and, for example, hydrolysed during fruit ripening to the corresponding alcohols. An example is oxidation of 5,6-epoxy-3-hydroxy-β-ionone to dehydrovomifoliol, which is reduced to blumenol A, from which arises blumenol B and subsequently the important fragrance compound theaspirone. Theaspirone occurs in passion fruit, black tea and tobacco (Figure 9.25).

Other spiroethers (8,9-dehydrotheaspirones) may arise analogously from 7,8-dehydrovomifoliol via 7,8-dihydrovomifoliol by reduction of two double bonds. 7,8-Dihydrovomifoliol is found in fruits and vegetables in the form of glycosides. The (*S*)-7,8-dehydrovomifoliol has a fruity and flowery odour, but the (*R*)-isomer has an odour resembling wood. Dehydrovomifoliol and blumenol A may also be formed by singlet oxygen oxidation of 3-oxo-β-ionone. Structurally similar theaspiranes are important odorous components of many fruits (strawberries, blackberries, grapes, passion fruit, guava and others) and black tea. (2*S*,5*S*)-Isomers (**9-197**) and (2*R*,5*R*)-isomers (**9-197**) have a slight smell resembling camphor, the (2*S*,5*R*)-isomer has the smell of camphor and naphthalene, but the (2*R*,5*S*)-isomer has a very attractive fruity odour reminiscent of blackcurrants. Thanks to the enantioselectivity of biochemical mechanisms, some chiral compounds

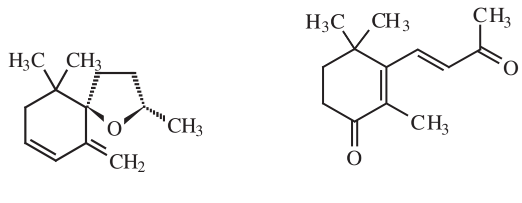
predominate in certain plant materials. For example, in green tea there is about 85% of (2*S*)-theaspiranes and about 15% of (2*R*)-theaspiranes. Related vitispirans (**9-198**) occurring in black tea and tobacco are important components of the aroma of grapes and wines. 4-Oxo-β-ionone (**9-199**) is formed by photooxidation of α-ionone.

The C_{13} damascones oxidised on carbon C-7 are very important fragrant compounds. β-Damascol, as a racemate, is an odorous component of papaya, black tea, rum and tobacco. It arises by oxidation of β-ionol with singlet oxygen (Figure 9.26) via β-damascone, which is reduced to β-damascol. α-Ionol may analogously be produced by oxidation of α-damascone. Its aroma resembles roses



9-198, (2*S*,5*R*)-vitispirane **9-199**, 4-oxo-β-ionone

and fruits. The precursor of related fragrant substance (*E*)-β-damascenone is grasshopper ketone formed by the cleavage of neoxanthin. Grasshopper ketone (Figure 9.27) is found in many fruits and vegetables (apricots, star fruit, grapes, kiwi, mango,

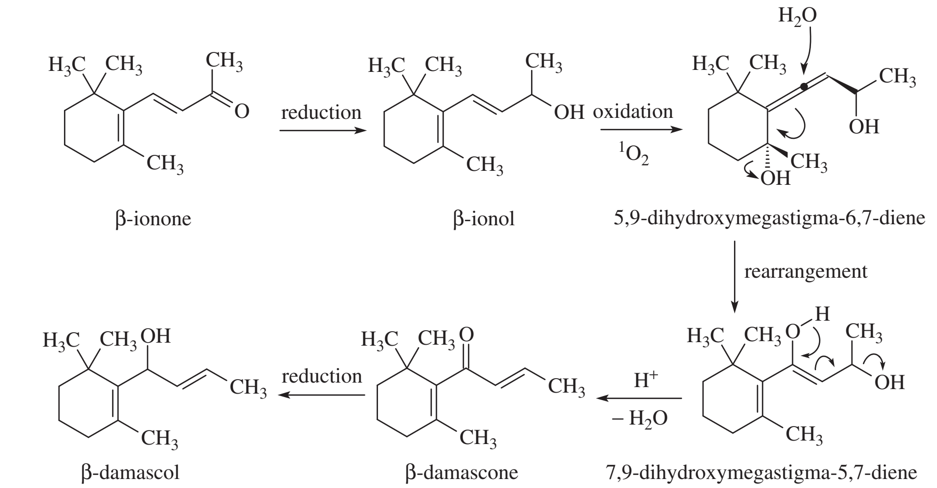


Figure 9.26 Formation of β-damascone and β-damascol from β-ionone.

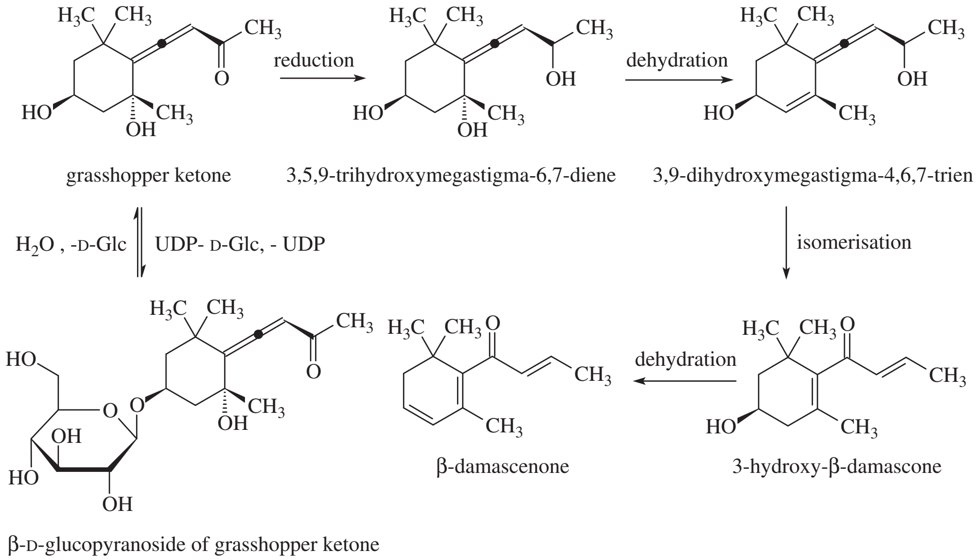

Figure 9.27 Formation of β-damascenone from grasshopper ketone.

apples, raspberries and tomatoes) and other foodstuffs (coffee, black tea, honey, beer, wine, rum and brandy). Hydroxylated damascones (such as grasshopper ketone and 3-hydroxy-β-damascenone) and other C_{13} alcohols are commonly found in plants as glycosides, the aglycones of which are released by enzymatic or acid hydrolysis. For example, glycosides present in grapes are hydrolysed during must production and wine fermentation.

9.9.5.2.2 Apocarotenoids C_{11}

An important compound of this group of apocarotenoids is the C_{11} apocarotenoid dihydroactindiolide presenting a cooling effect in the oral cavity. Dihydroactindiolide typically occurs as a constituent of tomato, black tea and tobacco odour. It is also a component of cassia oil, which is the oil of Chinese cinnamon called cassia (*Cinnamomum aromaticum*, syn. *C. cassia*, *Lauraceae*), and the wax obtained from sperm whale (see Section 3.4.1.3.1). Dihydroactindiolide is formed by oxidation of β-carotene, β-ionone and β-ionol with singlet oxygen (Figure 9.28).

9.9.5.2.3 Apokarotenoids C_{10}

Cleavage of carotenoids in the C-7/C-8 (C-7′/C-8′) double bond gives products, which are formally monoterpenoids. Cleavage of β-carotene yields 2,6,6-trimethylcyclohex-1-ene-1-carbaldehyde, which is known as β-cyclocitral (**9-200**). Citrocitral has been found in apricots, sugar melons *(Cucumis melo)*, watermelon (*Citrullus lanatus*, Cucurbitacaeae), tomatoes, bell peppers, peas, broccoli, black tea, rum and other materials. The best known aromatic substance of this group of apocarotenoids is safranal (4,5-dehydro-β-cyclocitral, **9-201**) with the smell and taste of saffron (see Section 9.9.2.3.2). Safranal arises by hydrolysis of a bitter tasting glycoside

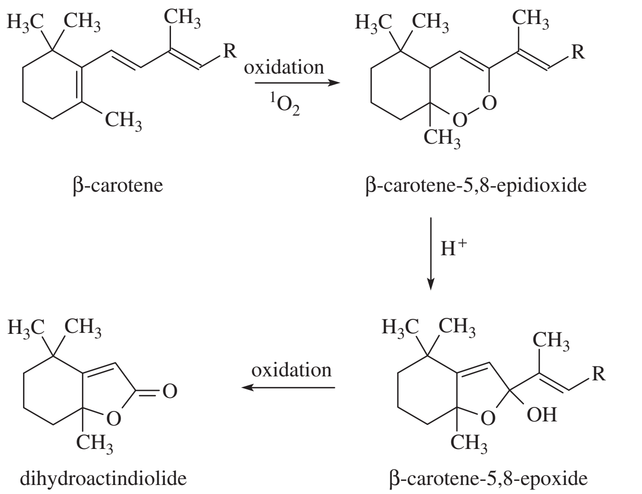

Figure 9.28 Formation of dihydroactindiolide from β-carotene.

picrocrocin and by dehydration of aglycone (*R*)-4-hydroxy-β-cyclocitral, respectively. Safranal is also a minor component of grapefruit juice, black tea and bell pepper aroma.

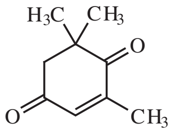
9-201, safranal

9.9.5.2.4 Apokarotenoids C_9 and C_8

The main formation pathway of C_9 apocarotenoids with cyclohexanone and cyclohexenone structures is conversion of hydroperoxides derived from β-damascol (Figure 9.29). Hydroperoxides generated by autoxidation of carotenoids are further oxidised, reduced and hydrated to form a variety of different structures. The most important compound of this apocarotenoid group is probably 2,6,6-trimethylcyclohex-2-en-1,4-dione (4-oxoisophorone, **9-202**), whose scent recalls dry straw. The starting compound is apparently (*R*)-3-hydroxy-β-damascol that is oxidised to (*R*)-4-hydroxy-2,6,6-trimethylcyclohex-2-en-1-one (**9-203**), oxidation of which yields 4-oxoisophorone. It occurs in black tea, saffron and tobacco. Acyclic carotene dehydrolycopene gives rise to methylketone (3*E*,5*E*)-6-methylhepta-3,5-dien-2-one (**9-204**), which is an aroma constituent of tomatoes.



9-202, 2,6,6-trimethylcyclohex-2-en-1,4-dione

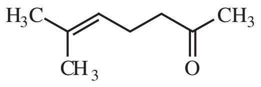
9-204, (3*E*,5*E*)-6-methylhepta-3,5-dien-2-one

An example of C_8 apocarotenoids occurring, for example, in tomatoes, is methylketone 6-methylhept-5-en-2-one (**9-205**), which is produced by C-5/C-6 (C-5′/C-6′) double bond cleavage of acyclic carotene lycopene. It may also arise from phytoene.



9-205, 6-methylhept-5-en-2-one

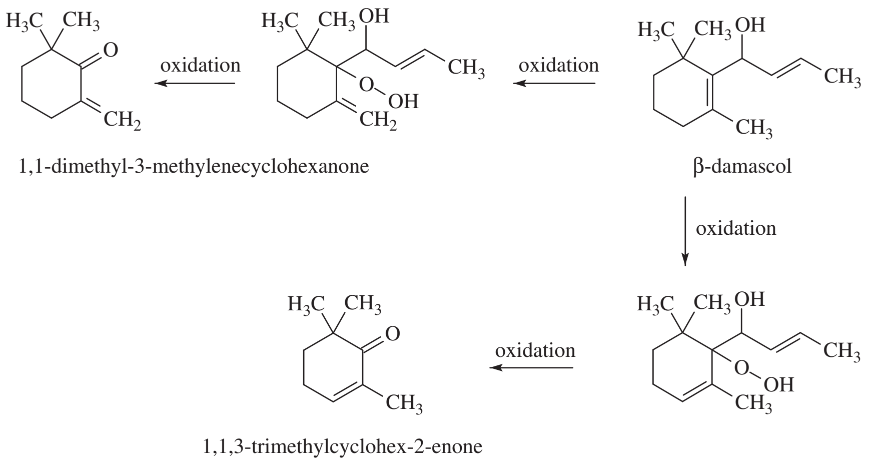


Figure 9.29 Formation of cyclohexanones and cyclohexenones.

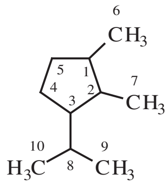
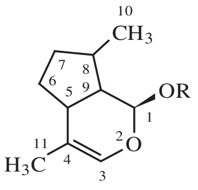
9.10 Iridoids

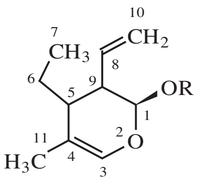
Iridoid monoterpenes called **iridoids** are a group derived from the skeleton of the hydrocarbon iridane (**9-206**). Their usual structure is represented by the formula **9-207.** The opening of a cyclopentane ring and introduction of various functional groups (mainly by oxidation) yields **secoiridoids** (**9-208**), which include many bitter substances of plants.



9-206, iridane



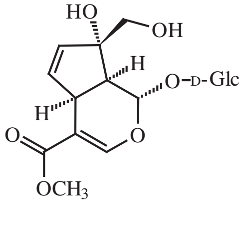
9-207, iridoids (basic structure)



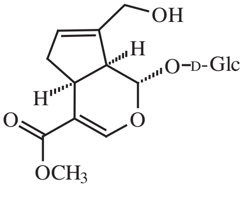
9-208, secoiridoids (basic structure)

Pigments derived from yellow to red fruits of common gardenia, also known as cape jasmine (*Gardenia augusta*, syn. *G. jasminoides*, Rubiaceae), an evergreen shrub growing in India, China and Japan, are iridoid pigments, important for their use as dyes in the textile industry and also for imparting colour to foods. Fruits located in pods contain three main groups of yellow and orange pigments: iridoid pigments, apocarotenoids (crocin and crocetin such as saffron) and flavonoids. Interest in the gardenia pigment was initiated in Japan through the pursuit of substitution of annatto and saffron pigments with cheaper pigments in cases where the specific flavour of the original materials was not required.

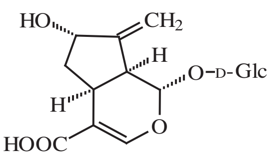
The main iridoid pigments of gardenia are the glucosides gardenoside (**9-209**), geniposide (**9-210**) and related compounds gardoside (**9-211**) and shanzhiside (**9-212**). They are accompanied by a number of related minor pigments (**9-213**). Their biosynthesis is based on geranyl diphosphate, and proceeds via (1*R*,2*S*,5*R*,8*S*)-iridodial (8-epiiridodial) and other intermediates.



9-209, gardenoside



9-210, geniposide



9-211, gardoside

acetylgeniposide, $R = COCH_3$, $R^1 = H$, glycosyl = β-D-glucosyl
genipin gentiobioside, $R = H$, $R^1 = CH_3$, glycosyl = β-gentiobiosyl

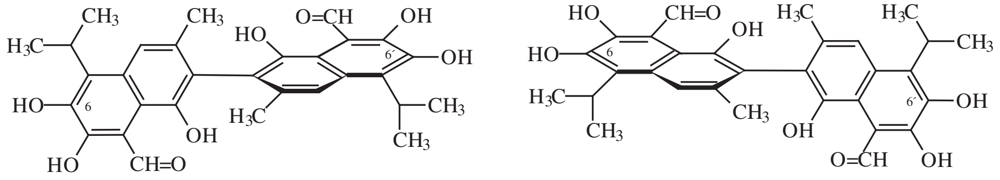
Preparation of pigments is based on their extraction with water, enzymatic hydrolysis of glycosides and reaction of aglycones with amines. By adjusting the process conditions (temperature, pH, oxygen concentration, type of reacting amino compounds and presence of metal ions) a number of pigments can be obtained whose colour is yellow-to-green, red, purple or blue, which is a combination of colours of the pigments produced. Gardenia pigments can be used to impart colour to ice creams, confectionery, pasta products and other foods.

9.11 Other terpenoid pigments

The toxic yellow pigment gossypol, 2,2′-bis(8-formyl-1,6,7-trihydroxy-5-isopropyl-3-methyl)naphthalene, resembles phenolic pigments, but its biosynthetic precursor is a sesquiterpene hydrocarbon (+)-δ-cadinene, with the chemical name (1*S*,8a*R*)-1-isopropyl-4,7-dimethyl-1,2,3,5,6,8a-hexahydronaphthalene (**8-8**). In a sequence of oxidation reactions, δ-cadinene is transformed into the gossypol intermediate 4-formyl-1-isopropyl-2,3,5,7-tetrahydroxynaphthalene, which is known as hemigossypol. Further one-electron oxidation of hemigossypol gives rise to a C-5 radical, the resonance form (C-6) of which dimerises to gossypol.

Gossypol occurs in buds and seeds of upland (Mexican) cotton (*Gossypium hirsutum*, Malvaceae) and in other *Gossypium* species (such as *G. herbaceum*). Cotton seeds usually contain 0.6–1.5% of gossypol localised in special pigment cells. Gossypol occurs in two enantiomers, as (+)-gossypol and (−)-gossypol (**9-214**), which are in the ratio of 3 : 2. Currently used cultivated cotton varieties lack these pigment cells and have a low content of gossypol. In some varieties of cotton, 6-methoxygossypol and 6,6′-dimethoxygossypol (**9-214**) are found as minor products. During cottonseed oil extraction, gossypol passes from the seeds to the oil and is present in flour, used in some countries for human nutrition, and in meal, used as feed for poultry and livestock.

Gossypol is a very reactive compound (Figure 9.30) forming salts with metal cations, which involves hydroxyl groups at C-1 and



(+)-gossypol (–)-gossypol

9-214, gossypol

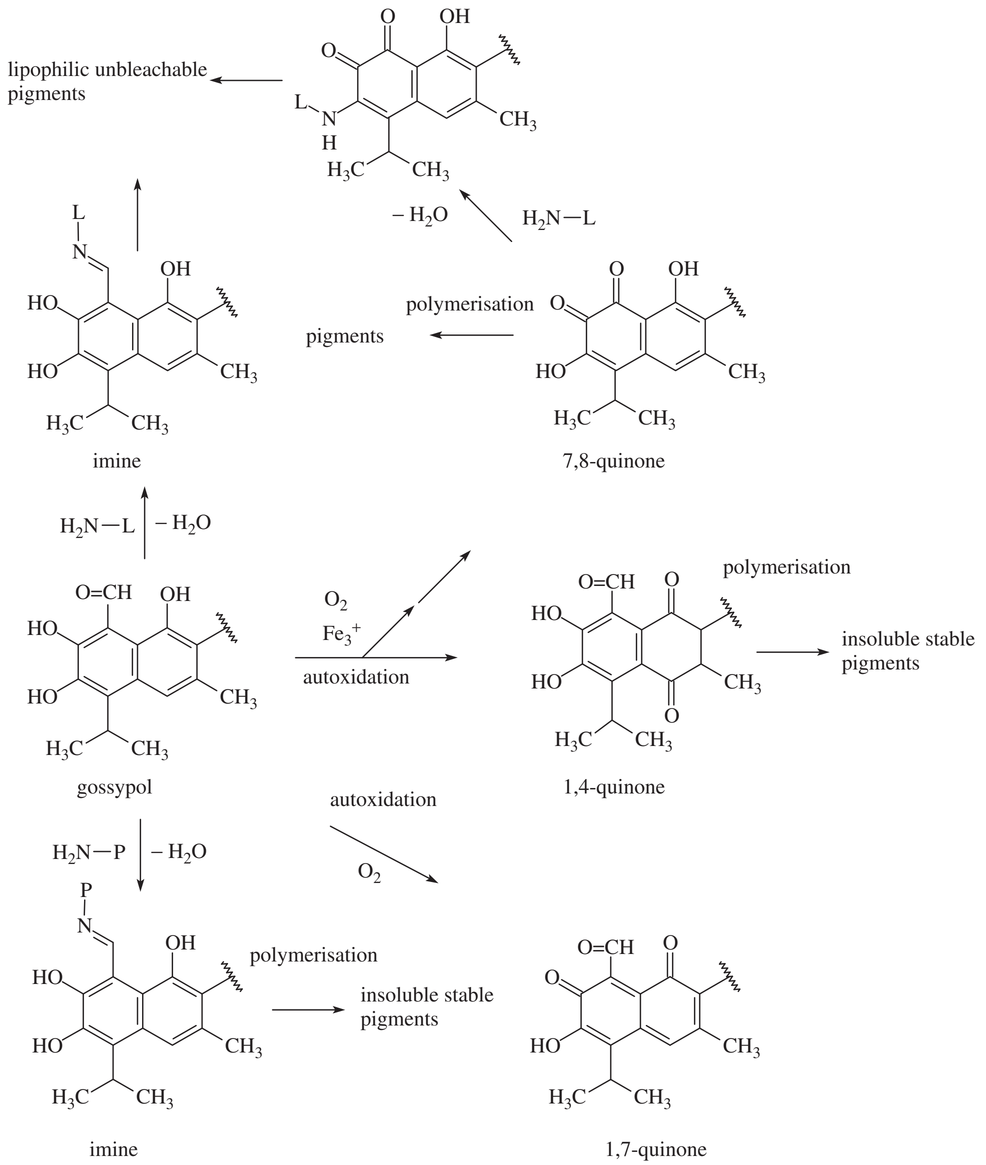


Figure 9.30 Reactions of gossypol (H_2N–P = protein with bound lysine, H_2N–L = phospholipid with bound ethanolamine).

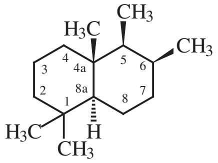
C-1′. By oxidation with oxygen or with ferric ions, the corresponding *o*- and *p*-naphthoquinones arise, which mutually polymerise and react with proteins and phospholipids with the formation of dark pigments. In scavenging free radicals, gossypol shows greater activity than both methylated derivatives.

The reaction of gossypol with proteins has been used to detoxify cottonseed oil. Gossypol in milled seeds reacts with seed globulins to form hydrophilic and hydrophobic pigments. The detoxifying effect is increased by seed steaming with the addition of ferrous sulfate, which catalyses decarbonylation of gossypol to

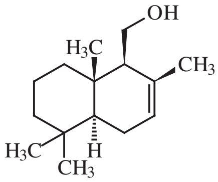
apogossypol, which is not stable and is less toxic than gossypol. Thus detoxified material contains 0.6–0.9% bound gossypol and 0.01–0.02% free gossypol. Small quantities of gossypol in oil react (either directly or after oxidation to quinone) with amino groups of phospholipids to form imines, which polymerise to fat-soluble macromolecular dark pigments, which cannot be effectively removed during subsequent refining.

Only (−)-gossypol is toxic, and only for omnivores. Chronic intoxication caused by low, long-term income is reflected in reduced appetite, liver damage and reduced blood clotting, and a reversible sterility in males at a dose of about 10 mg per day. In addition to these effects, gossypol has some activity as an anti-malarial drug and is studied for its anticarcinogenic properties.

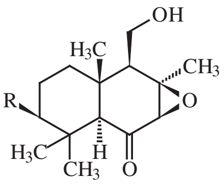
The colours of some higher fungi of the genus *Lactarius*, collectively known as milk caps, and of the closely related genus *Russula* (Russulaceae), are based on sesquiterpenoid pigments. The colour of the injured flesh as well as of the latex of several mushroom species of the genus *Lactarius* owe their colour changes to sesquiterpenoids. An example is *L. uvidus*, which has white latex which rapidly turns violet on exposure to the air. The compounds responsible for this colour change are mostly derivatives of sesquiterpene hydrocarbon drimane, (4a*R*,5*S*,6*S*,8a*S*)-1,1,4a,5,6-pentamethyltetrahydronaphthalene (**9-215**), such as drimenol (**9-216**), uvidin A and uvidin B (**9-217**) and their transformation products, respectively.



9-215, drimane



9-216, drimenol



9-217, uvidin A, R = H
uvidin B, R = OH

Blue pigments containing seven-membered rings are derived from sesquiterpene bicyclo[5.3.0]deca-1,3,4,6,8-pentaene, known as azulene (**9-218**). Azulene also gives the characteristic blue colour to chamomile oil (*Matricaria chamomilla*, Asteraceae). The pigments vetivazulene (4,8-dimethyl-2-isopropylazulene) and guaiazulene (1,4-dimethyl-7-isopropylazulene) are found in nature in mushrooms and some marine invertebrates. For example, the young fruiting body of *L. deliciosus* is first carrot-coloured, but slowly turns green on aging. The compounds responsible for these colour changes are the blue pigments 1,4-dimethyl-7-(1-methylethenyl)azulene, known as lactarazulene, and lipophilic red–violet 4-methyl-7-(1-methylethenyl)azulene-1-carbaldehyde, called lactaroviolin (**9-219**). However, neither lactarazulene nor lactaroviolin occur as such. The orange colour of the fungus is due to the labile and easily oxidisable dihydroazulen-1-ol (**9-220**, R = H) or to 1-hydroxymethyl-4-methyl-7-(1-methylethenyl)azulene stearate, R = $CO[CH_2]_{16}CH_3$. This lipophilic pigment is also responsible for the brilliant blue colour of the indigo milk cap (*L. indigo*) native to America and Asia, which has also been reported from southern France.

9.12 Enzymatic browning reactions

Enzymatic browning reactions, which have been known for almost 100 years, are complex enzyme catalysed reactions involving the oxidation of phenolic compounds by some oxidoreductases in the presence of air oxygen. Oxidation products are quinones that are transformed by subsequent enzymatic and spontaneous (non-enzymatic) reactions into various coloured pigments. Quinones and other reaction products in plants have microbistatic effects and are able to prevent the spread of microbial and viral infections. Polymeric insoluble reaction products are an effective mechanical barrier against further erosion at the injury site of a plant.

In foods of plant and animal origin, the enzymatic browning reactions occur in damaged cells. The reaction is manifested by the formation of brown discoloration, carriers of which are melanin-type pigments. Enzymatic browning reactions in foods are usually adverse reactions in cases where they lead to browning and discoloration in food during processing and storage (browning of apples, potatoes or mushrooms). Adverse enzymatic browning reactions also occur in the processing of some seafood (e.g. shrimp and crabs). In some cases (such as in fermentation of tea, cocoa beans, ripening dates, production of black olives, raisins, sherry-type wines and aging of red wines), these reactions are to some extent desirable, because they lead to the formation of the characteristic colour and flavour of the product. Similarly to enzymatic browning reaction, autoxidation of phenolic compounds and their oxidation with oxidising agents, such as hydrogen peroxide also proceeds.

9.12.1 Enzymes

Enzymes from the class of oxidoreductases catalysing enzymatic browning reactions are most often known trivially as polyphenol oxidases. Two groups of enzymes can be identified:

- **catechol oxidases**
- **laccases**.

Catechol oxidases, formerly known as monophenols oxidases, catalyse two different reactions (Figure 9.31). The first reaction is oxidation (hydroxylation) of monophenols to *o*-diphenols (1,2-dihydroxybenzenes), which relates to the enzyme activity known as cresolase activity. These enzymes are now called monophenols oxygenases (an example is tyrosinase, which produces dopa from tyrosine). The second reaction catalysed by catechol oxidases is oxidation of *o*-diphenols to *o*-quinones (benzo-1,2-quinones also called 1,2-dioxobenzenes), which concerns the enzyme activity known as catecholase activity. Enzymes showing this activity were previously called diphenol oxidases or *o*-diphenolases and now are known under the systematic name *o*-diphenol:O_2 oxidoreductases. Some catechol oxidases lack this type of activity, but if they have this activity, then the ratio of creasolase and catecholase activities is usually 1 : 10 to 1 : 40. Laccases oxidise not only *o*-diphenols to *o*-quinones, but also *p*-diphenols to *p*-quinones (benzo-1,4-quinones also called 1,4-dioxobenzenes) (Figure 9.31). Other enzymes that are able to oxidise phenols to quinones are peroxidases. Their direct participation in enzymatic browning reactions is not yet fully understood.

Polyphenol oxidases are widespread in most plant species. They occur mainly in plastids of plant cells. For example, polyphenol oxidases in apples are located in chloroplasts and mitochondria, usually tightly bound to the membrane. The cytoplasm contains soluble polyphenoloxidases, whose activity increases with maturation.

The activities of polyphenol oxidases in plant tissues increase with mechanical injury. The activity depends mainly on the type, variety and age of plant material (e.g. unripe fruits turn brown faster), cultivation conditions and method of processing. The optimal pH for the enzyme activity is pH 4.5–5.5, but the enzymes are active even in more acidic media. For example, they show approximately 40% of optimal activity at pH 3. The highest activity of polyphenol oxidases is in the outer layers of fruits, especially in the skin. In animals, the enzyme tyrosinase is located mainly in the skin, hair and eyes.

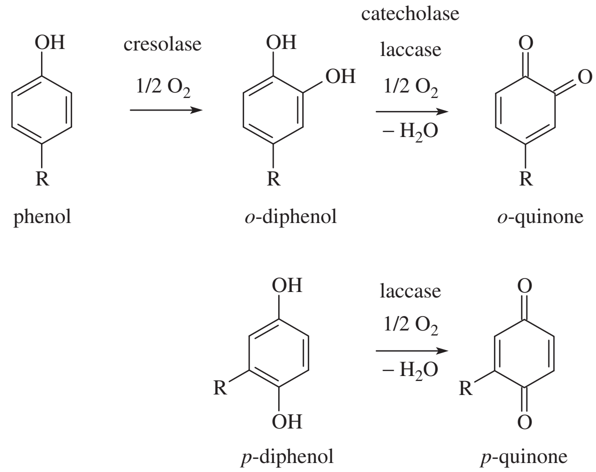

Figure 9.31 Reactions catalysed by polyphenol oxidases with creasolase, catecholase and laccase activities.

9.12.2 Substrates

The tendency of plant material towards browning varies within plant species, but the enzyme activity also depends on the type and amount of substrates available. The substrates of polyphenol oxidases may be a large number of different phenolic compounds, but usually only a few are of practical importance (Table 9.16). The individual compounds are given in the section dealing with sensorially active substances.

Phenolic compounds are present separately from the substrates, predominantly located in the cell vacuoles. Particularly prominent substrates are caffeic acid and its esters, as well as some flavonoid substances, of which monomeric flavan-3-ols (catechins) are the most important. Other groups of phenolic compounds, such as condensed forms of flavan-3-ols and flavan-3,4-diols (tannins), flavonols, flavones, flavans, chalcones, dihydrochalcones and anthocyanins, are only partly oxidised. One of the reasons for this is probably the steric hindrance caused by the corresponding glycosides and substrate specificity of polyphenol oxidases. The content of phenolic compounds depends on genetic factors (on plant species and varieties), the degree of maturity and external (environmental) factors (light, temperature, nutrients, use of pesticides and so on). The only substrate in animal tissues is the amino acid tyrosine.

9.12.2.1 Apples

The main substrates of polyphenol oxidases in apples are hydroxycinnamic acid derivatives, especially caffeic acid depsides, such as chlorogenic acid, and some groups of flavonoid compounds, such as flavan-3-ols, flavonols, dihydrochalcones and (in red-skinned apple varieties) also anthocyanins. In the flesh of apples, the main phenolics are chlorogenic (3-caffeoylquinic) acid, flavan-3-ol epicatechin, and procyanidin B_2 representing condensed tannins. These three compounds represent more than 90% of the phenolic compounds present. The main substrates in apple peel are flavan-3-ols and flavonols (quercetin glycosides) and to a lesser extent derivatives of hydroxycinnamic acids are present (chlorogenic acid and some other depsides).

The concentration of phenolic compounds is highest in young fruit and decreases rapidly with its development. After harvesting, the total content of phenolic compounds is roughly constant or slightly lower. The total content of phenolic compounds in ripe apples ranges between 0.5 and 11 g/kg in the flesh and between 8.7 and 19.2 g/kg in the skin. The phenolic compounds concentration in apple juice is around 1.5 g/kg.

Table 9.16 Important substrates of polyphenol oxidases in food materials.

Food	Substrate	Food	Substrate
Fruits		***Vegetables and potatoes***	
Apples	Chlorogenic acid, catechins, tannins	Lettuce	Tyrosine
Pears	Chlorogenic acid	Beans (green)	3,4-Dihydroxyphenylalanine (dopa)
Grapes	Catechins	Onion	Protocatechuic acid
Peches	Catechins	Potatoes	Tyrosine, chlorogenic acid, catechins
Olives	3,4-Dihydroxyphenylethanoland its derivatives	***Others***	
Bananasy	3,4-Dihydroxyphenylethylamine,	Mushrooms	Tyrosine, pulvinic acids and other phenols
Dates	Dactyliferic acid	Tea leaves	Catechins
Mango	Gallic acid, gallotannines	Coffee beans	Chlorogenic and caffeic acids
Avocado	Phenolic acids	Cocoa beans	Catechins

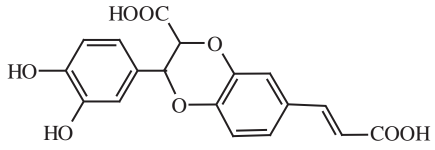
9.12.2.2 Potatoes

Common phenolics of potatoes are caffeic acid, its depsides (chlorogenic acid and its isomers), flavonol rutin and hydroxycinnamic acids and their conjugates. The content of phenolic compounds varies over a wide range depending on several factors, for example, variety. Chlorogenic acid and its isomers have been found in potato tubers in a range of from 0.3 to 13.7 g/kg dry weight, and rutin of from 0 to 190 mg/kg dry weight.

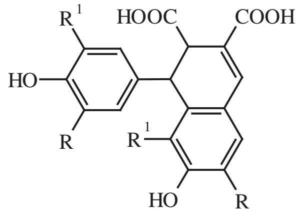
9.12.3 Non-enzymatic oxidation

In a neutral and alkaline medium, phenols spontaneously oxidise under the action of air oxygen, forming products of higher molecular weights. Some of these reactions are shown by the example of gallic acid in Figure 9.32. The main reaction product is hexahydroxybiphenylic acid, which is a biochemical precursor of ellagic acid. Hexahydroxybiphenylic acid and partly gallic acid also produce acyclic oxidation products.

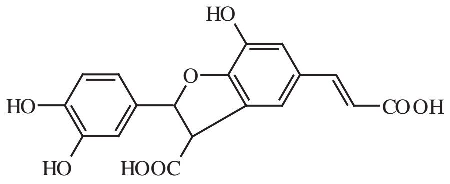
A large number of autoxidation products are similarly produced from cinnamic acids. The structures of certain dimers produced by autoxidation of caffeic acid in alkaline media at elevated temperatures are given in formulae **9-221**, **9-222** (R = OH, R^1 = H) and **9-223**. These dimers are lignans, trivially called **caffearins**. Products of similar structures arise from other cinnamic acids, for example the autoxidation product of sinapic acid is thomasidioic acid (**9-222**, R = R^1 = OCH_3). In neutral media of pH 7, thomasidioic acid is produced from about 30% of the initially present sinapic acid. In alkaline media of pH 8.5, virtually all sinapic acid is transformed into thomasidioic acid.



9-221, dimer of dioxolane type



9-222, dimer of cyclohexene type



9-223, dimer of furan type

Phenols can also be oxidised to the corresponding *o*-diphenols and *o*-quinones by hydrogen peroxide, which arises, for example, as a product of ascorbic acid oxidation, autoxidation of *o*-diphenols or autoxidation of cuprous ions in an acidic solution:

$$O_2 + 2Cu^+ + 2H^+ \rightarrow 2H_2O_2 + 2Cu^{2+}$$

In acidic fruit juices, hydrogen peroxide preferably oxidises other substances (e.g. in wine it oxidises ethanol to acetaldehyde and in strawberries it oxidises anthocyanins). Diphenols are relatively

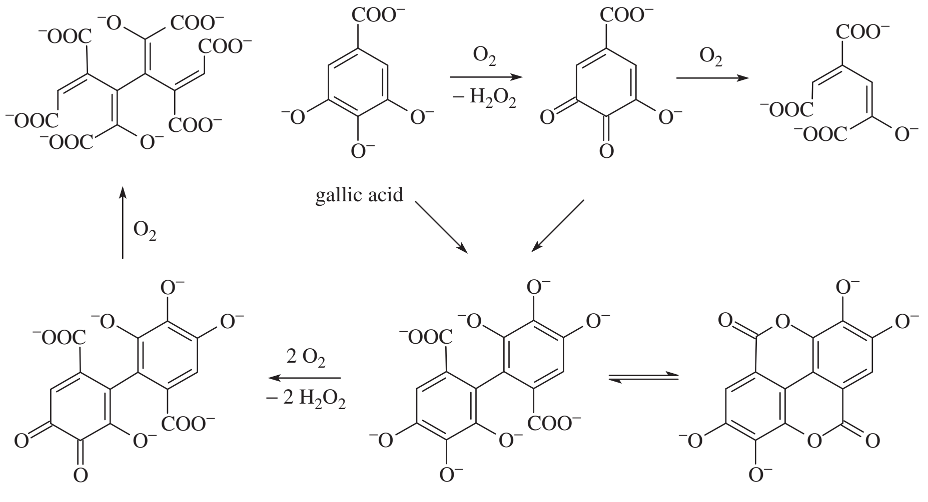


Figure 9.32 Gallic acid autoxidation in alkaline solutions.

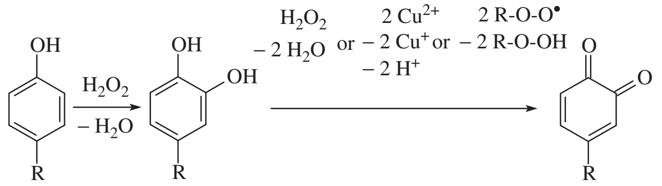

Figure 9.33 Non-enzymatic oxidation of phenols to *o*-diphenols and *o*-quinones.

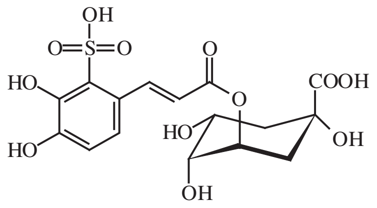
easily oxidised to the corresponding quinones by oxygen, metal ions (such as copper ions) or hydroperoxyl radicals (Figure 9.33), which arise in rancid fats.

9.12.4 Subsequent reactions

Quinones themselves are coloured compounds. Simple quinones are usually red when they contain an *o*-quinoid structure (such as *o*-benzoquinone) in the molecule, while compounds with the *p*-chinoid arrangement are yellow (e.g. *p*-benzoquinone). The catechin oxidation product is bright yellow, quinone formed of chlorogenic acid has a yellow–orange colour and quinone derived from amino acid dopa (dopaquinone) is pink.

o-Quinones formed by oxidation of phenolic compounds are highly reactive compounds. In food materials, they react with a variety of nucleophilic reagents to form adducts with the regenerated structure of the original diphenol, which have a lower redox potential than the original diphenol. These adducts are easily oxidised to the corresponding substituted *o*-quinones (Figure 9.34). The reactivity of *o*-quinones depends on the structure of the starting phenol, and is determined by the redox potential of reacting compounds. For example, *o*-quinones resulting from oxidation of chlorogenic acid may oxidise catechins to *o*-quinones and chlorogenic acid is regenerated, but the opposite reaction is not possible. Reactivity also depends on pH, temperature and the presence of other compounds. Reaction with water yields derivatives of 1,2,4-trihydroxybenzene as intermediates, which on oxidation produce hydroxy derivatives of *o*-quinones and *p*-quinones. Reactions of this type with tyrosine residues in the molecules of oxidoreductases lead to the inactivation of enzymes.

In materials containing ascorbic acid (abbreviated as H_2A), *o*-quinones are reduced to the original 1,2-diphenols of lighter colour and ascorbic acid is oxidised to dehydroascorbic acid (abbreviated A). This reaction can be monitored at home by the addition of lemon juice to tea, which results in a lighter tea colour. Quinones can be also reduced by hydrogen sulfites (bisulfites) or sulfites with the formation of the corresponding colourless 2′-sulfo derivatives (2′-sulfonic acids). The addition of hydrogen sulfites or sulfites to peeled potatoes is employed, for example, to prevent potato browning. The main 2′-sulfo derivatives identified in hydrogen sulfite-treated potatoes were derived from 5-*O*-caffeoyl-L-quinic acid (neochlorogenic acid, **9-224**) and 4-*O*-caffeoyl-L-quinic acid (cryptochlorogenic acid). The reaction with hydrogen sulfite includes the caffeic acid quinone produced by oxidation with polyphenol oxidase. The reaction is analogous to the reaction of quinones with amino acids (Figure 2.70). It proceeds via the nucleophilic attack of hydrogen sulfite anions to the C-2′ of quinones derived from chlorogenic acids, which yields 4′-anions of chlorogenic acids as intermediates. Other caffeoyl derivatives and derivatives of quercetin glycosides are produced as minor sulfo-adducts. Feruloyl and sinapoyl derivatives do not form



9-224, 2′-sulfo-5-*O*-caffeoyl-L-quinic acid

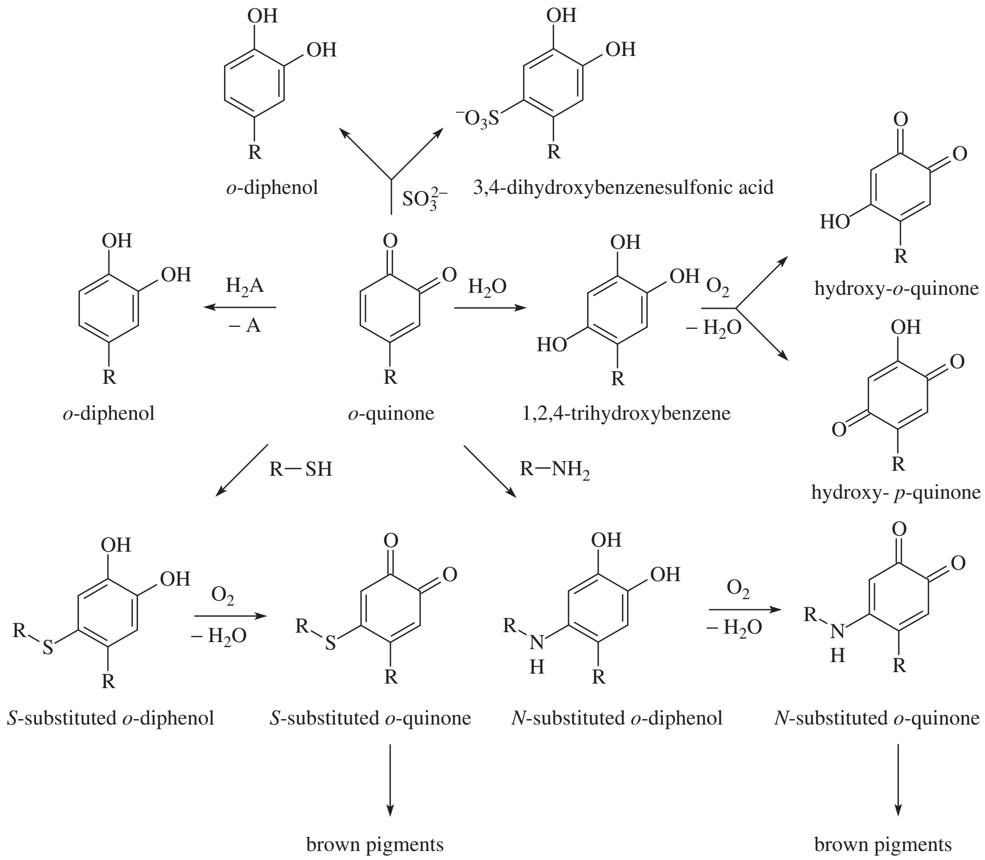


Figure 9.34 Reaction of quinones with food components.

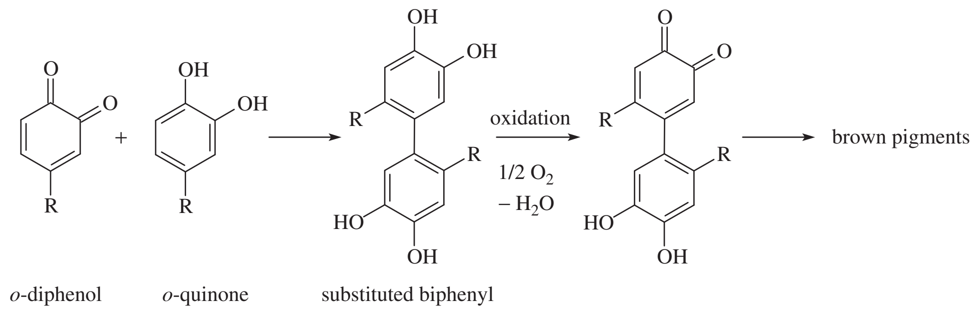

Figure 9.35 Condensation of quinones with *o*-diphenols.

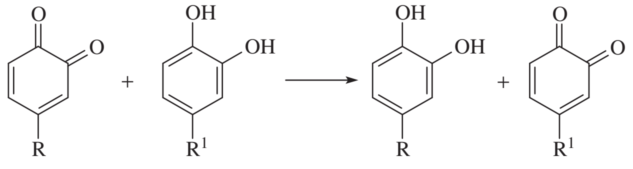
adducts with hydrogen sulfites. Reactions leading to brown pigments are based on condensation of *o*-quinones with the original *o*-diphenols to dimeric products. A similar reaction also occurs, for example, in the formation of astringent tannins and pigments during red wine maturation. Dimers of phenolic compounds with the structure of *o*-diphenols are further oxidised by the action of polyphenol oxidases or by other quinones, and oxidation products condense again with phenols to give brown coloured higher oligomers and polymers (Figure 9.35). Quinones can even react with such *o*-diphenols, which are not otherwise oxidised to *o*-quinones. This reaction regenerates the original phenol, from which quinone was derived (Figure 9.36). Seven-membered tropone derivatives can also arise as reaction products. Their formation is analogous to the



Obrázek 9.36 Reaction of *o*-quinones with *o*-diphenols

Figure 9.36 Reaction of *o*-quinones with *o*-diphenols.

formation of theaflavin, which is produced during fermentation of green tea leaves.

Important reactions leading to the formation of brown polymeric pigments are reactions of quinones with thiol and amino groups

of proteins, which are described in detail in Section 2.5.2.5. In the presence of certain amino acids, quinones may yield stable low molecular weight coloured products and then the browning reaction cannot proceed. Some plant materials, such as apples, sweet potatoes (*Ipomoea batatas*, Convolvulaceae) and other raw materials, especially when treated with alkaline agents, such as baking powder, turn green during culinary processing. Greening can also be seen during extraction of sunflower meal protein with alkaline reagents. Greening cause caffeic acid esters, particularly chlorogenic acid, to be oxidised to the corresponding *o*-quinones that reacts with the primary amino group of amino acids or with primary amines. The mechanism of this green pigment formation is shown in Figure 9.37. The immediate precursor of the green pigment is yellow substituted trihydroxyacridine, the oxidation of which yields the green pigment. Reduction of the green pigment (e.g. with ascorbic acid) temporarily yields the yellow pigment. Oxidation of the green pigment in an alkaline solution produces a blue pigment. Amino acids with additional functional groups, such as serine and threonine, as well as proline and cysteine, do not form the green pigment.

9.12.4.1 Tea

The common commercial types of tea prepared from the leaves and buds of *Camellia sinensis* (Theaceae) are green tea, oolong tea and black tea (usually called red tea in China). The processing methods of the leaves are similar, except for the manner of fermentation and firing. The fermentation level increases from unfermented green tea to partially fermented oolong tea to well-fermented black tea. Firing involves heating at high temperature by means of a hot plate, hot air or flame after drying, and some species of green tea and oolong tea leaves are subjected to strong firing at >160 °C to enhance stability, taste and flavour.

Tea is one of the richest sources of flavonoids and phenolic acids. Green tea flavonoids are mainly catechins (flavan-3-ols) and their gallates, which constitute 80–90% of the phenolic compounds of leaves and 25–35% of their dry weight. The main catechins are epigallocatechin-3-*O*-gallate (7–13%), epigallocatechin (3–6%), epicatechin-3-*O*-gallate (3–6%), epicatechin (1–3%) and catechin (1–3% dry matter). Green tea also contains epicatechin and catechin oligomers, epicatechin-(4β→8)-epicatechin (procyanidin B_2), and catechin-(4α→8)-catechin (proanthocyanidin B_3) are also present, but their amount is lower than that of catechins. Important polyphenols are gallic acid and depsides of gallic acid with quinic acid, such as 1-*O*-galloylquinic acid (theogallin), 3-*O*-galloylquinic acid, 4-*O*-galloylquinic acid and 5-*O*-galloylquinic acid, and various di-*O*-galloyl, tri-*O*-galloyl, *O*-(digalloyl), *O*-galloyl-*O*-(digalloyl) and other depsides.

During fermentation of tea leaves, oxidoreductases oxidise catechins of green tea in enzymatic browning reactions, which leads to the formation of *o*-quinones that condense with catechins, forming

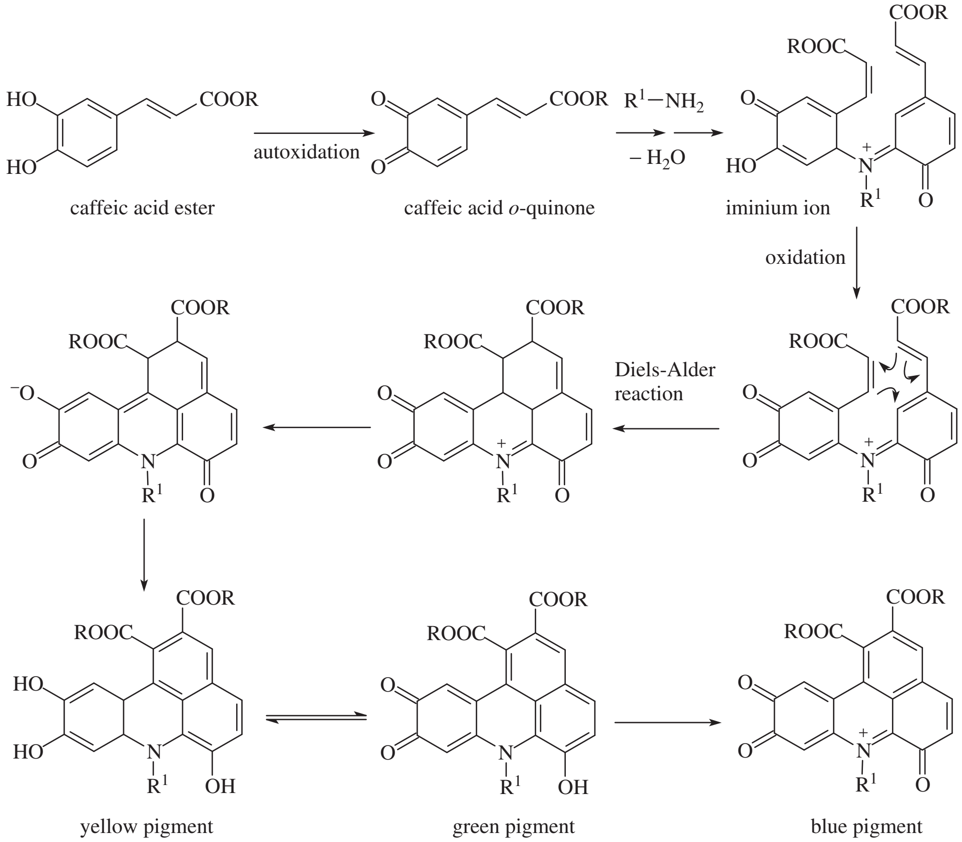


Figure 9.37 Formation of pigments from chlorogenic acid and amino acids.

the coloured oolong or black tea pigments. Owing to differences in manufacturing, the types of polyphenols in green tea, oolong tea and black tea are very different. Traditionally two main groups of black tea pigments (collectively known as oxytheotannins) are recognised:

- **theaflavins**, soluble dimeric flavonoids of bright orange to red colour (about 10% of dry matter) containing a seven-membered tropone ring;

- **thearubigins**, very heterogeneous mixtures of red and yellow to orange–brown soluble to insoluble products of oxidation and polymerisation of catechins and gallates of unknown structure, having a relative molecular weight of 700–400 000 Da (about 23% of solids), low molecular weight compounds exhibit an astringent taste.

Apart from these two more or less defined groups of pigments, a number of other products of enzymatic reactions have also been identified in tea. Examples of these products are isotheaflavins, neotheaflavins, red epitheaflavic acid and its gallate, oxidation product of epigallocatechin-3-gallate called theasinensin A, colourless dimeric bisflavanols and dehydrotheasinensins, yellow theacitrins, polymeric brown theafulvins of not yet fully known structure and other products. About 20% of tea leaf flavonoids are transformed into insoluble compounds during fermentation. These are covalently bound to proteins via thiol groups and remain in the remnants of tea leaves in the preparation of brine. The dark colour of tea is also significantly influenced by phaeophytins arising from chlorophylls during fermentation.

The structure of theaflavin, which is derived from epicatechin and epigallocatechin, is given in formula **9-225** as an example ($R^1 = R^2 = H$). Analogously, theaflavin-3-*O*-gallate ($R^1 = H$, $R^2 =$ galloyl) is produced from epicatechin and epigallocatechin-3-*O*-gallate, theaflavin-3′-*O*-gallate ($R^1 =$ galloyl, $R^2 = H$) from epicatechin-3-*O*-gallate and epigallocatechin and theaflavin-3,3′-*O*-digallate from epicatechin-3-*O*-gallate and epigallocatechin-3-*O*-gallate. The structure of epitheaflavic acid (R = H) derived from theaflavin is illustrated in formula **9-226**. Examples of products arising from epigallocatechin-3-*O*-gallate include 3-*O*-galloylepitheaflavic acid (**9-226**, R = galloyl), bisflavanols exemplified by bisflavanol A (**9-227**, $R^1 = R^2 =$ galloyl), theasinensin A (**9-228**), dehydrotheasinensins exemplified by dehydrotheasinensin A (**9-229**, R = galloyl) and theacitrins exemplified by theacitrin A (**9-230**, $R^1 = R^2 =$ galloyl).

9.12.5 Inhibition

The enzymatic browning reaction is an important technological problem, especially in the case of subsequent cold or freezing storage. Therefore, in addition to the reaction mechanisms, considerable attention is paid to its possible prevention. Prevention should begin early by selection of materials suitable for the given method of processing.

Fruits and vegetables with white flesh are prone to enzymatic browning, especially apples and pears, but also apricots, peaches, plums, potatoes and other materials. In most berries (raspberries, black- and redcurrants and blueberries) the enzymatic browning process has practically no impact due to the high content of natural pigments. The tendency to browning is due to activity of polyphenol oxidase and to the content and composition of phenols. Generally, it is possible to use the total content of phenols, tyrosine content or activity of polyphenol oxidase as criteria for selecting varieties for a particular type of treatment. One promising route may be breeding varieties with a lower tendency to enzymatic browning, or the use of gene manipulation. The technological inhibitory interventions can be divided into:

- physical methods
- chemical methods.

9.12.5.1 *Physical methods*

This group of methods includes gentle material handling before and during the process, where the intensity of browning, in this case induced by mechanical means, may be influenced by the style of some technological operations, such as clean cutting of the fruit.

The most important physical method of polyphenol oxidase inhibition is exposure of the material to higher temperatures. Polyphenol oxidases are inhibited by temperatures above 70 °C, are most stable in media of pH around 6.0, and in both directions from this value their resistance against heating decreases quite sharply.[5] Blanching, consisting in a rapid immersion of the material in hot water (salt or sugar solution) or exposure to water vapour, is used in the processing of vegetables that are eaten cooked and possibly also for the treatment of fruit pickles. Blanching is not very suitable for the inactivation of enzymes of fruits, which causes changes in consistency and organoleptic properties, nor is it suitable for the treatment of aromatic herbs used as spices.

Merely reducing the temperature reduces the reaction rate, but the colour changes are quite rapid even at 0 °C. This means that sensitive products that have not been pre-treated should be frozen as quickly as possible, for example mushrooms and sliced peaches.[6] Rapid intensive browning occurs during defrosting, when the activity of polyphenol oxidases increases due to disruption of cellular structures by ice crystals.

Another physical method of browning prevention is to restrict the access of oxygen. The production process for frozen sensitive materials uses four basic processes: packaging in hermetically sealed containers under either normal or reduced pressure; packaging in an inert atmosphere; and addition of sucrose. The first three methods differ only in the input treatment and their common feature is a temporary effect only for freezer storage. After opening the package at normal temperature, the browning reactions usually proceed even faster due to tissue disruption. The effects of low pressure can also lead to changes in fruit consistency. Dipping the fruit in sucrose solution before freezing or filling the entire package with sugar has, in addition to the suppression of browning, even more positive effects, especially increased viscosity of the liquid phase within the tissue. Significant inhibition of enzymatic reactions, however, occurs only at concentrations of sucrose higher than 20% as a result of increased osmotic pressure. Sugar also enhances the taste and aroma of fruit, but sweetening limits the possibility of further use of such processed raw material, which is then only suitable for the production of liqueurs, syrups, fruit purees and similar products.

Limiting access of air is also used in cold processing, such as in the production of so-called pre-processed vegetables and peeled cut potatoes. Using plastic foils with limited permeability for oxygen, foils impermeable to oxygen, or modification of the atmosphere can slow the browning reactions, but the composition of modified atmospheres must also take into account other physiological demands of packaged products.

9.12.5.2 *Chemical methods*

Another option to reduce or inhibit the enzymatic browning reaction is the use of chemical reagents. Many substances capable of inhibiting polyphenol oxidases are known, but the mechanism of their action is often unknown. Complexing agents are able to bind copper ions, which the enzyme requires. Interaction with

[5]The enzyme sensitivity towards heating is expressed by thermoinactivation curve empirically obtained as a dependence of temperature on the logarithm of heating time, after which the enzyme activity is reduced by one order. The tangent line to the curve for polyphenol oxidase = 12 °C. For inactivation, heating at a temperature of 82 °C for 1.1 min (that means $F_{82} = 1.1$ min) is sufficient.

[6]Effect of temperature on reaction rate is expressed by the coefficient Q_{10}, which is equal to the ratio of rate (e.g. rate constant) at temperature $t + 10$ °C and the rate at temperature t. Coefficient Q_{10} for enzymatic browning reactions has a relatively high value (e.g. for the browning of peaches $Q_{10} = 18$). Therefore, browning of peaches does not occur during freezer storage (−18 °C) thus stored fruits are sufficiently stable.

Table 9.17 Inhibitors of enzymatic browning reactions.

Compound	Mechanism of action
Tropolone (2-hydroxycyclohepta-2,4,6-trien-1-one)	Copper binding
Citric acid	Copper binding, acidification
Phosphoric acid, polyphosphates	Copper binding, acidification
Ethylenediamintetraacetic acid (EDTA)	Copper binding, slight acidification
D-Gluconic acid kyselina	Copper binding, slight acidification
Sodium chloride, sodium fluoride	Copper binding
Benzoic, *p*-coumaric, cinnamic and feruic acids	Competitive enzyme inhibition
4-Hexylresorcinol and other 4-substituted resorcinols	Competitive enzyme inhibition
Proteases (ficin from figs, actinidin from kiwi, papain from papaya, bromelain from ananas)	Enzyme inhibition
Sodium hypochlorite, calcium hypochlorite	Enzyme inhibition
Modified substrates, such as (+)-catechin 3′-*O*-α-D-glucoside	Enzyme inhibition
Cyclodextrins	Formation of complexes with phenols
Ascorbic acid and its derivatives	Reduction of quinones, slight acidification
Hydrogensulfites, sulfur dioxide	Reduction of quinones and addition products, enzyme inhibition
Thiols (cysteine, *N*-acetylcysteine, glutathion)	Reduction of quinones and addition products, enzyme inhibition

copper is also the cause of the inhibitory effects of some inorganic ions, especially halides. Substances structurally similar to substrate (such as benzoic and cinnamic acids and their derivatives) may competitively inhibit polyphenol oxidases. Also considered is the possibility of direct influence on the active sites of enzymes by free radicals, which can be produced, for example, from added ascorbic acid. The inhibitory effect of hydrogen peroxide on mushroom tyrosinase is explained by the same mechanism. Acidification below the polyphenol oxidase optimum pH (pH 4–4.5) may also slow or stop the browning reactions.

Another group of inhibitors of polyphenol oxidases are reducing agents capable of reducing the resulting quinones back to diphenols (ascorbic acid, thiols and some other agents). The antibrowning effect of ascorbic acid has been associated with its ability to reduce quinones to their precursor phenolics and with lowering the pH with a concomitant inhibition of polyphenol oxidase activity. However, if the effect of the inhibitor is a mere reduction of quinones, browning is inhibited only until the exhaustion of the reagents. The sulfur-containing agents (such as bisulfites) seem to control the browning reaction by irreversible inactivation of polyphenol oxidase as well as by reacting with quinones to produce colorless compounds (see Section 9.12.4). An overview of the main inhibitors is given in Table 9.17.

The practical use of chemical inhibitors is limited by several factors. Most substances with a strong inhibitory effect, when tested in model systems, are not effective in real materials, where other factors also play a role. It is easier to use an inhibitor in a homogeneous material, such as juice or puree. In the case of cut fruits, leaves and spices there are two possible alternatives: soaking the material for some time in the inhibitor solution or spraying the inhibitor over the material surface. Individual substances differ in their ability to penetrate the plant tissue. Bisulfites in particular are very effective. Another limitation may be material properties. For example, the use of acid is avoided in green plants, where browning will be suppressed, but the acid will accelerate the conversion of chlorophylls to phaeophytins (phaeophytinisation).

Health regulations normally allow only the use of ascorbic acid and some of its derivatives, citric acid, sodium chloride and hydrogen bisulfites. Hydrogen bisulfites and sulfur dioxide are very effective in protection against browning and are widely applied (e.g. in packed peeled potatoes). In practical terms, mixtures of citric and ascorbic acids are used. As a very effective means to stabilise the colour of apple slices and other fruits, a mixture of phosphates, citric acid and glucose is recommended. The use of an inhibitor is often part of a complex procedure also involving other methods, especially the limitation of air access. No agent (perhaps with the exception of hydrogen sulfites) and no treatment are universally applicable. A prerequisite for a reliable method of prevention and inhibition of browning is the search for perfect ways of treating individual materials appropriate to the available technology and processing methods.

10

Antinutritional, Toxic and other Bioactive Compounds

10.1 Introduction

As we have seen in the preceding chapters, foods contain many beneficial and also indifferent substances. In this chapter, we shall discover that foods can also contain antinutritional and toxic substances. Antinutritional substances found in the human diet or animal feed have the potential to adversely affect health, as they may interfere with the body's ability to digest and utilise nutrients, especially proteins, vitamins and minerals. It has been said that about 99% of all toxins are naturally occurring, and also that all things are toxic at a sufficiently high concentration. Certainly, many food raw materials contain chemicals, which, if consumed in excess, might lead to health problems. Terminology and definitions for materials that cause toxic effects are not always used consistently. A toxic substance or toxicant is a substance that produces an adverse biological effect of any nature, and which may, depending on the extent of exposure (dose), cause disease or damage to the body. Toxicity is the ability of a substance to produce an unwanted effect when the compound has reached a sufficient concentration at a certain site in the body. Toxicants causing immediate toxic effects (death or illness) when experienced in very small amounts are known as poisons. Natural toxic substances, mainly specific proteins produced by living organisms, such as microbial and mushroom toxic products, are called toxins. Toxinogenicity is the ability of organisms to produce toxins.

Depending on the origin, antinutritional and toxic substances include two types of compounds:

- natural components that are natural antinutritional and toxic compounds, found in food as a result of genetic predisposition of organisms;
- foreign substances.

Foreign substances are divided according to the way they get into food:

- compounds added intentionally to improve the food quality during processing, storage and other operations (extending their shelf life, improving sensory, nutritional and technological quality) that are therefore classified as additive substances or **food additives** (see Chapter 11);
- compounds getting into food accidentally from the environment during production, storage, transportation, marketing and other manipulations or arising in physical and chemical processes of food production that are classified as **pollutants** or **food contaminants**; a special case is food contamination by microbial toxins (bacterial toxins and mycotoxins) (see Chapter 12).

Products of anthropogenic activities that do not occur in nature are called **xenobiotics** (from the Greek word *xenos* meaning foreign). In relation to food, we often distinguish exogenous or primary contaminants (contaminants from the environment, such as residues of pesticides or residues of veterinary medicines used in agriculture) and endogenous or secondary contaminants that arise during food processing from natural food components by different physical and chemical factors (such as products of ionising radiation, thermal and oxidation reactions). According to some classifications, food additives are not regarded as foreign substances, but natural toxic substances in food are regarded as food contaminants. The nature, properties, adverse effects and analysis of toxic substances related to food and the human food chain with respect to the human organism and disease manifestations in humans are of interest in food toxicology.

Natural toxic substances and food contaminants may exhibit different effects (biological effects) upon living organisms, largely depending on where and how they are taken in:

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

- orally (through the mouth)
- by inhalation (through breathing)
- by absorption through mucous membranes and skin (dermally).

Adverse biological effects, bringing the risk of possible poisoning are called toxic effects. Toxic effects may manifest as:

- **acute**, after a single dose of a toxin[1]
- **chronic**, after repeated or continuous administration of toxic substances (over a period of time).

On the basis of biological action, toxic substances may, for example, act as:

- **asphyxiants** (exerting their effects through a depletion of oxygen to the tissues – asphyxia, such as carbon monoxide and hydrogen cyanide);
- **carcinogenic agents** or carcinogens[2] (inducing cancer, such as some lipophilic synthetic dyes, acrylamide, polycyclic aromatic hydrocarbons, *N*-nitrosamines, polychlorinated dibenzodioxins and dibenzofurans);
- **hepatotoxic agents** or hepatotoxins (producing liver damage, such as pyrrolizidine alkaloids, aflatoxins, amatoxins and phallotoxins);
- **irritants** and **sensitising agents** (irritation occurs from contact with irritants, such as ammonia, allyl isothiocyanate and some essential oils of spices; sensitisation is a reaction after exposure to sensitising agents that may cause allergic responses, such as hypericin, fagopyrin and some coumarins);
- **mutagenic agents** or mutagens (that may cause cancer or undesirable mutations, such as reactive oxygen species, some carbonyl compounds and aromatic amines);
- **nephrotoxic agents** or nephrotoxins (producing kidney damage, such as some halogenated hydrocarbons, amatoxins and phallotoxins);
- **neurotoxic agents** or neurotoxins (that may damage nervous tissue), such as 3-(*N*-oxalyl)-L-2,3-diaminopropionic and ibotenic acids;
- **teratogenic agents** or teratogens (that may cause defects in the foetus in pregnant women (such as alkaloids chaconine, tomatine, anabasine and anatabine).

According to the potential dose-related risk, the following categories are usually recognised:

- **contaminants** (mainly microbial toxins, as well as industrial contaminants, residues of veterinary drugs and pesticides), which can be a significant risk, but the long-term effects are difficult to estimate;
- **natural toxicants**, where risks exist, but knowledge of the effects is generally inadequate;
- **additives**, where the risks are small (with a few exceptions, which are nitrites and some flavouring substances);
- **antinutritional substances**, where risks are potential rather than real, which is largely derived of antinutritional effects manifested in animals.

The maximum amounts of antinutritional substances, natural toxins, additives and contaminants which may be present in wholesome foods and tobacco products are indicated in the relevant legislation, as a result of toxicological and epidemiological studies (using data on the food consumption). These data include safety factors so that foods containing toxic substances can be consumed daily over a lifetime without demonstrable negative effects.

To date, more than a dozen terms or measures are used to denote directly or indirectly a health risk as significant or insignificant. These risk measures include, but are not limited to: NOEL, NOAEL, RfD and ADI. In animal experiments (at least in two animal species, although the intention is to replace these experiments *in vivo* by testing *in vitro* using cell or tissue cultures), the ineffective concentration of a toxic substance that does not result in observable damage to the health of the animal is determined. This ineffective concentration (a threshold in mg per kg body weight, below which adverse effects do not occur) of a substance is called the No Adverse Effect Level (NOAEL). Toxicologists can also report results as the Lowest Observed Adverse Effect Level (LOAEL). These numbers, preferably the NOAEL and sometimes the LOAEL values, are used by risk assessors and regulatory agencies to determine such values as the Reference Dose (RfD) for a substance used by the USEPA (U.S. Environmental Protection Agency). RfD is the dose or concentration that is assumed to cause no harm to human populations upon daily exposure to that substance. $RfD = NOAEL$ (or LOAEL)/$UF \times MF$, where UF is uncertainty factor, which is often a tenfold factor for each uncertainty, and MF is modifying factor, which can range between 0 and 10, with 1 as the default; UF is based on animal tests and animal to target species extrapolation, along with other causes of uncertainty.

The term ADI (Acceptable Daily Intake, typically expressed in mg/day per kg body weight) was first used by the joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives and is now used extensively by the USFDA (U.S. Food and Drug Administration). ADI is the predetermined

[1]The acute toxicity of a compound is generally measured by experiments on animals (quite often rats). The most common measure of acute toxicity is lethal dose value (LD_{50}) usually given in weight of compound per kg of body weight (also used to classify poisons), which causes death in 50% of the test animals.

[2]The International Agency for Research on Cancer (IARC), a part of the World Health Organization (WHO), recognises the following groups of carcinogenic substances: Group 1 – carcinogenic to humans, Group 2A – probably carcinogenic to humans, Group 2B – possibly carcinogenic to humans, Group 3 – unclassifiable as to carcinogenicity in humans and Group 4 – probably not carcinogenic to humans.

amount of a substance (such as a pesticide or food additive) that can be consumed daily by humans for an entire lifetime without causing appreciable adverse effects. ADI is calculated according to the equation: ADI = NOAEL/SF, where SF is safety factor, usually of a multiple of 10, to account for intraspecies sensitivity, interspecies difference and other factors of concern (such as completeness of data). If it concerns a toxicologically significant effect of a toxic substance (such as reproductive disorders) or if sufficient data are not available, the SF value is increased to 100 or even to 1000.

In the case of pesticides, the calculation of Maximum Residue Levels (in mg/kg food) also reflects the quantity of food consumed. The MRL is calculated from the equation: MRL = ADI × body weight/food consumption in kg. If the same toxic substance is present in several foods, then the food basket (food per day) is examined, and the total amount of toxic substance must not exceed the determined value. Information about the chronic effects of toxic substances is provided by long-term tests on sub-chronic and chronic toxicity.

Toxicological evaluation of veterinary drug residues in food is based on the toxicological and pharmacological effects of antimicrobial veterinary drugs (antibiotics) on representative pathogenic and non-pathogenic microflora of the human digestive tract and representative microorganisms of the genera *Lactococcus*, *Leuconostoc*, *Bifidobacterium*, *Lactobacillus*, *Enterococcus* and *Propionibacterium* used in biotechnology. The equation used for deriving the ADI value (in μg/kg body weight) is calculated using the following equation $ADI = MIC_{50} \times MCC/FA \times SF \times BW$, where MIC_{50} = Minimal Inhibitors Concentration (the minimum inhibitory concentration in μg/g for 50% of test organisms), MCC = Mass of Colonic Content (amount of 220 g is used), FA = Fraction of an oral dose Available to act upon microorganisms in the colon, SF = Safety Factor (ranging from 1 to 10, a value of 1 being used when extensive, relevant microbiological data are available) and BW = body weight (60 kg).

According to current knowledge, however, a number of natural compounds formerly classified as toxins or indifferent substances show desirable and even beneficial biological effects. The term bioactive food component refers to non-essential molecules that are present in foods and exhibit the capacity to modulate one or more metabolic processes, which results in the promotion of better health. Bioactive food components also have multiple metabolic activities allowing for beneficial effects in several diseases. In general, it is thought that bioactive food components are predominantly found in plant foods, such as cereals, nuts, fruits and vegetables. For example, isothiocyanates and other degradation products of glucosinolates, occurring in broccoli, cauliflower, Brussels sprouts and other *Brassica* vegetables, were known as potential antithyroid compounds, but it has been shown that many of them induce detoxifying enzyme systems and have antimicrobial, immunomodulatory and anticancer properties. Phytooestrogens of soybeans, soy-based products and flaxseeds have anti-oestrogenic, anti-osteoporotic and anti-proliferative properties. While a few plant saponins are toxic in large doses, most saponins found in food (cereals, legumes, potatoes, spinach, tomatoes and other products) are safe and may even have many beneficial health effects. Studies have illustrated the beneficial effects of some saponins on blood cholesterol levels (by forming complexes with cholesterol and bile acids), a hypolipidaemic effect, or show antioxidant, antimutagenic and anticarcinogenic properties and stimulate the immune system,[3]

Attention in this chapter is paid to natural antinutritional and toxic substances of food and to those raw materials that are used in the diet directly or after technological and culinary processing. Attention is also paid to natural substances that enter the food chain indirectly through livestock feed. The first part of this chapter deals with antinutritional compounds (enzyme inhibitors, antivitamins, compounds binding minerals and other antinutritional factors). Toxic food constituents are divided into two large groups: compounds that are toxic for certain individuals and cause food intolerance (such as non-allergic food hypersensitivity and immune system reactions known as food allergies) and compounds that are toxic for the whole population. The second group of toxic constituents of food includes alkaloids found in edible plants and plants that are consumed by livestock, saponins, cyanogens (cyanogenic glycosides and lipids), and glucosinolates. Important phenolic compounds (oestrogens and phototoxic compounds), lectins, toxic amino acids, biogenic amines and polyamines and, last but not least, marine toxins (shellfish and fish toxins) and toxic substances of mushrooms. Each section concentrates on the structure and occurrence of antinutritional and toxic compounds, and their biological effects, changes and reactions in raw materials and foods. However, a number of the so-called toxic substances and their decomposition products are beneficial at low concentrations for human well-being and health, and many find use in the pharmaceutical industry and medicine.

10.2 Antinutritional compounds

Antinutritional substances include:

- enzyme inhibitors (antienzymes)

[3]Most foreign substances (food contaminants, xenobiotics, but also natural toxins) are normally metabolised in two phases. The first phase is mainly oxidation catalysed by microsomal enzyme systems. In the second phase, the oxidised metabolites are converted into polar compounds (e.g. in conjugation reactions with D-glucuronic acid or glutathione) and are eliminated from the body. During the first phase, however, some compounds (called procarcinogens, which are carcinogens requiring metabolic activation) may produce highly reactive metabolites able to attack the DNA and initiate the development of cancer. Development of cancer is a multi-step process that can be arbitrarily subdivided into initiation, promotion and progression steps.

Every organism has, however, protective systems, which may hinder the process of carcinogenesis. Substances with anticarcinogenic activity can be divided into three groups according to the mechanism of action. The group A anticarcinogens inhibit enzymes involved in the metabolic activation of procarcinogens, but are ineffective for carcinogens, which do not require activation (so-called direct carcinogens). The other two groups are substances that efficiently convert carcinogens into harmless products. Group B consists of substances that activate the detoxification enzyme systems (such as glutathione-*S*-transferase, which catalyses the binding of a variety electrophiles to glutathione thiol group). Group C substances reduce the risk of DNA damage, either by directly reaction with electrophiles or by preventing their reaction with DNA. Naturally occurring anticarcinogenic compounds can play an important role in cancer prevention by inhibiting one or more of the important steps in tumour cell development.

- antivitamins
- compounds interfering with the metabolism of minerals
- antinutritional phenolic compounds
- antinutritional oligosaccharides.

10.2.1 Enzyme inhibitors

Enzyme inhibitors, also known as antienzymes, are various low molecular weight and high molecular weight natural food components and foreign substances that affect the activity of various enzymes. In nutrition terms, the most important antienzymes are inhibitors of digestive enzymes, particularly **inhibitors of proteases** also known as antiproteases. A less important group are **inhibitors of saccharases**.

10.2.1.1 Inhibitors of proteases

Protease inhibitors, which are important from the nutritional point of view, are proteins or polypeptides capable of inhibiting the digestive enzymes proteases.

10.2.1.1.1 Classification

Protease inhibitors are classified according to the type of proteases, which are inhibited. Recognised inhibitors are:

- serine protease inhibitors (e.g. inhibitors of trypsin, chymotrypsin, elastase and plasmin)
- sulfhydryl protease inhibitors (e.g. inhibitors of pepsin and thrombin)
- acidic protease inhibitors (e.g. inhibitors of cathepsin D)
- metaloprotease inhibitors (e.g. inhibitors of pancreatic carboxypeptidase).

The most important inhibitors are inhibitors of serine proteases, which include two main groups of protease inhibitors:

- Kunitz type inhibitors (KI)
- Bowman–Birk type inhibitors (BBI).

10.2.1.1.2 Occurrence and properties

Protease inhibitors are naturally present in plant foods, especially in legume seeds, but they also occur in cereals and some other plant materials (such as potatoes and tomatoes). Protease inhibitors of microbial and animal origins also exist. In plants, protease inhibitors fulfill several functions. They probably serve as a cytosol protection against endogenous proteases released in disrupted cellular structures. In addition, they act as storage proteins during seed germination and are involved in the protection of plant tissues against elicitors (viruses, bacteria and fungi) and predators (animals).

Kunitz type inhibitors

Kunitz type inhibitors have a relative molecular weight of about 20 kDa and have two disulfide bridges in the molecule. They primarily exhibit specificity to trypsin. Examples are Kunitz type inhibitors of soya beans called STI (Soybean Trypsin Inhibitor), which are a group of isoinhibitors with relative molecular weights of 18–24 kDa. The main component is a protein containing 181 amino acid residues and two disulfide bridges (20 kDa). The binding sites, where the inhibitor interacts with trypsin, are the amino acid residues Arg^{63} and Ile^{64}. A complex with trypsin arises in a stoichiometric ratio (one inhibitor molecule interacts with one molecule of trypsin). The complex is analogous to the enzyme–substrate complex, but does not in practice dissociate into the original protein (trypsin) and enzyme inhibitor.

Bowman–Birk type inhibitors

Inhibitors of the Bowman–Birk type have a relative molecular weight of about 6–10 kDa, a higher number of disulfide bridges, and exhibit specificity against trypsin and chymotrypsin, as they contain two independent binding sites in the molecule. Bowman–Birk type inhibitors belong to the most common inhibitors. They occur in legumes, cereals, pseudocereals, potatoes and some other materials.

In soya beans (*Glycine max*, Fabaceae), for example, five isoinhibitors of this type occur, which belong to the group of PI (Potato Inhibitor) and are labelled PI-I to PI-V. In potatoes, as well as in barley, inhibitors PI-I and PI-II occur. Inhibitor PI-I is a polypeptide of molecular weight of 8 kDa, which contains a polypeptide chain consisting of 71 amino acids and seven disulfide bridges. The inhibitor PI-I has dual binding specificity. The binding sites of trypsin are amino acids Lys^{16}-Ser^{17}, while the interaction with chymotrypsin occurs via amino acids Leu^{44}-Ser^{45}. Similar structures and properties have inhibitors present in other legumes and oilseeds. Common bean (*Phaseolus vulgaris*) contains inhibitor GBI (Garden Bean Inhibitor), the lima (butter) bean (*P. lunatus*) contains inhibitor LBI (Lima Bean Inhibitor), in chickpeas (*Cicer arietinum*) is found inhibitor CPI (Cow Pea Inhibitor) and in peanuts (*Arachis hypogaea*) inhibitor GI (Groundnut Inhibitor).

Buckwheat (*Fagopyrum esculentum*, Polygonaceae) contains the inhibitor BTI (Buckwheat Trypsin Inhibitor), and, correspondingly, three isoinhibitors of the Bowman–Birk type that are called BTI-1, BTI-2 and BTI-3, which consist of a single polypeptide chain containing 69 amino acids. The content of protease inhibitors in selected legumes is shown in Table 10.1.

Sulfhydryl protease inhibitors, for example, are found in the seeds of legumes of the genus *Vigna*; inhibitors of acid proteases occur in potatoes, and inhibitors of metaloproteases occur in potatoes, tomatoes and other crops.

Table 10.1 Protease inhibitors content in selected legumes.

Legume seed	Content of protease inhibitors (g/kg)	
	Kunitz type inhibitors	Bowman-Birk type inhibitors
Soya bean (*Glycine max*)	20	2–3
Peas (*Pisum sativum*)	–	0.05–3
Cowpea (*Cicer arietinum*)	–	2.3

10.2.1.1.3 Mechanism of action

Knowledge of the antinutritive effects of protease inhibitors in humans is still limited and mainly derived from the knowledge gained in animal nutrition. When feeding raw or undercooked legumes to farm animals, inhibitors of proteases (trypsin inhibitors) cause disturbances that are manifested by slow growth of the animals. In chronic cases it leads to enlargement of the pancreas, which is histologically described as hypertrophy (enlargement of the pancreas or its parts due to enlargement of individual cells) and hyperplasia (enlargement of pancreas by pancreatic cell multiplication). This is due to increased secretion of digestive enzymes, including trypsin, chymotrypsin and elastase by the hyperactive pancreas. It is thought that the growth retardation of animals is actually the result of endogenous loss of amino acids, particularly sulfur amino acids, which are used for the synthesis of proteases that subsequently pass into the faeces and cannot be used for the synthesis of muscle proteins.

Trypsin inhibitors are not the only antinutritive factors in soya beans that may slow the growth of farm animals. For example, the slowdown of animal growth, for which trypsin inhibitors are responsible, is about 40% of the total antinutritive activity of raw soya beans. About 25% of the antinutritive activity can be attributed to lectins and the rest to other antinutritional substances.

10.2.1.1.4 Inactivation

Adverse effects of protease inhibitors are relatively easy to eliminate by thermal processing of plant materials. Reduction of inhibitor activity depends on temperature, time of heating, material particle size and water content. For soya beans, the most common way of thermal inactivation of protease inhibitors is the so-called toasting process (effect of water vapour), but other methods are also effective, such as boiling in water, dry roasting, microwave heating and extrusion. For example, trypsin inhibitors of most commercial soya products for human consumption (tofu, soya beverage, incorrectly called soya milk, soya isolates and concentrates and textured soya meat substitutes) are sufficiently inhibited showing only about 20% of the activity of raw soya beans. Inactivation of inhibitors to 50–60% is necessary to eliminate their adverse effects (animal growth retardation and impaired pancreatic function). Germination of mature soya beans also gradually decreases the activity of Kunitz type inhibitors, because modified forms of these proteins arise by proteolysis and *de novo* synthesis.

10.2.1.2 Inhibitors of saccharases

Many cereals and cereal products (such as wheat, rye, breakfast cereals and bread) contain proteins inhibiting animal, but not plant amylases. Invertase inhibitors are found in potato tubers, for example. The significance of these enzyme inhibitors is negligible and the consequences of their presence in food are not yet known. It is believed that amylase inhibitors could potentially be used in preparations for diets to promote weight loss.

10.2.2 Antivitamins

Antivitamins (vitamin antagonists) are those substances that eliminate the biological effects of vitamins, which can lead to deficiency symptoms. Antivitamins are dealt with in detail in Chapter 5.

10.2.3 Compounds binding minerals

In foods of plant origin, certain compounds are found as natural components that interfere with the metabolism of minerals. The most important groups of these compounds include:

- **phytic acid** and **phytin**
- **oxalic acid**
- **glucosinolates** and their degradation products.

10.2.3.1 Phytic acid and phytin

Phytic acid, *myo*-inositol-1,2,3,4,5,6-hexakisdihydrogenphosphate, is the main storage form of phosphorus used during germination of seeds of cereals, pulses and oilseeds. Phytic acid in seeds occurs primarily as a mixed calcium and magnesium salt, which is called phytin. Insoluble salts and ones that are utilised only slightly are also produced with other di- and trivalent ions, such as Fe and Zn in particular. The issue of phytin is discussed in detail in Chapter 6 (see Section 6.3.4.2.1).

10.2.3.2 Oxalic acid

Oxalic acid is a common component in many vegetables and other plant foods (Table 8.15). Oxalic acid yields insoluble calcium oxalate

with calcium ions, which may under certain circumstances (existing low intake of calcium and vitamin D) seriously interfere with the metabolism of calcium. It also occurs in the so-called beer stone, a greyish brown scale composed of calcium oxalate and organic substances, which forms on the inside surfaces of brewing apparatus.

Approximately 75% of all human kidney stones are composed primarily of calcium oxalate and hyperoxaluria, also known as oxalosis (urinary oxalate excretion that exceeds 40 mg/day) is a primary risk factor for this disorder. Urinary oxalate originates from a combination of absorbed dietary oxalate and endogenously synthesised oxalate, nevertheless boiling of vegetables markedly reduces dietary soluble oxalate content by 30–87% and is more effective than steaming (5–53%). The loss of insoluble oxalate during cooking varies greatly, ranging from 0 to 74%. Because soluble sources of oxalate appear to be better absorbed than insoluble sources, employing cooking methods that significantly reduce soluble oxalate may be an effective strategy for decreasing oxaluria in individuals predisposed to the development of kidney stones.

10.2.3.3 Glucosinolates

Glucosinolates, especially the glucosinolate progoitrin (whose decomposition yields the antithyroid substance goitrin), but also some other glucosinolates which produce antithyroid isothiocyanates (such as sinigrin, which produces allyl isothiocyanate) or antithyroid thiocyanates (such as indole glucosinolates) are often classified as compounds that interfere with the metabolism of iodine. The issue of glucosinolates is given elsewhere (see Section 10.3.2.4).

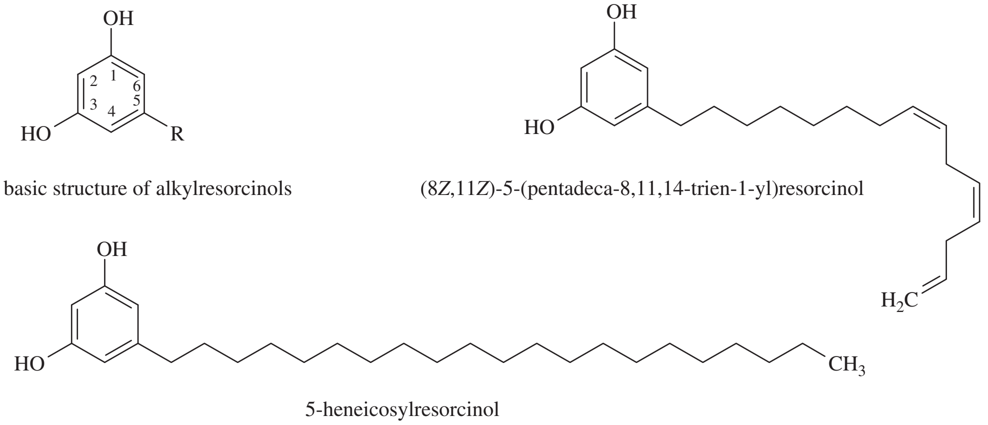
10.2.3.4 Alkylresorcinols

The term alkylresorcinols is used collectively for the group of 5-alkyl, 5-alkenyl, 5-alkadienyl and minor 5-(2-oxoalkyl) and 5-(2-oxoalkenyl) derivatives of resorcinol (benzene-1,3-diol, **10-1**). The resorcinol substituents have straight chains with an odd number of carbon atoms. The most common substituents have 13 to 29 carbon atoms.

Alkylresorcinols occur in rye, wheat and triticale and in smaller amounts in other cereals, such as barley, and in very small amounts in oats and maize. Alkylresorcinols with alkyl chains C17:0–C25:0 are abundant in whole-grain wheat and rye. They are located mainly in embryo (germ) and the outer layer of the kernel; therefore they remain predominantly in the bran during kernel milling. Their content in wheat is 200–1429 mg/kg (around 2000 mg/kg in the germ). Durum wheat (*Triticum durum*) content of alkylresorcinols is on average 455 mg/kg and the average relative homologue composition is C17:0 (0.4%), C19:0 (14%), C21:0 (58%), C23:0 (21%) and C25:0 (6.5%). The level of alkylresorcinols in rye kernels is 720–2000 mg/kg (in the germ about 3000 mg/kg) and in triticale it is between the values for rye and wheat, The main compound in wheat, rye and triticale is 5-heneicosylresorcinol (**10-1**) and in barley is 5-pentacosylresorcinol. Alkenylresorcinols represent about 30% of the content of alkylresorcinols in rye and about 10% in wheat. The content of alkylresorcinols is significantly reduced during dough fermentation and baking. In extruded cereal products, the original amount of alkylresorcinols is reduced to about 50–80%.

5-Alkyl, 5-alkenyl and 5-alkadienyl resorcinols also occur as allergenic compounds in mango (*Mangifera indica*, Anacardiaceae). Depending on cultivar, their contents range from about 80 to 1850 mg/kg of dry matter in mango peels and from about 5 to 190 mg/kg of dry matter in mango pulp. The profile of these substances was found to be highly characteristic, with an average homologue composition of C15:0 (6.1%), C15:1 (1.7%), C17:0 (1.1%), C17:1 (52.5%), C17:2 (33.4%), C17:3 (2.4%), C19:1 (2.1%) and C19:2 (0.8%).

Alkylresorcinols in cereals negatively influence the growth of animals. Their toxicity decreases with increasing length of the substituent and grows with the number of double bonds in the chain. The most toxic are homologues with unsaturated and shorter (13 or less carbon atoms) chains. The toxicity of alkylresorcinols is based on influencing the hydrophobic properties (permeability) of membranes for potassium ions and some organic compounds (such as glycerol). Alkenylresorcinols also exhibit haemolytic activity. Some synthetic substituted resorcinols (e.g. 4-hexylresorcinol approved as a food additive in the EU, E586) proved to be inhibitors of enzymatic browning reactions, causing blotches on canned shrimps.



10-1, structures of substituted resorcinols

Toxic 5-alkatrienyl, 5-alkadienyl, 5-alkenyl and 5-alkyl resorcinols, collectively known as cardol, occur in the cashew nutshell liquid (CNSL), also known as cashew shell oil, a natural resin found in the honeycomb structure of the cashew nutshell. It is a byproduct of cashew nuts processing (see Section 8.2.6.1.6). A typical solvent-extracted CNSL contains 15–20% of cardol. The main components are (8*Z*,11*Z*)-pentadeca-8,11,14-trien-1-yl (**10-1**), (8*Z*,11*Z*)-pentadeca-8,11-dien-1-yl, (8*Z*)-pentadeca-8-en-1-yl and pentadecyl derivatives.

10.2.3.5 Tannins

Antinutritional substances also include tannins, which are found in relatively large quantities in the seeds of leguminous plants (in amounts up to 0.45 g/kg in soya beans and 20 g/kg in common beans) and in oilseed extraction meals. Their complexes and reaction products with proteins are resistant to enzymatic hydrolysis, which results is lower digestibility and subsequently in reduced weight gain in livestock. Excessive consumption of tannins may also lead to decreased absorption of some minerals and can cause damage to the intestinal mucosa.

10.2.3.6 Carbohydrates

A special group of antinutrients are α-galactosides also called α-D-galactosides of saccharose. They are found in a significant number in legumes, where they have a role as storage carbohydrates. An important representative of these sugars is trisaccharide raffinose and its higher homologues, while a less common compound is trisaccharide manninotriose (Table 4.16) and α-galactosides of cyclitols that are classified as pseudooligosaccharides (see Section 4.3.1.2.2). The presence of these substances in legumes limits to some extent the use of legumes for human consumption and in nutrition of monogastric animals, because their flatulent activity results in gastrointestinal discomfort. In ruminants, these problems do not occur because α-galactosides are hydrolysed by α-galactosidase.

10.3 Toxic compounds

Natural toxic substances can be classified into two major groups:

- substances causing food intolerance that are toxic only to certain individuals
- toxins that are toxic to all individuals.

10.3.1 Food intolerance

Food intolerance is an adverse reaction of the body to some food or food ingredient that occurs every time the food is eaten, but particularly if larger quantities are consumed. It is estimated that about 0.3–7% of the population suffer from food intolerance symptoms, an abnormal physiological reaction to an accepted food, usually because the body does not produce enough of the particular chemical or enzyme that is needed for that food's digestion. The unpleasant symptoms of food intolerance include nausea, bloating, abdominal pain and diarrhea, which can begin hours or days after eating or drinking the food in question, but are not usually life threatening.

Food intolerance does not include psychological reactions to food and eating disorders, such as *anorexia nervosa* and *bulimia nervosa*. *Anorexia nervosa*, commonly referred to simply as anorexia, is an eating disorder that consists of the complete opposition of a person to eating. It makes the person sick or constantly feeling hunger-free, which can lead to malnutrition and other problems associated with starvation. *Bulimia nervosa*, also called bulimia, is an eating disorder that consists in seizure eating and attempts to vomit (purge) the food by inducing diarrhea, use of appetite suppressants or other substances to control weight loss.

Conditions resulting in food intolerance caused by non-immunological reactions of the organism include metabolic disorders, sensitivity to certain food (anaphylaxis), aversion to certain food (idiosyncrasy) and poisoning manifested by similar symptoms as allergies. The cause of these metabolic disorders of the organism is usually insufficient activity of some enzymes, which is hereditary, so food intolerance of this type is a congenital metabolic disorder. A common example is alcohol intolerance caused by deficiency of an enzyme alcohol dehydrogenase, which is common among Asian people, where about 50% are affected. Drinking even small amounts of alcohol can make affected people feel unwell. Other most common non-immunological reactions caused by insufficient activity of enzymes include:

- **lactose intolerance**
- **phenylketonuria**
- **favism**.

A well-known type of hypersensitivity to food (anaphylaxis) is a reaction to strawberries, which is manifested by urticaria (hives). Among the manifestations known as aversion to food (idiosyncrasy), whose mechanism is not yet known, is the so-called Chinese restaurant syndrome (associated with a higher intake of sodium-hydrogen glutamate) and migraine occurring after eating certain foods. An ordinary poisoning presenting as an allergy is histamine-induced poisoning, which is caused by eating some fish or fermented products with higher content of histamine (such as smoked tuna and wine).

10.3.1.1 Lactose intolerance

Lactose intolerance, often confused with milk allergy, is one of the most common metabolic disorders. Under normal conditions, lactose in the digestive tract is hydrolysed by β-galactosidase (lactase) to glucose and galactose, which are then used as an energy source. In the case of lactose intolerance, this key enzyme in the body is missing or not very active. Disaccharides are generally not absorbed by the wall of the small intestine, so in the absence of lactase, lactose

passes from food into the colon, and is fermented there by intestinal bacteria, similarly to other non-utilisable carbohydrates, forming gases (hydrogen, carbon dioxide and methane). Three types of lactose intolerance are recognised:

- primary lactose intolerance, which is common among non-breastfed children in many Asian and African countries;
- secondary lactose intolerance, in which lactase is not biosynthesised as a result of various gastrointestinal diseases, such as giardiose (intestinal parasitic disease caused by the flagellate *Giardia intestinalis*), viral diseases, acute gastroenteritis (intestinal flu), in which the person is vomiting, experiencing diarrhea and high temperature;
- congenital lactose intolerance, a genetic disorder in which lactase is not biosynthesised from birth (since it is a metabolic disorder, the disease is lifelong, but may show a slight improvement with age).

Lactose intolerance also increases with age. It is estimated that globally about 75% of the adult population shows a decrease in lactase activity during adolescence and adulthood (in Northern Europe about 5% of the population, in southern Europe about 71% and in some African and Asian countries up to 90%).

Elimination of milk, or accordingly a control of the diet containing milk, is the best way to prevent this metabolic disorder. Lactose intolerance can be avoided through the use of appropriate technological procedures. One of them is enrichment of milk by β-galactosidase and milk fermentation. Fermented milk products largely contribute to reducing adverse patient reactions to milk as much of the lactose present in milk is converted into lactic acid. Foods with low lactose intended for consumption have to contain up to 10 g/kg (or 10 g/l) lactose, lactose-free foods can contain only 100 mg/kg (or 100 mg/l) lactose and no galactose.

Lactose intolerance is secondarily manifested in individuals using antidepressant drugs by digestive problems caused by biogenic amine tyramine.

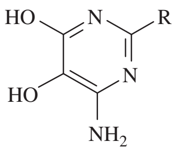
10.3.1.2 Phenylketonuria

Phenylketonuria is a congenital (a condition that is present at birth) metabolic disorder consisting in the disruption of the metabolism of the amino acid phenylalanine, which is a component of all proteins. Very low activity or absence of phenylalanine hydroxylase enzyme, which breaks down phenylalanine, is caused by mutations (damage) of the gene for this enzyme. If this condition is not treated, phenylalanine metabolites, such as phenylpyruvic, phenyllactic and phenylacetic acids (urine of patients has a characteristic mice-like odour), accumulate in the body and cause total disruption of child development. The result is damage to the development of the nervous system, leading to mental disability (microcephaly) manifested by termination of the growth of the brain and delayed psychomotoric development. The prevalence of phenylketonuria shows considerable geographic variation. It is estimated to be present in 1/10 000 live births in Europe and the United States, with a higher rate in some countries (Ireland and Italy). Prevalence is particularly high in Turkey, where it is 1/4000 live births, but it is far rarer in the Finnish, African and Japanese populations.

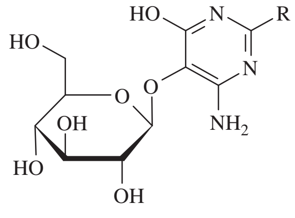
Phenylketonuria of children cannot be cured, and so, as in the case of celiac disease or lactose intolerance, they need to follow a controlled diet. The diet is based on nutrition with a reduced content of natural proteins. The phenylalanine content in foods cannot exceed 200 mg/kg (200 mg/l). The aim is to keep the level of phenylalanine in the blood at the lowest possible level. Reducing protein intake depends on the individual and is based on the degree of tolerance to phenylalanine (below 30% compared wiht the general population). According to the age and nutritional needs of the person, the natural protein can be replaced by an artificial mixture of individual amino acids without phenylalanine, but the use of a mixture of phenylalanine-free higher peptides is more advantageous with respect to sensory and osmotic properties. Higher peptides can be prepared by plastein synthesis (partial protein hydrolysis, treatment with protease under suitable conditions leading to release of hydrophobic amino acids, plastein reaction in the presence of added tryptophan and tyrosine, which yields practically phenylalanine-free plastein).

10.3.1.3 Favism

Favism is caused by the toxic pyrimidines divicine (2,4-diamino-5,6-dihydroxypyrimidine) and isouramil (4-amino-2,5,6-trihydroxypyrimidine, **10-2**), which occur in broad (fava) beans (*Vicia faba*, Fabaceae) and horse beans (*V.f.* var. *equina*), and in small quantities in some other legumes as 5-*O*-β-D-glucopyranosides known as vicine and convicine (**10-3**), respectively. These glycosides probably offer some protection against elicitors (bacteria and fungi) as they exhibit bacteriostatic and fungistatic effects. Sweet pea (vetchlings) (*Lathyrus* spp.) and pea (*Pisum* spp.) species do not contain pyrimidine glycosides. The vicine content of fava beans generally ranges from 4.2 to 10.8 g/kg, while the convicine content tends to be lower, within 0.3 to 0.5 g/kg. Divicine and isouramil arise from the respective glucosides, mainly in the large intestine, by hydrolysis with microbial β-glucosidases.



10-2, divicine, R = NH_2
isouramil, R = OH



10-3, vicine, R = NH_2
convicine, R = OH

The main favism symptom is acute haemolytic anaemia, accompanied by high fever, jaundice and swelling of the liver and spleen, as toxic pyrimidines oxidise the reduced form of glutathione in erythrocytes. Favism is manifested especially in individuals with low (usually hereditary) activity of the enzyme glucose 6-phosphate dehydrogenase in erythrocytes that reduces the oxidised form

of glutathione. This results in a lower concentration of reduced glutathione, which has a protective effect on the erythrocyte membrane. In addition to active substances of fava beans, medical drugs that oxidise glutathione can also invoke favism. The addition of vitamin A, C and E and chelating agents partially protects the body against favism. The glycoside content in the beans can be reduced by extraction with water. In this way it is possible to remove 80–90% of the original amount of glycosides in beans.

The presence of fava beans in feed mixtures for laying hens negatively affects the quality of eggs, because the eggs have a lower weight and increased yolk fragility.

10.3.2 Food allergy

Food intolerance, often called a pseudo-allergic reaction, is not the same as a food allergy, because it does not involve the immune system. Food allergy is an abnormal response of the immune system to even a tiny amount of a particular food, which is manifested by symptoms such as sneezing, itching, nasal obstruction (hay fever), redness of the eyes (conjunctivitis), nausea, diarrhea, vomiting, eczema, coughing and wheezing (asthma). Because the body is reacting to something that is otherwise harmless, this type of allergic reaction is often called a hypersensitivity reaction. Rarely, allergic reactions to food can sometimes cause serious illness and death, such as a life-threatening set of symptoms called anaphylaxis, or anaphylactic shock. It is estimated that about 2.5% of adults and about 6–8% of children, mainly younger than 6 years, have true food allergies.

Recognised are allergies induced by immunological reactions of the organism caused by **allergens** that cause production of immunoglobulin E (IgE), and allergies that do not cause the production of IgE.

10.3.2.1 Allergens causing abnormal production of IgE

Allergens, the agents causing the allergy (in immunological term antigens), may be proteins, polysaccharides and low molecular weight compounds called **haptens**. A food allergy is an allergic reaction of the organism when the allergen is a component of food. The most common manifestations of an allergy are skin reactions (such as atopic eczema, hives and swelling), respiratory system reactions (rhinitis) or reactions of digestive system (vomiting, diarrhea and abdominal pain). Allergens acquire immunological properties by interactions with serum proteins of the organism. Immunogenicity of proteins that are hosts for foreign substances is given by the amino acid sequences and their constitution and conformation. The mechanism of allergies takes place in two stages. The first stage is a specific immunological reaction, in which the allergen reacts with antibodies (called immunoglobulin E, in short IgE) with the release of mediators (such as prostaglandins and biogenic amines, one of which is histamine). In the second, non-specific stage, the hypersensitive organism responds to mediator stimulation by pathological manifestations. Hapten is a non-proteinaceous substance that acts as an antigen by combining with particular bonding sites on an antibody. Unlike a true antigen, it does not induce the formation of antibodies.

In theory, any food can be an allergen, but all foods do not have the same ability of allergising the organism. Among the foods that tend to cause the most allergic problems are milk, eggs (egg white), some fish, some fruits (apples, pears, apricots, peaches and strawberries), some vegetables (tomatoes, celery, spinach and parsley), cereals (hypersensitivity to cereals usually persists to a certain stage of life and improves with age), legumes (such as soya beans), seeds and nuts (sesame seeds and peanuts; reactions are usually very severe).

Allergens are substances that are very thermostable and stable in acidic media, so they resist the digestive processes. The most common ways to reduce allergenicity is the enzyme hydrolysis of proteins and their thermal denaturation. One of the modern ways to reduce allergenicity is inhibition of hyaluronidase, one of the target enzymes that control allergic responses, by pectin. Its inhibition is thus an indicator of antiallergic activity. Tea extracts have similar effects as pectin, inhibiting hyaluronidase.

The World Health Organization and International Union of Immunological Societies (WHO/IUIS) Allergen Nomenclature Sub-committee was founded in 1984 to establish a system for nomenclature of allergens and their characterisation.

10.3.2.1.1 Milk

Allergic symptoms have been reported for casein fractions and serum (whey) globulins of cow's milk. The most important allergens include α- and β-casein and β-lactoglobulin. Allergic effects have also been seen in α-lactoglobulin and α-lactalbumin.

Allergenicity of milk proteins can be reduced to some extent by enzymatic hydrolysis of proteins, their thermal denaturation or combined effects of both procedures. For the same reasons, fermented dairy products show a reduced allergenicity. Enzyme cleavage of casein can yield fragments with a relative molecular weight lower than 1000 Da with reducing allergenicity, but this procedure may also produce bitter peptides. The most commonly used proteases are proteases of the human gastrointestinal tract (pepsin, trypsin and chymotrypsin). Better performance is achieved by enzymatic hydrolysis in combination with thermal denaturation, but caseins are very resistant to thermal denaturation. A reduction of milk allergenicity can be also achieved by ultrafiltration, in which the high molecular weight allergens resistant to denaturation and hydrolysis are removed. By combining enzymatic hydrolysis, thermal denaturation and ultrafiltration, the allergenicity can be reduced by about 1000 times.

10.3.2.1.2 Eggs

Egg allergy accounts for one of the most prevalent food hypersensitivities in industrialised countries. The estimated prevalence of egg allergy varies between 1.6 and 3.2% and, thus, makes it the second most common cause of food allergy in children. The majority of the relevant egg allergens (Gal d 1 to Gal d 6) have been identified in the egg white: Gal d 1 (ovomucoid, 28 kDa), Gal d 2 (ovalbumin, 44 kDa), Gal d 3 (ovotransferrin, 78 kDa) and Gal d 4

(lysozyme C, 14 kDa). Allergens Gal d 5 (serum albumin, 14 kDa) and Gal d-6 (YGP42, 35 kDa) are allergens found in the egg yolk.

10.3.2.1.3 Cereals

Cereal proteins are not significant as allergens. For example, buckwheat (*Fagopyrum esculentum*, Polygonaceae) contains thermostable allergens Fag e 2 (2S albumin, 16 kDa) and Fag e 3 (vicilin fragment, 19 kDa), but some allergenicity was even observed for rice (containing allergens Ori s 1 and Ori s 12), barley (Hor v 1 identical to Hor v 15, Hor v 12, Hor v 16, Hor v 17 and Hor v 20) and wheat (Tri a 12, Tri a 14, Tri a 15, Tri a 18, Tri a 19, Tri a 21 and Tri a 25 to Tri a 37). The disease caused by wheat allergens is called Duhring's disease or *dermatitis herpetiformis* and is different from celiac disease. Wheat flour may cause baker's asthma, one of the most common forms of occupational asthma. This allergic disease is caused by inhalation of flour dust containing proteins of relative molecular weight of around 15 kDa, which act as α-amylase inhibitors in the grain. It can affect workers in bakeries, flour mills and kitchens.

10.3.2.1.4 Legumes

Soya is one of the most important sources of food allergens (Gly m 1-Gly m 7) that are responsible for about 90% of allergic reactions in the child population. The allergen Gly m 1 is a hydrophobic protein, Gly m 2 is a small cysteine-rich cationic protein (defensin), Gly m 3 is an actin-binding protein (profiling), Gly m 4 is a member of the PR-10 proteins family, Gly m 5 is β-conglycinin (vicilin, 7S globulin), Gly m 6 is is glycinin (legin, 11S globulin) and Gly m 7 is a seed biotinylated protein. Reduction of allergenicity can be achieved by thermal denaturation or enzymatic hydrolysis of proteins. Some soy proteins are relatively heat-stable, so that the complete elimination of allergenicity just by heating is impossible. Enzymatic hydrolysis with subsequent thermal denaturation is an appropriate way of producing hypoallergenic soya protein hydrolysates. Soy proteins are often cross-linked by disulfide bonds. To reduce allergenicity, these bonds must be cleaved, for example with *N*-acetylcysteine. Carbohydrates reduce the allergenicity of soy proteins by modifying the molecules in locations that are responsible for allergenicity. The reaction products of soya proteins with oxidised lipids increase the allergenicity, but oxidised soybean oil does not cause any allergic response.

10.3.2.1.5 Nuts

Peanuts contain several allergens (Ara h 1-Ara h 13) that are highly resistant to heat. The three major ones (Ara h 1-Ara h 3) are members of the cupin superfamily of proteins (Ara h 1 and Ara h 3, containing a conserved barrel domain, cupa is the Latin term for a small barrel), to the 7S and 11S globulin families, respectively, and Ara h 2 is a conglutinin related to 2S albumins. Peanut allergy (affecting 1.3% of the general population) is the most common cause of severe allergy attacks, especially in children, and appears to be on the rise. Peanut allergy symptoms can range from a minor irritation to a life-threatening reaction (anaphylaxis). For some people with peanut allergy, even tiny amounts of peanuts can cause a serious reaction.

10.3.2.1.6 Other foods

Allergenicity has been demonstrated in a number of other plant materials, exemplified by green peas, rapeseed, mustard, sesame seed and other materials. The common characteristics of these allergens are low molecular weight and high content of cysteine/cystine. Methods for reducing their allergenicity have not been found. Owing to the high content of disulfide bonds in the molecule, these allergens are resistant to hydrolysis by proteases.

10.3.2.2 Other allergens

10.3.2.2.1 Coeliac disease

Coeliac disease (also known by the Latin name *coeliac sprue*), non-tropical sprue or gluten enteropathy is an autoimmune malabsorption disorder of the small intestine caused by sensitivity to gluten (a protein found in wheat) and to similar proteins in rye, barley and oats. The disease is caused by gliadine (prolamine) and gluteline fractions of wheat protein (called gluten) or gluteline fractions of barley (hordeine) and rye (secaline) having two amino acid sequences: Pro-Ser-Gln-Gln and Gln-Gln-Gln-Pro. Coeliac disease does not cause abnormal production of IgE.

Coeliac disease may occur in genetically predisposed people of all ages from middle infancy onward. The prevalence of coeliac disease in different countries varies considerably. The global average is about 1/3350. In children, celiac disease usually occurs soon after they are first given a diet containing gluten (semolina porridge, biscuits or soup thickened with flour). Infants, toddlers and young children may often exhibit growth failure, vomiting, bloated abdomen, behavioural changes and failure to thrive. In adults, celiac disease can be triggered for the first time between 30 and 50 years of life after surgery, viral infection, severe emotional stress, pregnancy or childbirth. It can manifest similarly as in children, but often there are cases with less developed symptoms.

At present, the only sure way to cure celiac disease is to follow a gluten-free diet for life, avoiding wheat, rye and barley. As alternatives, products containing millet, maize, rice, amaranth, buckwheat, soybeans and edible chestnuts may be consumed. Vegetables, including potatoes, fruits, meat, fish, eggs, milk and milk products are also allowed.

The EU adopts common rules concerning the composition and labelling of foods for people who are intolerant to gluten. Very low gluten foods containing ingredients made from wheat, rye, barley, oats or their crossbred varieties that have been especially processed to reduce gluten, must not contain a level of gluten exceeding 100 mg/kg. In order to be labelled 'Gluten-free', products must not exceed 20 mg gluten content per kilogram.

10.3.3 Toxins

Toxins are produced by microorganisms, plants and some animals. They are classified according to various criteria, such as structure,

biological effects, origin and so on, but so far there is no clear system of classification. Classification according to the structure of toxins is thus largely applied in this chapter, but in some cases this system is also combined with classification according to origin (occurrence) and biological effects. Not all toxic compounds are included. Many others are described in sections devoted to amino acids, peptides, proteins, lipids, carbohydrates, minerals, flavourings, pigments, food additives and contaminants. No attempt has been made to cover toxic compounds that are primarily of pharmaceutical and medicinal interest, nor has an attempt been made to cover toxic compounds accidentally ingested or taken as illicit drugs.

10.3.3.1 Alkaloids

Alkaloids are a heterogeneous group of substances comprising more than 10 000 compounds of different structures. Alkaloids are basic nitrogenous compounds produced as secondary metabolites that exhibit a variety of biological effects, depending on the amount consumed. They often occur as a mixture of compounds of related structures, either as free compounds, *N*-oxides, salts of carboxylic acids, their esters or amides, or as glycosides. Some products are considered as detoxification plant products, growth regulators, and spare forms of nitrogen that may have an important role in protecting plants against elicitors and pathogens and in the evolution of plant species.

Alkaloids are found in about 15–20% of vascular plants, in seeds, leaves, roots, bark and other parts, but they similarly occur in certain species of mosses, fungi, bacteria and some invertebrates (centipedes, beetles, butterflies and crustaceans) and vertebrates (e.g. in frogs and salamanders). Alkaloids of certain species of insects and other animals are often of plant origin, but may also be synthesised *de novo*.

No evaluation criterion exists that would allow the characterisation of alkaloids as a single group of natural substances. Some alkaloids are also classified as herbal antibiotics (natural pesticides), because they are a part of the defence mechanisms of plants against elicitors and predators. Some alkaloids are classified as natural toxic amino acids (such as ibotenic acid and agaritine), biogenic amines (e.g. histamine, hordenine or psilocin) and natural dyes (betalaine or berberine). Many alkaloids and related compounds also arise during thermal processing of foods from essential nutrients. For example, a number of indole alkaloids are produced in the Maillard reaction, such as β-carbolines (see Section 2.5.2.3.1), quinoline and quinoxaline derivatives and other biologically active nitrogen heterocycles, such as aminoimidazoazaarenes.

Alkaloids are normally classified into three main basic groups:

- **true alkaloids**
- **pseudo alkaloids**
- **protoalkaloids**.

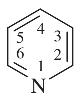
True alkaloids are typically heterocyclic nitrogen bases derived from amino acids. They exhibit a wide range of physiological effects and are often highly toxic to humans and other animals (such as nicotine in tobacco). Pseudo alkaloids are heterocyclic nitrogen bases, nevertheless their precursors are not amino acids, but terpenoids or purines. They are generally less toxic than true alkaloids. Examples of pseudo alkaloids are caffeine in coffee and solanine in potatoes. Protoalkaloids are basic amines derived from amino acids, but the nitrogen is not a part of the aromatic (heterocyclic) system. An example is capsaicin present in hot peppers.

Common to all three groups is the classification of the individual alkaloid groups according to the heterocyclic compounds from which the basic skeletons are derived. True alkaloids with a pyridine ring are, for example, nicotine and many other tobacco alkaloids. Besides the pyridine ring, these alkaloids also contain pyrrolidine and piperidine rings. The black pepper alkaloid piperine is also derived from the piperidine ring. Many alkaloids of medicinal plants called necines are derived from pyrrolizidine, lupine alkaloids are derived from chinolizidine, quinine from the bark of the cinchona tree is derived from quinoline and berberine found in barberry and other plants is derived from isoquinoline. Pseudo alkaloids, such as caffeine in coffee and tea, are derived from purine, glycoalkaloids containing nitrogen in the molecule, such as solanine in potatoes, are derived from steroids. Protoalkaloids of hot peppers are derivatives of vanillic acid amide, called capsaicinoids.

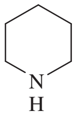
Another aspect is also frequently applied, which is the alkaloid origin. Nicotine, for example, is included among the tobacco alkaloids and quinolizidine alkaloids occurring in different types of lupine are lupine alkaloids. For practical reasons, classification based on these principles has also been used in the following sections. Today, classification according to the precursors of alkaloid biosynthesis is often promoted. This, however, requires a detailed knowledge of the biogenesis mechanisms (Table 10.2).

10.3.3.1.1 Pyridine alkaloids

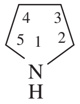
The most important alkaloids, which contain the pyridine ring (**10-4**) in the molecule, are tobacco alkaloids. Besides the pyridine ring, tobacco alkaloids also contain some 1,2,5,6-tetrahydropyridine (piperidine, **10-5**) and pyrrolidine (**10-6**) rings.



10-4, pyridine



10-5, piperidine



10-6, pyrrolidine

Structure, nomenclature and occurrence

The main alkaloid of different cultivars of commercial tobacco species (*Nicotiana tabacum* and *N. rustica*, Solanaceae) is nicotine, (*S*)-1-methyl-2-(pyrid-3-yl)pyrrolidone or (*S*)-3-(1-methylpyrrolidin-2-yl)pyridine, **10-7**. Nicotine is also present in small quantities in other plants (about 24 species of 12 plant families), but especially in plants of the nightshade family, which also includes potatoes, tomatoes and eggplants (aubergines). Biosynthesis of nicotine takes place in the roots of plants, from where nicotine is transported to the aerial parts, especially to the leaves.

Table 10.2 Overview of important alkaloids occurring in foods.

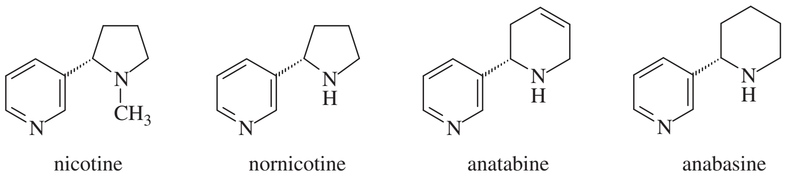
Structural types of basic skeleton	Precursors	Occurrence	Examples
True alkaloids			
Pyridine, piperidine and pyrrolidone alkaloids[a]	Arg, Lys, Orn, nicotinic acid	Tobacco leaves	Nicotine, nornicotine, anatabine, anabasine
	Lys, Phe	Black pepper seeds	Piperine
Pyrrolizidine alkaloids[b]	Arg, Ile, Leu, Orn, Val, Thr	Ragworts, groundsels	Senecionine
Nortropane alkaloids	Putrescine	Potatoes, tomatoes	Calystegines
Quinolizidine alkaloids	Lys	Lupin seeds	Lupanine, lupinine, sparteine
Quinoline alkaloids[c]	Trp, mevalonic acid	Cinchona bark	Quinine, quinidine
Protoalkaloids			
Capsaicinoids (vanillylamides)[d]	Leu, Phe, Val, malonyl-CoA	Chili pepper	Capsaicine, nordihydrocapsaicine, homodihydrocapsaicine
Pseudoalkaloids			
Purine alkaloids	Purines	Coffee, tea, cocoa	Coffeine, theobromine, theophylline
Steroid (terpenoid) glycoalkaloids	Mevalonic acid	Potatoes, tomatoes	Solanine, tomatine

[a]Pyridine ring is derived from nicotinic acid, which arises from aspartic acid and glyceraldehyde 3-phosphate via quinolinic acid; pyrrolidine ring in nicotine and nornicotinu arises from Orn, piperidine ring in anatabine and anabasine arises from Lys. Dihydropyridine ring of natural pigments betalaines arises from Tyr via DOPA and betalamic acid.

[b]Pyrrolizidine skeleton is derived from Orn. Necic acids, by which some alkaloids are esterified, such as senecic acid, arise from Ile.

[c]Precursors are Trp and monoterpenic glycoside loganin. Not listed are numerous other alkaloids derived from Trp (up to about a quarter of all alkaloids), such as indole protoalkaloids tryptamines that are covered under biogenic amines (e.g. gramine) as well as hordenine arising from Tyr. Excluded are also toxic components of higher fungi (such as psilocin) and toxic byproducts of amino acids (such as β-carbolins). Phe is a precursor of vanillylamine.

[d]The fatty acid in capsaicine is derived from Val.



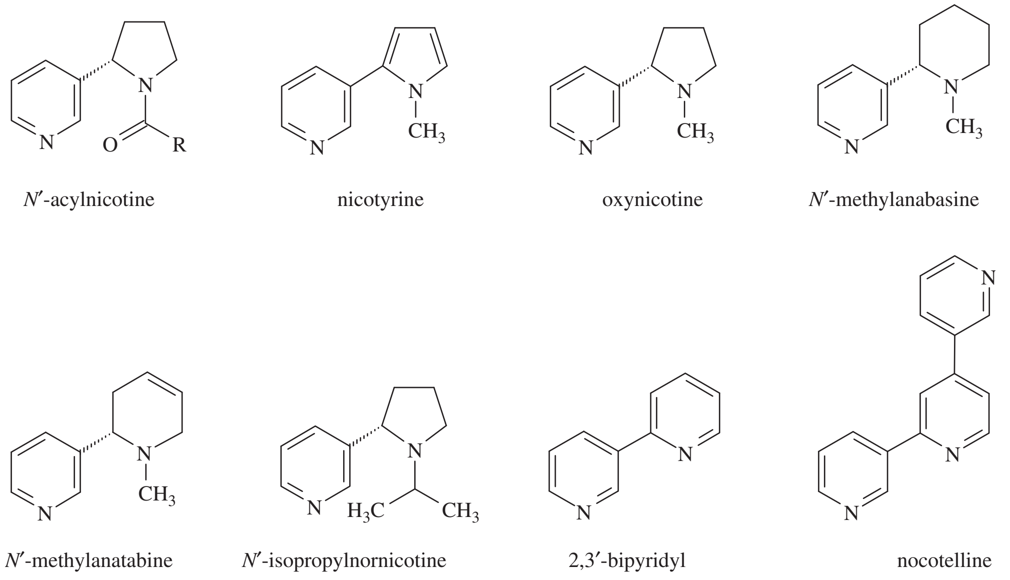
10-7, main tobacco alkaloids

Nicotine in tobacco is always accompanied by three other prominent alkaloids: nornicotine, (*S*)-2-(3-pyridyl)pyrrolidone, anatabine, (*S*)-2-(pyrid-3-yl)-1,2,5,6-tertrahydropyridine and anabasine, (*S*)-2-(pyrid-3-yl)piperidine (**10-7**). Apart from these main alkaloids, more than 20 other minor tobacco alkaloids (**10-8**) have been identified.

The total content of alkaloids in tobacco ranges from 0.3 to 3% of dry matter, depending on the species and varieties of plants, climatic and soil conditions and other factors. Approximately 95% of this amount is represented by nicotine. For example, leaves of the so-called bright-leaf tobacco, commonly known as Virginia tobacco (*N. tabacum*), with a total alkaloid content of 1.93%, containing 1.85% of nicotine, contains 0.04% of anatabine, 0.03% of nornicotine and 0.01% of anabasine. The content of other (minority) alkaloids is less than 0.01%.

Reactions and changes

The content of nicotine and other alkaloids in fresh tobacco leaves decreases slightly during post-harvest treatment, drying and fermentation. During tobacco drying and fermentation, nicotine produces nornicotine through transmethylation, which partially decomposes to nicotinic acid via myosmine. Anabasine and anatabine are formed as products of nicotine catabolism (Figure 10.1). In tobacco products, the content of alkaloids does not change. One cigarette (about 0.8 g of tobacco) contains 1 mg



10-8, minor tobacco alkaloids

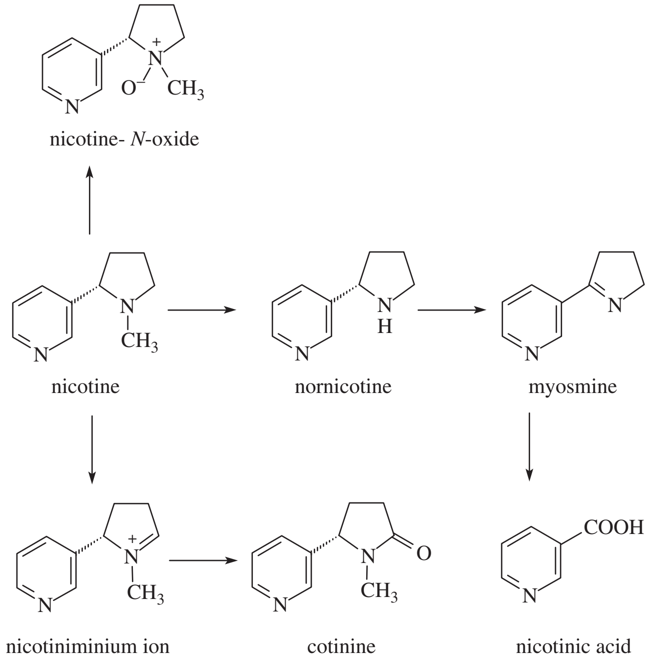


Figure 10.1 Products arising from nicotine during tobacco fermentation.

of absorbable nicotine and new products with reduced nicotine content (light, superlight and ultra light cigarettes) usually have a nicotine content of from 0.1 to 0.8 mg.

During tobacco burning, nicotine is partially oxidised to cotinine and oxynicotine that rapidly decomposes at higher temperatures. Pyrolysis of nicotine also produces hydrogen cyanide (0.004–0.270 mg per one cigarette) and other products. The resulting nitrogen oxides react with the decomposition products of nicotine to form carcinogenic nitrosamines.

Biological effects

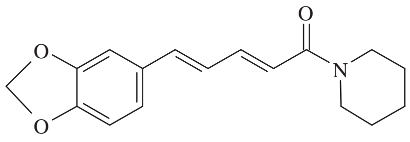
Nicotine is a potent neurotoxin, particularly for insects. In the past, a tobacco extract was used as an insecticide. In mammals, nicotine in low concentrations acts as a stimulant, but it is also the main addictive component of tobacco, which is absorbed by the body primarily from smoke. Smaller volume tobacco products are snuff and chewing tobacco. Moderate nicotine doses increase respiratory and motor activity and lead to vomiting, high doses results in tremors and end in coma. The sensitivity of animals to nicotine ranges from 6 to 30 mg/kg. Somewhat lower toxicities are exhibited by nornicotine and anabasine. Anabasine (and probably also anatabine) show teratogenic effects. Chronic pathological changes in the respiratory system and carcinogenicity of tobacco smoke have been clearly demonstrated; therefore Directive 90/239/EEC established maximum limits for the carcinogenic tar, nicotine and carbon monoxide yields of cigarettes marketed in the EU Member States. Since 1 January 2004, the amount per cigarette must not be greater than 10 mg for tar, 1 mg for nicotine and 10 mg for carbon monoxide.

10.3.3.1.2 Piperidine alkaloids

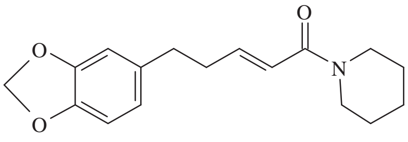
The most important alkaloids derived from piperidine (**10-6**) are alkaloids of black pepper (*Piper nigrum*, Piperaceae).

Structure, nomenclature and occurrence

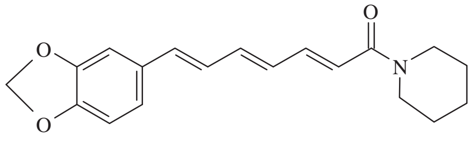
The main hot component of black pepper is piperine, piperic acid amide or (2*E*,4*E*)-piperoyl-1-piperidine or (2*E*,4*E*)-5-(1,3-benzodioxol-5-yl)-*N*-piperidinylpenta-2,4-dienamide (**10-9**). Black pepper also contains a number of related compounds as minor components, such as piperanine (**10-9**) and *N*-(3,4-methylendioxyphenyl)acylpiperidines with C_3, C_5, C_7 and C_9 acyls and the corresponding pyrrolidines, such as piperettine, piperyline, piperoleine A, piperoleine B (**10-9**) and other compounds.



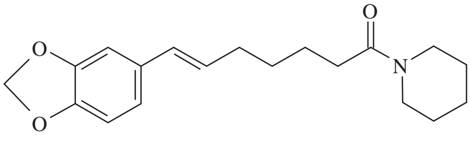
piperine



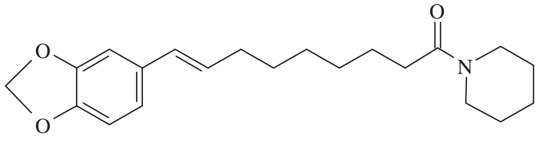
piperanine



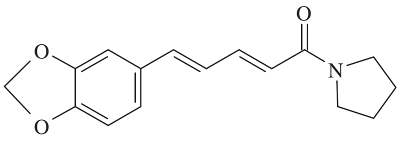
piperettine



piperoleine A



piperoleine B



piperyline

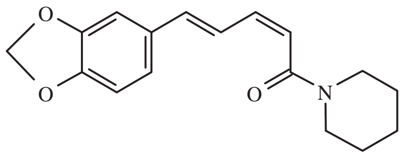
10-9, piperine and related alkaloids of black pepper

Many other unsaturated amides have been identified in *Piper* species from all tropical regions of the world.

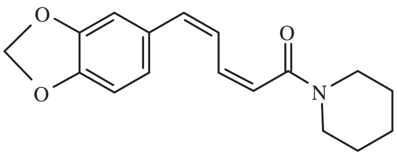
Piperine content is typically 3–8% (and sometimes more), but it depends on the origin and other variables. The highest amount of piperine in pepper fruits is just before full maturity. Green pepper, obtained from unripe fruits, therefore contains a considerable amount of piperine, as well as black pepper, which is obtained by fermentation of green seeds (see Section 8.3.6.2). The content of piperine in white pepper, which is obtained from ripe red seeds with the coloured skin removed, is somewhat lower. The level of minor alkaloids piperyline and piperettine is only 0.2–0.3% and 0.2–1.6%, respectively. The piperine content in oleoresins is normally 35–40%, which corresponds to minced spice in a ratio of about 1 : 25.

Reactions and changes

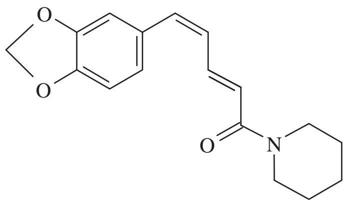
Piperine is very stable in intact seeds and in ground seeds. If protected from light, piperine is stable for at least 6 months if stored in paper and for 10 months in aluminum packaging, but is easily oxidised in air. Piperine in solutions, in ground spice and in oleoresins is accompanied by its diastereoisomers, (2*Z*,4*E*)-piperoyl-1-piperidine (isopiperine), (2*Z*,4*Z*)-piperoyl-1-piperidine (chavicine) and (2*E*,4*Z*)-piperoyl-1-piperidine (isochavicine, **10-10**), which arise by enzyme-catalysed and/or light-induced *cis/trans* isomerisations of the double bonds of the parent piperine molecule. However, they show little or no (isochavicine) pungency. Alkaline hydrolysis of piperine yields the salt of piperic acid, (2*E*,4*E*)-5-(3,4-methylenedioxyphenyl)-2,4-pentadienoic acid, and piperidine. In



isopiperine



chavicine



isochavicine

10-10, piperine isomers

slightly acidic solutions, piperine may react with nitrites to form nitrosamines.

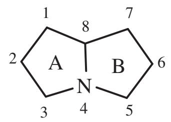
Biological effects

Piperine acts as a stimulant of the central nervous system, has weak antipyretic and mutagenic effects and inhibits some enzymes acting in the metabolism and transport of xenobiotics and drugs. Reportedly, piperine is beneficial for increasing thermogenesis (the process of generating energy in cells), which may also be helpful in reducing inflammation, improving digestion, and relieving pain and asthma. At higher concentrations, piperine damages tongue tissue, and lowers blood pressure and breathing rate. Other piperine derivatives of pepper show irritating, antimicrobial and insecticidal effects. Some related compounds in pepper exhibit antioxidant effects.

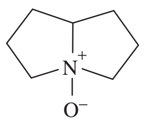
10.3.3.1.3 Pyrrolizidine alkaloids

Pyrrolizidine alkaloids are a large and important group of about 250 alkaloids produced by approximately 6000 plant species belonging to 13 families. The most important plants belong to the families Boraginaceae, Asteraceae, Heliotropiaceae, Fabaceae and Rhamnaceae. Pyrrolizidine alkaloids occur in relatively small amounts (0.1–1% of dry matter) as a complex mixture of more than ten different compounds. Important sources of alkaloids are some herbs and certain fodder plants.

The skeletons of pyrrolizidine alkaloids are derived from 2,3,5,6,7,8-hexahydro-1*H*-pyrrolizine, known as pyrrolizidine (**10-11**), and from pyrrolizidine-*N*-oxide (**10-12**). The bases of the pyrrolizidine alkaloids are necines (necine bases) derived from bicyclic amino alcohols, which have their origin in 1-hydroxymethylpyrrolizidine. Necines may be saturated or may have a double bond at C-1 of ring B and may also have an additional one or two hydroxyl groups at C-2, C-6 or C-7. Necines are esterified with carboxylic acids, which are called necic acids. Biosynthesis takes place in the roots, where the alkaloids occur as the corresponding *N*-oxides. They are then transported to the aerial parts of the plant and stored in vacuoles.



10-11, pyrrolizidine



10-12, pyrrolizidine-*N*-oxide

Structure, occurrence and terminology

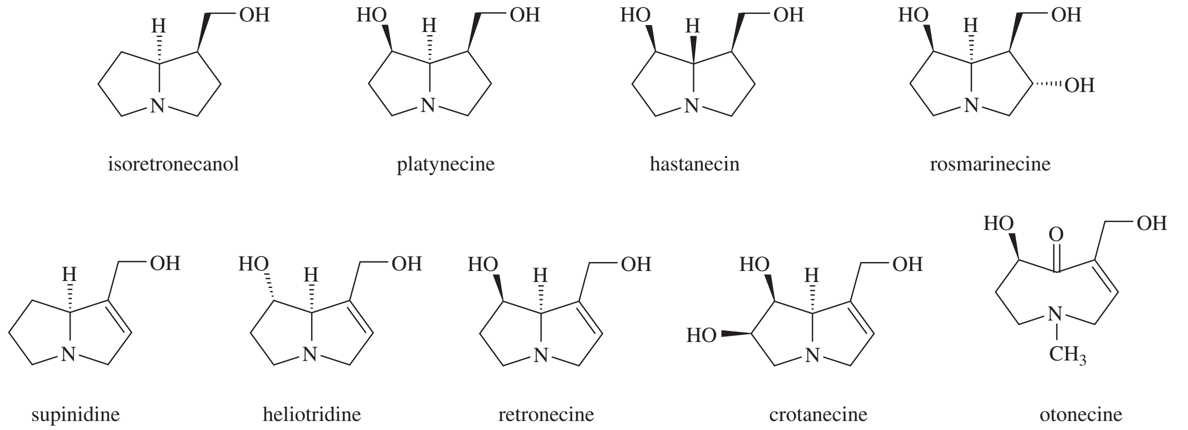
The most frequently occurring necines in medicinal plants are supinidine, isomeric retronecine and heliotridine, platynecine, hastanecine and otonecine (**10-13**).

Necine bases are esterified by different carboxylic acids. With the exception of acetic acid, these acids have 5–10 carbon atoms and include mono- and dicarboxylic acids with branched chains substituted with hydroxyl, methoxyl (other alkoxyl), epoxy, carboxy and acetoxy groups. Necines with two hydroxyls, such as 7,9-necinediol, may be esterified with carboxylic acids in positions C-7 and C-9 or in both positions. Esterification with dicarboxylic acids produces macrocyclic alkaloids with 11 to 14-membered rings. Depending on the ester type, the following alkaloids can be recognised:

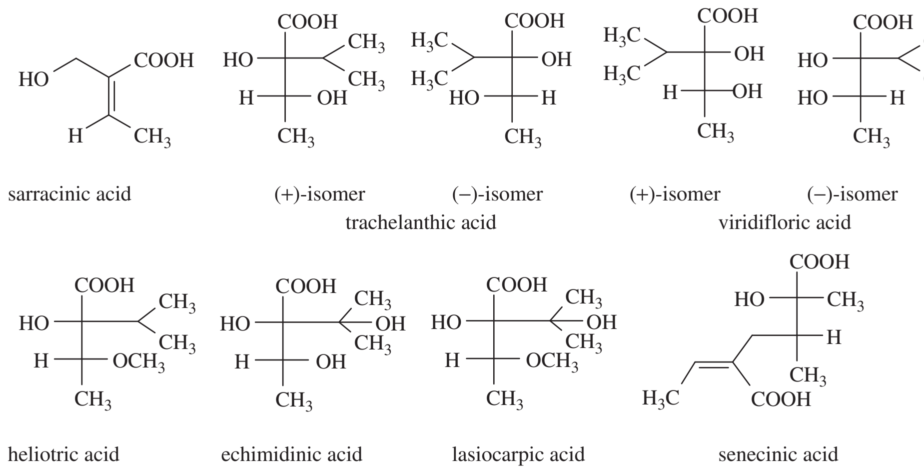
- monoesters
- diesters
- macrocyclic diesters.

The most frequently occurring carboxylic acids with five carbon atoms per molecule are (*Z*)-2-methylbut-2-enoic acid, also known as (*Z*)-2,3-dimethylacrylic or angelic acid, its isomer (*E*)-2-methylbut-2-enoic acid, known as (*E*)-2,3-dimethylacrylic (tiglic) acid, (*Z*)-3-methylbut-2-enoic acid (senecioic) acid (8-62) and (*Z*)-2-hydroxymethylbut-2-enoic (sarracinic) acid (**10-14**).

Frequent carboxylic acids with seven carbon atoms per molecule are (+)-trachelanthic acid, namely (2*S*,3*R*)-2,3-dihydroxy-2-isopropylbutanoic acid, (−)-trachelanthic acid, which is (2*R*,3*S*)-2,3-dihydroxy-2-isopropylbutanoic acid, (+)-viridifloric



10-13, necine bases



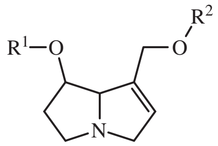
10-14, necic acids

acid, also known as (2*R*,3*R*)-2,3-dihydroxy-2-isopropylbutanoic acid, and (−)-viridifloric acid, namely (2*S*,3*S*)-2,3-dihydroxy-2-isopropylbutanoic acid (10-14). Methyl derivatives of these acids have eight carbon atoms in the molecule. For example, a methyl derivative of (+)-trachelanthic acid is (2*S*,3*R*)-2-hydroxy-3-isopropyl-3-methoxybutanoic (heliotric) acid, three hydroxyl groups in the molecule has (2*R*,3*R*)-2,3-dihydroxy-2-(1-hydroxyethyl)-3-methylbutanoic (echimidinic) acid and its methyl derivative is (2*R*,3*R*)-2,3-dihydroxy-2-(1-methoxyethyl)-3-methylbutanoic (lasiocarpic) acid (**10-14**). An example of necic acid bound in the macrocyclic diesters (having ten carbon atoms) is (2*S*,3*R*,5*Z*)-5-ethylidene-2-hydroxy-2,3-dimethylhexane-1,5-dioic acid (senecinic) acid (**10-14**).

Pyrrolizidine alkaloids are found in some medicinal herbs that are used as a traditional medicine in many countries. These plants grow mainly in temperate climates, but some require tropical or subtropical climates. The Boraginaceae family is represented by common comfrey (*Symphytum officinale*), borage (*Borago officinalis*), common bugloss (*Anchusa officinalis*), viper's bugloss or blueweed (*Echium vulgare*) and houndstongue (*Cinoglossum officinale*). The Asteraceae family includes coltsfoot (*Tussilago farfara*), butterbur (*Petasites hybridus*) and the Rhamnaceae family includes buckthorn (*Rhamnus cathartica*). For example, butterbur, used as a remedy for headache and inflammation, has the total alkaloid content in the root of about 0.01%, but the alkaloid content in other parts of the plant is negligible. The main alkaloid is senecionine.

Pyrrolizidine alkaloids also contain a number of plants that can become part of the feed, and therefore may cause poisoning of livestock. Examples are the legume forage plants of the genus *Crotalaria* (Fabaceae), commonly known as rattle pods, and especially *C. spectabilis* used for green manure and as cover crops in subtropical and tropical regions of Africa, Asia and the United States. Also poisonous to cattle are some plants of the Asteraceae family, such as ragwort (*Senecio jacobaea*), hemp-agrimony (*Eupatorium cannabinum*), summer ragwort (*Ligularia debtata*) and bill goat weed (*Ageratum conyzoides*) and European heliotrope (*Heliotropium europeum*) of the Boraginaceae family.

The main comfrey alkaloids (echinatine, echimidine, heliosupine and lasiocarpine) and European heliotrope alkaloids (heliotrine, lasiocarpine and symphytine, **10-15**) formulae are shown as examples of monoesters and diesters of various necines. Echimidine is derived from retronecine; other alkaloids are derived from heliotridine. Examples of macrocyclic diesters derived from retronecine are alkaloids of ragwort senecionine and seneciphylline and alkaloids of the *Crotalaria* legumes fulvine and monocrotaline (**10-16**).



10-15, monoesters and diesters

echinatine, R^1 = H, R^2 = viridifloroyl

monocrotaline, R = OH

Reactions and changes

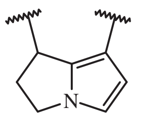
The concentration of alkaloids in toxic plants is highly variable, even between different parts of the same plant, and depends on many other factors. When preparing medicinal herbal teas, most

alkaloids leach into water. Stability of individual compounds is not known, but it can be supposed that partial hydrolysis of esters to necine bases and carboxylic acids may occur.

Biological effects

Most plants containing pyrrolizidine alkaloids are toxic to humans and domestic animals. Poisoning occurs most frequently after eating different parts of plants as food (such as salads from young leaves of comfrey and butterbur), extracts from medicinal herbs or contaminated cereals. Cattle, horses, farmed deer and pigs are most susceptible; sheep and goats require about 20 times more plant material than cattle. Acute poisoning is rare and is characterised by sudden death from haemorrhagic liver necrosis and visceral haemorrhages. Chronic exposure is more typical. The signs in horses and cattle include loss of condition, anorexia, dullness and constipation or diarrhea. Residues of alkaloids may appear in milk and other animal products, but these residues are not risky. Another example may be contamination of honey to which the pyrrolizidine alkaloids are transferred by bees. Pyrrolizidine alkaloids have been identified in floral honeys attributed to plants in the Boraginaceae (*Heliotropium* spp., *Echium* spp.) and the Asteraceae (*Senecio* spp.) families. For example, honey from viper's bugloss flowers may contain 0.3–1 mg/kg of alkaloids with echimidine as the main component.

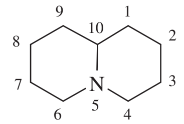
Pyrrolizidine alkaloids are hepatotoxins (substances that deplete the liver) and carcinogens. Characteristic symptoms of toxicose are magnification of liver cells (hepatocytes) called megalocytosis, hyperplasia (enlargement of the liver due to multiplication of cells), liver fibrosis (extensive scarring of the liver) and subsequent symptoms of liver dysfunction, such as hyperbilirubinaemia (an elevated blood level of the pigment bilirubin), hypoalbuminaemia (an abnormally low blood level of albumin), oedema, jaundice and cirrhosis. Alkaloids are not responsible for the toxic effects as such, but rather it is the pyrrole structures (**10-17**) arising from alkaloids that act as alkylating agents. These structures arise by transformation of 1,2-unsaturated compounds (supinidine, retronecine, heliotridine and otonecine derivatives) in the liver. Toxic substances are also aldehydes formed as breakdown product of alkaloids, such as (*E*)-4-hydroxyhex-2-enal.



10-17, toxic metabolites of pyrrolizidine alkaloids

10.3.3.1.4 Quinolizidine alkaloids

Quinolizidine alkaloids, hypothetically derived from quinolizidine (**10-18**), are a special group of bicyclic, tricyclic and tetracyclic secondary metabolites of some legumes, especially legumes of the genera *Lupinus*, *Baptisia*, *Thermopsis*, *Genista*, *Cytisus*, *Chamaecytisus*, *Laburnum* and *Sophora* (Fabaceae), which occur as a complex mixture of several compounds. Quinolizidine alkaloids are also secondary metabolites of some plants of the Chenopodiaceae, Ranunculaceae, Berberidaceae and Solanaceae families.



10-18, quinolizidine

Structure, nomenclature and occurrence

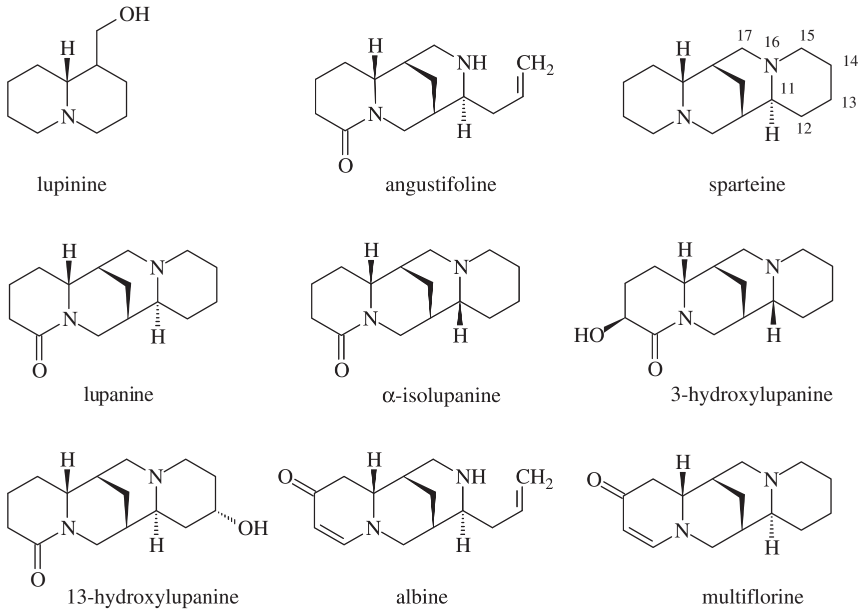
Quinolizidine alkaloids occur in seeds (beans) of certain species of lupines (*Lupinus* spp., Fabaceae), including domesticated varieties. In Europe, Africa and America, lupines have been used as valuable pulses for human nutrition and feeding livestock from ancient times. Native species growing in south-western Europe are white lupine (*L. albus*), blue (narrow leaf) lupine (*L. angustifolius*) and yellow lupine (*L. luteus*). Yellow lupine is currently grown in Western Australia, particularly for feed, and for human nutrition in many countries of Asia. Beans of pearl (Andean) lupine (*L. mutabilis*), called tarhui or tarwi, are eaten as pulses by South American Indians of the Andes region and also used as an oil crop (mainly in Chile).

Seeds of different lupines contain more than 100 bicyclic, tricyclic and tetracyclic quinolizidines. With respect to economically important lupine species, the major alkaloids are lupinine, angustifoline, sparteine, also known as lupinidine, lupanine, α-isolupanine, 3β-hydroxylupanine, 13α-hydroxylupanine, albine and multiflorine (**10-19**). These alkaloids are accompanied by a series of related alkaloids and esters of hydroxylated alkaloids with benzoic, *p*-coumaric, sinapic acids and other organic acids. The hydroxyl group of *p*-coumaric acid is often glycosylated by α-L-rhamnose. The content of alkaloids in plant seeds is highly dependent on the plant species and climatic conditions. The alkaloid content in seeds of original bitter varieties of *L. angustifolius* normally ranges from 1 to 3 and can be up to 5%. The alkaloid content of sweet varieties obtained by breeding is only 0.01–0.03%, but can be also 0.001%. For example, the maximum alkaloid content of seeds of sweet lupine varieties in Australia is 0.002% and in Chile 0.05%.

The composition of the major alkaloids of different lupine seed species is shown in Table 10.3. The main alkaloids of white lupine seeds are lupanine and albine, of blue lupine seeds lupanine and 13-hydroxylupanine and of yellow lupine seeds lupinine and sparteine. The content of other toxic and antinutritional substances (lectins, trypsin inhibitors and phytates) in lupine seeds is similar to the content of other legume seeds.

Reactions and changes

Lupine alkaloids are very stable compounds. During processing and storage of lupine seeds, their content does not change. The most common way of debittering (removal of alkaloids) is extraction of ground seeds with water (by soaking or boiling). These procedures can reduce the alkaloid content by about 100 times.



10-19, quinolizidine alkaloids of lupin seeds

Table 10.3 Main alkaloids content in lupine seeds.

	Content (% of total alkaloid content)			
Alkaloid	***L. albus***	***L. angustifolius***	***L. luteus***[a]	***L. mutabilis***
Lupinine	-	-	60	-
Sparteine	<1	<1	30	16
Albine	15	-	-	-
Angustifoline	<1	10–16	-	1
Lupanine	70	70	<1	46
3-Hydroxylupanine	-	-	-	12
13-Hydroxylupanine	8	12–38	-	7
Multiflorine	3	-	-	-

[a]The seeds of some varieties contain up to 1200 mg/kg of protoalkaloid gramine.

The fat content of lupine is relatively small, except for the South American species *L. mutabilis*, which contains about 22–24% of oil in dry matter). In the technological production of oil from this lupine, about 60% of alkaloids present in bitter varieties are removed during extraction with hexane. Subsequent refining decreases their concentration in the oil down to 0.0005%. Meals are debittered by extraction with ethanol containing hydrochloric acid, which decreases the alkaloid content from the original amount of 3.2% to 0.1–0.2%.

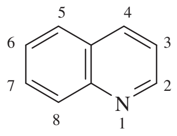
Biological effects

Individual alkaloids exhibit different toxicities as they are hepatotoxic and teratogenic and may represent a hazard for humans and livestock. Lupanine and sparteine are the most toxic substances. Ingestion of 11–25 mg of lupine alkaloids per kilogram of body weight may cause serious health disorders that are manifested by nervousness, vomiting, breathing difficulties, impaired vision and sweating, progressive weakness and, in extreme cases, may end in coma. Alkaloids obtained during lupine seed debittering are used as pesticides and in human medicine.

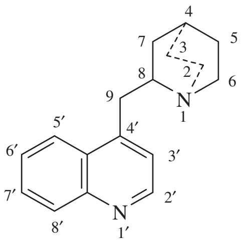
10.3.3.1.5 Quinoline alkaloids

Alkaloids hypothetically derived from quinoline (**10-20**) are a large group of secondary plant metabolites, also called terpenoid indole alkaloids. These alkaloids are found in many plant families, such as Apocynaceae, Loganiaceae, Rubiaceae and Nyssaceae. More than 3000 quinoline alkaloids are known, some of which are used in medicine. The most important quinoline alkaloids are alkaloids

derived from the basic skeleton of rubane (**10-21**), which are found in bark of cinchona or quina trees (*Cinchona* spp., Rubiaceae) native to the tropical forests of western South America, but which today are grown also in other countries.



10-20, quinoline



10-21, rubane

Structure, nomenclature and occurrence

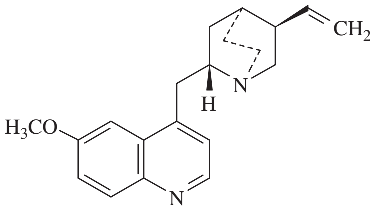
The quinine molecule consists of a quinoline ring with a methoxyl group in position C-6′ and quinuclidine bicyclic structure with a vinyl group (at C-3) in position C-4′, which is bound through carbon C-9 bearing a hydroxyl group. Quinine has asymmetric centres at carbons C-3, C-4, C-8 and C-9. The steric configurations at C-3 and C-4 in the major cinchona bark alkaloids quinine, quinidine, cinchonine and cinchonidine (**10-22**) are the same. Quinidine, the optical isomer of quinine, has a different spatial arrangement of C-8 and C-9 and cinchonidine, which lacks the C-6 methoxyl group, has the same spatial arrangement as quinine. Its isomer is cinchonine, which corresponds in spatial arrangement to quinidine.

The genus *Cinchona* includes about 40 tree species, of which about 12 are of commercial importance. Alkaloids in the bark of *Cinchona officinalis* occur in an amount of 5–8%, of which 2–7.5% is quinine (10-22). The total alkaloid content of *C. succiruba* (syn. *C. pubescens*) bark is 6–16% (quinine content is 4–14%), 5–14% (3–13% represents quinine) is in the bark of *C. ledgeriana* and 3–7%, of which 0–4% is quinine, occurs in *C. calisaya* bark.

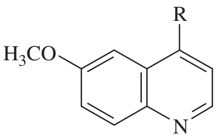
Quinine, isolated from cinchona bark in the form of hydrochloride or sulfate, is mainly used in medicine as an antimalarial and antipyretic medication. In sensory analysis it is used as a standard of bitterness and in the food industry for the production of bitter soft drinks, such as bitter lemon and Indian tonic waters, and in some alcoholic beverages (such as the flavoured wine Barolo Chinato in Italy) for its distinctive bitter taste. The taste threshold concentration of bitter taste perception is about 10 mg/l.

Reactions and changes

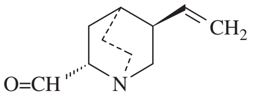
In light, quinine is degraded by photochemical reactions. The main product of degradation in acidic media is 9-deoxyquinine (**10-23**), in slightly acidic and neutral solutions (e.g. in beverages) quinine yields 6-methoxy-4-methylquinoline, 6-methoxyquinoline (**10-24**) and 2-formyl-5-vinylquinuclidine (**10-25**). In drinks exposed to direct sunlight, quinine is totally degraded within 6 hours of exposure, the degradation is accompanied by a light opalescence, and the bitter taste is no longer perceptible. Dark bottles substantially reduce quinine degradation, and artificial light does not affect the quinine stability.



10-23, 9-deoxyquinine



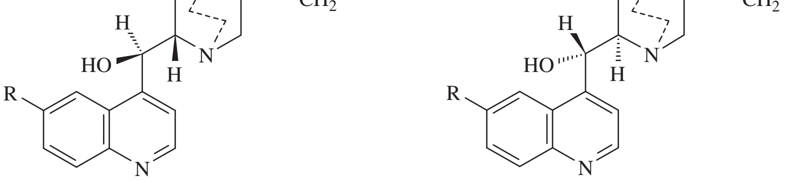
10-24, 6-methoxyquinoline, R = H
6-methoxy-4-methylquinoline, R = CH_3



10-25, 2-formyl-5-vinyl-quinuclidine

Biological effects

Quinine is a protoplasmic toxin (adversely damaging living cells), which inhibits various important enzymes. The ADI value for quinine hydrochloride for adults is 40 mg/kg. Quinine is a teratogenic substance and should never be used by pregnant women, as birth



10-22, cinchona bark alkaloids

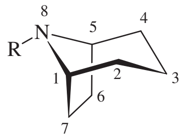
(–)-cinchonidine, R = H
(–)-quinine, R = OCH_3

(+)-cinchonine, R = H
(+)-quinidine, R = OCH_3

defects and miscarriages may occur. Side effects can include ringing in the ears, nausea, blurred vision, chest pain, upset stomachs and breathing problems. The use of quinine is therefore regulated. For non-alcoholic beverages, quinine (sulfate or hydrochloride) may be used in the highest allowable amount of 75 mg/l, while for spirits (bitter alcoholic beverages) the highest amount is 300 mg/l (calculated as free base). According to a new European Commission directive 2002/67/EC, the consumption of quinine in moderation is unlikely to present any health risks and there is no objection from the point of view of toxicology to the continued use of quinine up to a certain maximum level in bitter drinks.

10.3.3.1.6 Calystegines

Calystegines are a relatively new group of bicyclic polyhydroxy alkaloids with a nortropane skeleton (**10-26**), which were originally isolated from the roots of the larger bindweed *Calystegia sepium* (Convolvulaceae). They are biosynthesised together with tropane alkaloids from putrescine via *N*-methylputrescine and other metabolites. The pathway to tropone alkaloids (exemplified, for example, by cocain from the leaves of coca plants, *Erythroxylum coca* and *E. novogranatensen*, Erythroxylaceae, native to western South America) branches and the loss of the *N*-methyl group provides the nortropane skeleton of calystegines.



10-26, nortropane, R = H
tropane, R = CH_3

Structure, nomenclature and occurrence

The structure of calystegines falls into three main classes, calystegines A, B and C (**10-27**), having three, four or five hydroxyl groups, respectively. Diversity within these three classes arises from the positional and stereochemical configuration of these hydroxyl groups. A few calystegines exist that deviate in structure. For example, calystegine N_1 carries an amino group instead of a hydroxyl group on C-1 of the nortropane structure, in addition to three hydroxyl groups on C-2, C-3 and C-4. This calystegine is very labile and undergoes conversion into calystegine B_2. Conversely, calystegine N_1 may be an arefact formed from calystegine B_2 and ammonia.

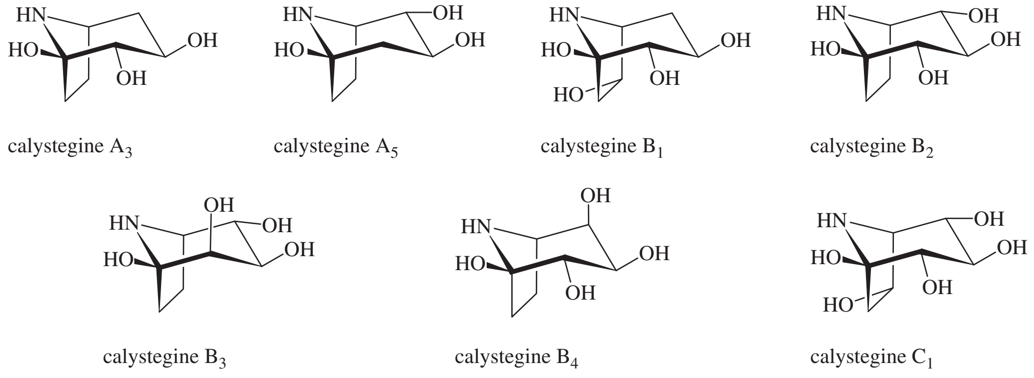
Calystegines have been identified in the plant families Convolvulaceae, Solanaceae, Moraceae and Brassicaceae and have been found in numerous edible fruits and vegetables, especially members of the Solanaceae family, such as potatoes, tomatoes, eggplants and sweet and chili peppers, but also in mulberries and some *Brassica* vegetables and spices, such as kohlrabi, Brussel sprouts and black mustard leaves.

The major calystegines of potatoes are calystegine A_3 and calystegine B_2. Dormant tubers directly after harvest contain less calystegines in all parts than sprouting tubers. In the majority of the potato cultivars their concentration in the peel is between one and two orders of magnitude greater than in the flesh. In the potato cultivars grown in the United States calystegine A_3 and calystegine B_2 ranges were 6–316 mg/kg in dry flesh, 218–2 581 mg/kg in dry peel, 34–326 mg/kg in dry whole potatoes, 1–68 mg/kg in wet flesh, 35–467 mg/kg in wet peel and 5–68 mg/kg in wet whole potatoes. Concentrations in the sproutings are on average 100 times higher than that in the tuber flesh and eight times higher than in the peel. The calystegines in the sproutings include, in addition to the more abundant calystegines A_3 (on average 3999 mg/kg dry matter) and B_2 (7425 mg/kg dry matter), small amounts of four additional types, B_3 (86 mg/kg dry matter), B_4 (319 mg/kg dry matter) and N_1 (15 mg/kg dry matter).

Mulberries (*Morus alba*, Moraceae) contain 4-*O*-β-D-galactopyranosyl-calystegine B_2 (10 mg/kg dry matter), calystegines A_3 and B_2 occur in kohlrabi leaves in amounts of 26 and 7 mg/kg, respectively, calystegine A_3 occurs in the leaves of Brussel sprouts (5 mg/kg dry matter) and calystegines A_3, A_5 and B_2 have been identified in black mustard leaves in concentrations 13, 3 and 2 mg/kg dry matter, respectively.

Reactions and changes

Removal of the peel reduces the calystegine content by an average of over 50% in common potato varieties. Calystegines are water-soluble compounds and their leaching into water can be expected during potato processing.



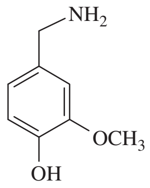
10-27, calystegines

Biological effects

Calystegines exhibit potent specific inhibition of glycosidases that are universally required for normal cell function. Although no human toxicity data for calystegines have been reported, consumption of calystegines has been associated with gastrointestinal upset and it is reasonable to suppose that the calystegines may be responsible, given their propensity to inhibit digestive and hepatic enzymes. The recent discovery of calystegines in widely consumed members of the Brassicaceae family raised concerns about the tolerable overall levels of these alkaloids in the human diet.

10.3.3.1.7 Capsaicinoids

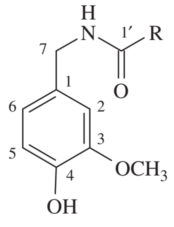
Protoalkaloids capsaicinoids are vanillylamine derivatives, amides of vanillylamine with fatty acids (**10-28**), whose occurrence is restricted to species of hot pepper (*Capsicum* spp.) of the Solanaceae family (see Section 8.3.6.1).



10-28, vanillylamine

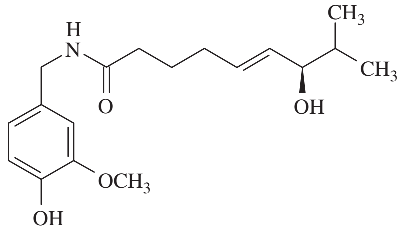
Structure, nomenclature and occurrence

Capsaicinoids (**10-29**) are vanillylamides (*N*-vanillylacylamides) derived from C_8 to C_{11} branched and straight chain *trans*-monoenic and saturated fatty acids. The main components causing a burning sensation when in contact with mucous membranes are capsaicin (*E*)-8-methyl-*N*-vanillylnon-6-enamide and dihydrocapsaicin (8-methyl-*N*-vanillylnonanamide), which constitute about 90% of total capsaicinoids. These capsaicinoids are accompanied by minority alkaloids such as nordihydrocapsaicin, nordihydrocapsaicin II, homodihydrocapsaicin, homodihydrocapsaicin II, homocapsaicin, homocapsaicin II and related compounds, such as pungent (−)-capsaicinol (**10-30**), which also acts as an effective antioxidant.



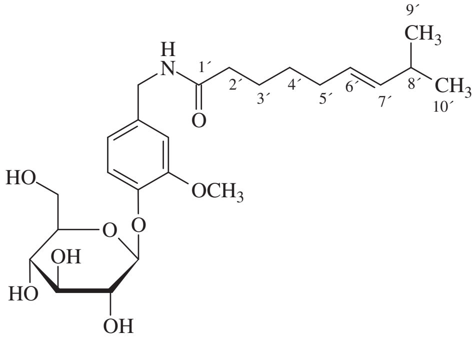
10-29, capsaicinoids

capsaicin, R = $[CH_2]_4CH{=}CHCH(CH_3)_2$
dihydrocapsaicin, R = $[CH_2]_6CH(CH_3)_2$
nordihydrocapsaicin, R = $[CH_2]_5CH(CH_3)_2$
nordihydrocapsaicin II, R = $[CH_2]_4CH(CH_3)CH_2CH_3$
homodihydrocapsaicin, R = $[CH_2]_7CH(CH_3)_2$
homodihydrocapsaicin II, R = $[CH_2]_6CH(CH_3)CH_2CH_3$
homocapsaicin, R = $[CH_2]_4CH{=}CHCH_2CH(CH_3)_2$
homocapsaicin II, R = $[CH_2]_4CH{=}CHCH(CH_3)CH_2CH_3$



10-30, (−)-capsaicinol

The content of capsaicinoids in fruits of *Capsicum* species depends on variety, age, maturity, season and agronomic conditions. Their amount in large bell peppers (*C. annuum*) is usually low, with a higher amount in medium-sized fruits (such as Tabasco, *C. frutescens*) and the highest amount in small chilli peppers (*C. frutescens*). Most alkaloids are found in the flesh and their concentrations are lower in the seeds and skin. Lower amounts of capsaicinoids occur in the young green fruits. The amount of alkaloids increases during the growing and ripening of fruits and reaches a maximum shortly before harvest, and then their concentration decreases slightly. The amount of capsaicinoids in sweeter pepper varieties cultivated in Europe varies in the range of from 0.001 to 0.01%. Chilli peppers typically contain about 0.2–1.5% of alkaloids. For example, of the total amount of 0.4% of capsaicinoids in chilli peppers, about 49% are represented by capsaicin, 44% by dihydrocapsaicin, 6% by nordihydrocapsaicin, 1% by homodihydrocapsaicin and 0.3% by homocapsaicin. In the fruits of hot *C. annuum* cultivars, capsaicin and dihydrocapsaicin can also be found in the form of β-D-glucopyranosides (**10-31**). For example, the concentration of capsaicin-β-D-glucopyranoside ranged from 0.11 to 2.65 mg/kg, while that of capsaicin was 0.03–0.48% fresh weight. Capsaicinoids were also found to be present in vegetative organs, such as stems and leaves. In this case, the proportion of individual capsaicinoids is different to that in fruits, and dihydrocapsaicin is the more abundant compound.



10-31, capsaicin-β-D-glucopyranoside

The burning sensation caused by capsaicinoids in the mouth and throat is their characteristic property. Vanillylamides with a longer or shorter acyl chain than capsaicin have less pungency. There are not particularly large differences between individual capsaicinoids (see Section 8.3.6.1). At concentration of about 10 mg/kg, capsaicin causes burning and pungency, which is perceptible even at a concentration of 0.1 mg/kg. The burning effect is amplified by sucrose and reduced by sodium chloride and solutions with higher viscosity (such as yoghurt). Vanillylamides containing more than 18 carbons in their chain do not stimulate any effect.

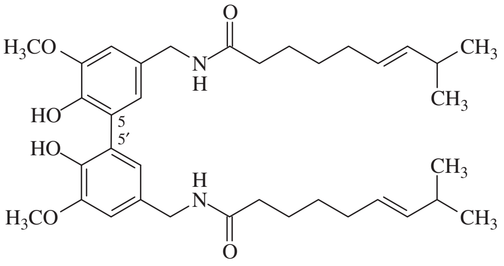
Capsicum plants also contain capsaicinoids with a long-chain acyl moiety. *Capsicum* oleoresin can provide isolation of vanillylamides derived from palmitic acid (palvanil), stearic acid (stevanil), elaidic acid (olvanil) and (9*E*,12*E*)-octadeca-9,12-dienoic acid (livanil) and the existence of myristic acid (myrvanil) and (9*E*,12*E*,15*E*)-octadeca-9,12,15-trienoic acid (linvanil) derivatives was suggested. The content ratios of the total long-chain vanillylamides, except for myrvanil, versus the capsaicin in the oleoresins were significantly larger (0.1–41%) than that in fresh fruits (<0.01%).

Recently identified was another group of non-pungent capsaicinoid analogues produced in *Capsicum* fruits, which were called **capsiconinoids**. Identified compounds were called capsiate, ester of vanillyl alcohol with (*E*)-8-methylnon-6-enoic acid, capsiconiate, ester of coniferyl alcohol with (*E*)-8-methylnon-6-enoic acid and dihydrocapsiconiate, ester of coniferyl alcohol with 8-methylnonanoic acid (**10-32**). The highest content of capsiconinoids was found in *C. baccatum* var. *praetermissum* (3314 mg/kg dry matter) and *C. chinense* (2694 mg/kg dry matter), while their content in *C. annuum* and *C. frutescens* varieties ranged from 0 to 239 and from 0 to 39 mg/kg dry matter.

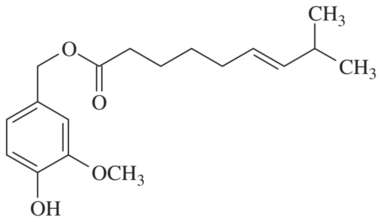
Reactions and changes

Boiling of hot peppers results in a partial leaching of capsaicinoids into water. Their concentration also decreases during other cooking procedures, but in some cases the amount may increase (Table 10.4). Peppers dried in the sun also contain lower amount of capsaicinoids.

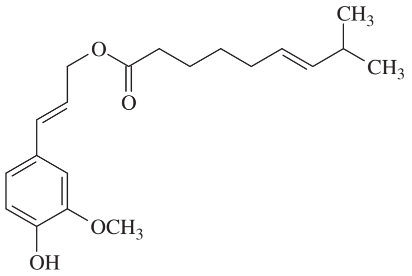
Capsaicinoids are relatively resistant to hydrolysis. Hydrolysis in acidic and alkaline media yields vanillylamine and corresponding fatty acids (their salts). During culinary procedures, which result in tissue disruption, the released enzymes partly hydrolyse capsaicinoids, which are transformed into the higher molecular weight compounds. The action of endogenous peroxidase results, for example, in the formation of 5,5′-dicapsaicin (**10-33**), dimeric 4-*O*-5′-dicapsaicin ether (**10-34**), higher oligomers and copolymers with proteins. In special beverages flavoured with pepper, 5,5′-dicapsaicin may arise by photooxidation in the presence of riboflavin and ascorbic acid (redox system riboflavin/1,5-dihydroriboflavin acts as a photocatalyst).



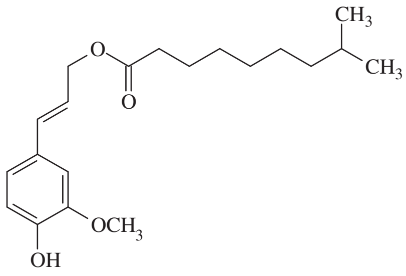
10-33, 5,5′-dicapsaicin



capsiate



capsiconiate

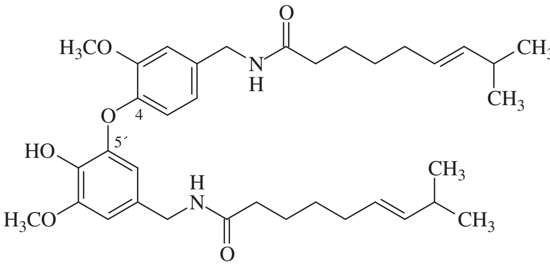


dihydrocapsiconiate

10-32, capsiconinoids

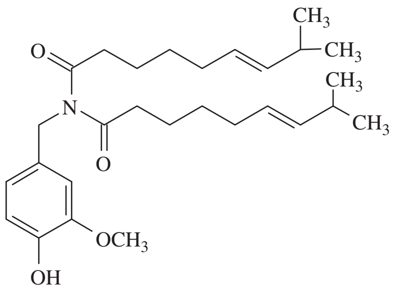
Table 10.4 Influence of technological processing on the content of capsaicinoids in Jalapeño peppers.

	Content (mg/kg)			
Pepper	Capsaicin	Dihydrocapsaicin	Nordihydrocapsaicin	Total
Raw	7300	6300	1200	14 800
Boiled (100 °C, 10 min)	8600	7700	1300	17 000
Blanched and sterilised (100 °C, 50 min)	4700	4500	700	9900
Blanched (100 °C, 3 min) and frozen (−18 °C)	4000	3700	600	8300



10-34, 4-*O*-5′-dicapsaicin ether

Thermal decomposition of capsaicin yields capsaicin dimer (*E*)-*N*-vanillyl-di(8-methylnon-6-en)imide (**10-35**), various amides, acids, hydrocarbons and phenols. The main product is (*E*)-8-methylnon-6-enamide, nonanamide, pentanamide and other amides, (*E*)-8-methylnon-6-enoic acid, nonanoic acid, (*E*)-hept -2-ene, vanillin and other substituted phenols (2-methoxy-4-methylphenol and 2-methoxyphenol), which are produced by decomposition of vanillin. Roasting of peppers in oil may produce fatty acid amides. For example, reaction with oleic acid yields (*Z*)-*N*-vanillyloctadec-9-enamide reaction of oleic acid with ammonia, originating from capsaicin, gives rise to (*Z*)-octadec-9-enamide (oleamide).



10-35, (*E*,*E*)-*N*-vanillyl-di(8-methylnon-6-en)imide

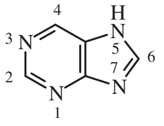
Biological effects

The burning sensation and enhancement of thermogenesis caused by capsaicinoids is induced by the direct activation of a non-selective cation channel, transient receptor potential vanilloid type 1, which is located at the end of sensory nerves. Capsiconinoids have agonist activity for this receptor and they are also involved in promotion of thermogenesis. Capsaicinoids also stimulate intestinal peristalsis and the production of bile, suppress fat accumulation and exhibit weak antimicrobial, antioxidant and anticancerogenic effects. Capsaicinoids derived from long chain fatty acids are anti-inflammatory and antinociceptive substances and enhance adrenaline secretion, despite its lack of irritancy or ungency. Also acting as an antioxidant is (−)-capsaicinol, which has similar effects as α-tocopherol. High concentrations of capsaicinoids may even be toxic.

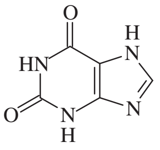
Capsaicin reduces the sensitivity of nerve cells (nocireceptors) for pain and is therefore used in medicine, in creams and sprays, against infectious diseases of the skin and mucous membranes, such as the viral infection *herpes simplex* and psoriasis and seems to be active in the treatment of lung and prostate cancer.

10.3.3.1.8 Purine alkaloids

Alkaloids derived from purine (**10-36**) and purine oxidation product xanthine (**10-37**), respectively, are called purine alkaloids. Purine alkaloids are the most widespread alkaloids in foods.



10-36, purine



10-37, xanthine

Structure, nomenclature and occurrence

Purine alkaloids are methyl derivatives of xanthine. The most common purine alkaloid is 1,3,5-trimethylxanthine, 1,3,7-trimethyl-1*H*-purine-2,6(3*H*,7*H*)-dione, known trivially as caffeine (**10-38**). It is accompanied by dimethylxanthines theobromine, theophylline and paraxanthine and also by methylxanthine heteroxanthine and methyluric acids, which are minority alkaloids, with the exception of cocoa and chocolate. Caffeine is found in the seeds, leaves and fruits of more than 60 species of plants. It is assumed that the purpose of accumulation of purine alkaloids by plants is the protection

Table 10.5 Alkaloids content in green coffee beans.

	Content in dry matter (%)		
Alkaloid	***Coffea arabica***	***Coffea canephora***	***Coffea liberica***

of young leaves, flowers and fruits against damage caused by pests. The contents of caffeine, theobromine and theophylline and alkaloid trigonelline in common species of green coffee beans (*Coffea* spp., Rubiaceae) is given in Table 10.5.

The amount of caffeine is dependent on the method of brine preparation (water temperature, time of extraction and other factors). The average content of caffeine in one cup of coffee (100 ml) is about 80 mg, 1–6 mg in decaffeinated coffee, 29–91 mg in instant coffee and 93–127 mg in filtered coffee. Decaffeinated coffee is produced by extraction of caffeine with organic solvents, in particular with dichloromethane or supercritical carbon dioxide. The caffeine obtained is used to enrich soft drinks and in the pharmaceutical industry.

Tea leaves (*Camellia sinensis*, Theaceae) contain about 2% caffeine and less than 0.2% theobromine per dry matter. The mixture of tea alkaloids was previously called **theine**. A normal cup of tea contains about half to one third of the caffeine found in a cup of coffee of the same size.

Leaves of the South American shrub yerba mate or mate plant (*Ilex paraguariensis*, Aquifoliaceae) contain 0.7–2.7% of caffeine per dry matter, between 0.3 and 0.9% of theobromine and traces of theophylline. Mate aqueous extracts have a caffeine content of 61–245 mg/l and theobromine content of 5.2–15.6 mg/l. The mixture of mate alkaloids was previously called **mateine**.

The total alkaloid content of cocoa beans (*Theobroma cacao*, Sterculiaceae) is in the range of from 0.7 to 3.2% of dry matter. The main alkaloid is theobromine, the content of which is 0.6–3.1% and the content of caffeine ranges from 0.02 to 0.5%. Dark chocolate contains 0.3–0.7% of theobromine and 0.02–0.03% of caffeine, theobromine in milk chocolate ranges from 0.1 to 0.4% and the caffeine content is 0.01–0.02%. Chocolate drinks contain theobromine at a level of 260–440 mg/l and 10–12.5 mg/l of caffeine.

In cola drinks (such as Coca Cola and Pepsi-Cola), part of caffeine usually comes from the nuts of some cola species (*Cola acuminata* and *C. nitida*, Malvaceae), where the caffeine content is 1.5–2.5%. The rest is supplemented by caffeine from other sources (it is mainly obtained in the production of decaffeinated coffee). The caffeine content in soft drinks is generally in the range of 50–250 mg/l.

Caffeine occurs at levels of 2.5–7.5% in guarana nuts, seeds of *Paullinia cupana* (Sapindaceae) native to the tropics of South America. These nuts are roasted to a mass that tastes like chocolate. It also serves in the preparation of a refreshing drink. The mixture of guarana alkaloids was previously called **guaranine**.

Reactions and changes

Methylxanthines are very stable compounds and, with the exception of non-enzymatic browning reactions during the fermentation of tea leaves and cocoa beans, they are virtually stable during storage and technological processing of the raw materials. In the manufacture of green and black tea, dimethylxanthines (including theophylline) and other purines result as products of caffeine catabolism.

When roasting coffee, the caffeine content is virtually unchanged. Trigonelline that accompanies coffee alkaloids decomposes to nicotinic acid and volatile sensorially active pyridines, therefore the trigonelline and caffeine contents ratio is used as an indicator of coffee roasting intensity.

Biological effects

Caffeine, together with quinine, is classified as a gustatory and stimulating substance and is used as a food additive. Formerly, its concentration in soft drinks was limited to a highest allowable amount of 250 mg/l; in energy drinks the highest amount was limited to 320 mg/l. The European Commission Directive 2002/67/EC states only that if a beverage intended for consumption contains caffeine in a proportion in excess of 150 mg/l, the product must have on the label message ‘High caffeine content’. In a small daily dose (<3 mg/kg), caffeine acts as a stimulant of the central nervous system and as a diuretic agent. High doses, however, have different neuroendocrine effects, and very high doses are reportedly teratogenic. Theobromine and theophylline exhibit weaker stimulatory effects than caffeine and may cause abnormalities of spermatogenic cells. Theobromine is toxic to some animals, such as dogs, which metabolise theobromine more slowly than humans. Theophylline is used therapeutically in certain respiratory diseases, such as chronic inflammatory disorder of the bronchial tube (bronchial asthma). In sensory studies, the flavanones homoeriodictyol, sterubin and eriodictyol and amides of aromatic amines with hydroxylated benzoic acids (as homoeriodictyol structural analogues) could significantly decrease the bitter taste of caffeine without exhibiting intrinsic strong flavours or taste characteristics.

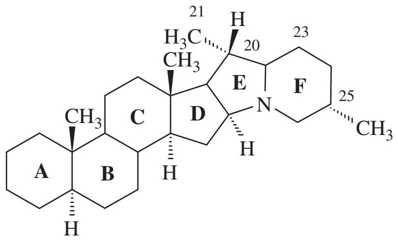
10.3.3.1.9 Steroid glycoalkaloids

Steroid glycoalkaloids (also called steroid alkamines) occur in dicotyledonous plants of the family Solanaceae, Liliaceae and of the subfamily Asclepiadoideae in the Apocynaceae. The fully saturated core of steroid alkaloids is derived from C_{27} hydrocarbon 5α-cholestane, which is composed of three cyclohexane rings (designated as rings A, B and C and one cyclopentane ring (D ring) with a C_8 side chain attached to C-17 in (20*R*)-configuration (see Section 3.7.4.1). Only plants of the genus *Solanum* of the nightshade family, which include potatoes (*S. tuberosum*), eggplants (*S. melongena*) and tomatoes (*S. lycopersicum*), have practical importance in foods.

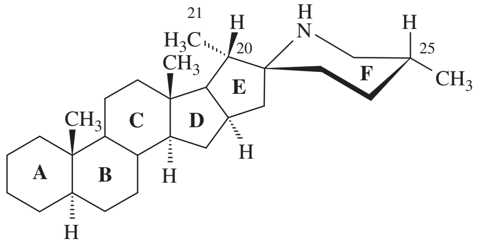
Structure, nomenclature and occurrence

In more than 300 species of plants of the nightshade family, there are at least 90 different steroid glycoalkaloids, which are, according to the structure of the aglycone, divided into five structural types (most of these alkaloids occur as glycosides):

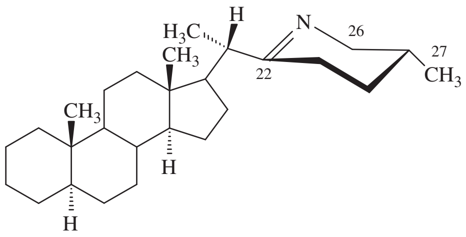
- solanidanes (**10-39**)
- spirosolanes (spiroaminoacetals, **10-40**)
- 22,26-epiminocholestanes (**10-41**)
- α-epiminocyclohemiacetals (**10-42**)
- 3-aminospirostanes (**10-43**).



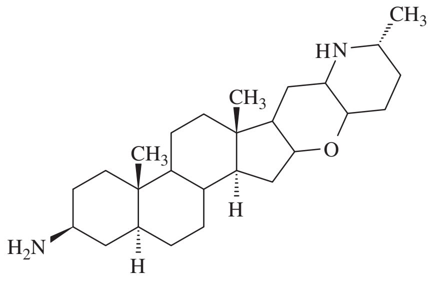
10-39, solanidanes



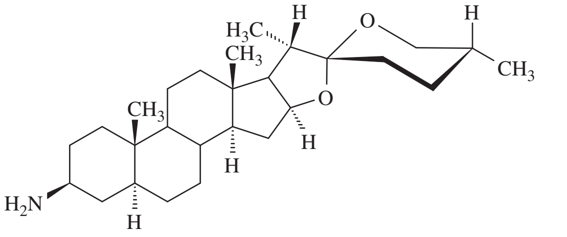
10-40, spirosolanes



10-41, 22,26-epiminocholestanes



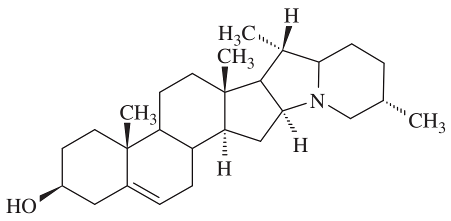
10-42, α-epiminocyclohemiacetals



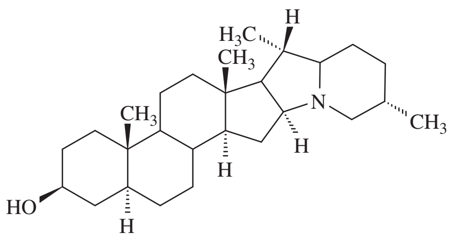
10-43, 3-aminospirostanes

Aglycones

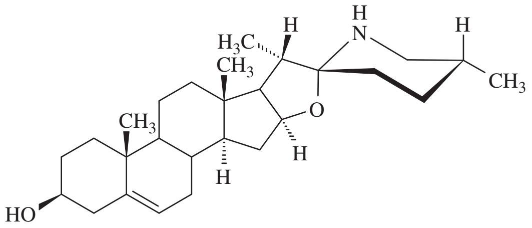
Only glycoalkaloids, the aglycones of which are 3β-hydroxy derivatives of solanidane or spirosolane are found in plant foods used for human nutrition. Solanidane derivatives are solanidine (**10-44**) and demissidine (**10-45**) and solasodine (**10-46**), tomatidenol (**10-47**) and tomatidine (**10-48**) are derived from spirosolane.



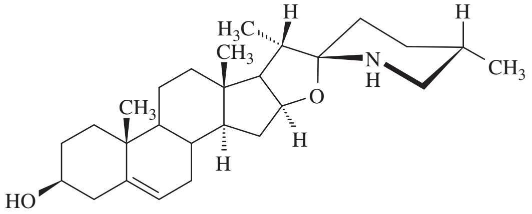
10-44, solanidine



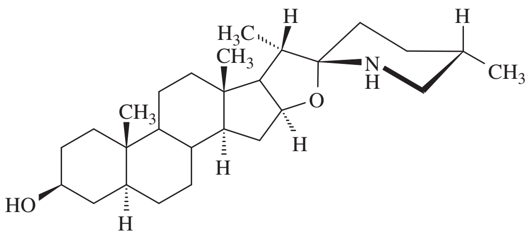
10-45, demissidine



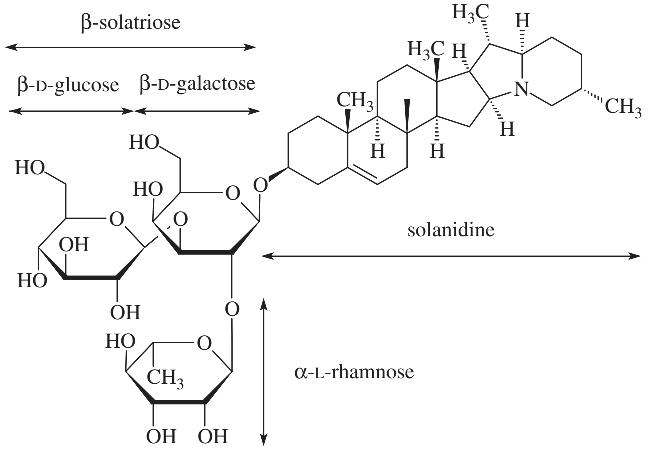
10-46, solasodine



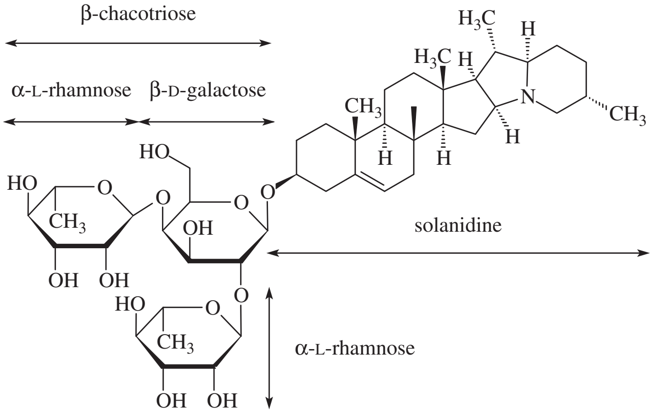
10-47, tomatidenol



10-48, tomatidine



10-49, α-solanine



10-50, α-chaconine

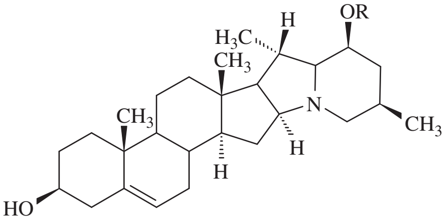
Glycosides

The main compounds in plants are glycosides of sterols, which are accompanied by small amounts of free aglycones. Sugars (linear and branched tetrasaccharides, trisaccharides, disaccharides and monosaccharides) are bound to aglycones via the hydroxyl group at C-3.

Solanidine is the aglycone of two major potato glycoalkaloids that are known as α-solanine (**10-49**) and α-chaconine (**10-50**). Their mixture was previously called solanine. These glycoalkaloids represent about 95% of the potato glycoalkaloids. Sugar bound in α-solanine is β-solatriose; the sugar bound in α-chaconine is β-chacotriose. Besides α-solanine and α-chaconine, cultural potato varieties contain some minority alkaloids, such as β-solanines and β-chaconines, γ-solanine, γ-chaconine, α-solamarine and β-solamarine (Table 10.6). In addition to solanine and chaconine, in the wild potato species growing from the United States to southern Chile there are a number of other glycosides with different aglycones (e.g. leptines, leptinines, commersonine and demissine).

Spirosolanes, namely solasodine, the (25*R*)-stereoisomer, and tomatidenol, the (25*S*)-stereoisomer, are found in wild potato species and varieties obtained by cross breeding the wild varieties, such as *S. berthaultii* and *S. vernei*. They mutually differ only in the position of the heterocyclic nitrogen in ring F. Solasodine occurs as glycoside α-solasonine containing trisaccharide β-solatriose, which is also bound in α-solanine. The same aglycone is in α-solamargine containing β-chacotriose, which is also bound in α-chaconine. Both glycosides, α-solasonine and α-solamargine are found, for example, in wild potato species *S. berthaultii* and *S. vernei* and eggplants (*S. melanogena*).

The (25*S*)-stereoisomer tomatidenol (**10-47**) is present in potatoes in a steroid glycoside α-solamarine containing bound solatriose, or as β-solamarine, which is coupled with β-chacotriose. Most potato varieties containing solamarines come from *S. demissum* species, which also contain (only in the leaves, not in tubers) alkaloids known as leptines and leptinines. The aglycone of leptinines I and II is 23-hydroxysolanidine called leptinidine, the aglycone of leptines I and II is leptidine (23-acetylleptinidine, **10-51**). Leptinine I and leptine I contain β-chacotriose, while leptinine II and leptine II contain β-solatriose (Table 10.6).



10-51, leptinidine (23-hydroxysolanidine), R = H
leptidine (23-acetylleptinidine), R = $COCH_3$

Table 10.6 Potatoe glycoalkaloids.

Glycoalkaloids	Aglycone	Saccharide	Abbreviated notation
α-Solanine	Solanidine	β-Solatriose	β-D-Glc*p*-(1→3)-[α-L-Rha*p*-(1→2)]-β-D-Gal*p*
β_1-Solanine	Solanidine	β-Neohesperidose	α-L-Rha*p*-(1→2)-β-D-Gal*p*

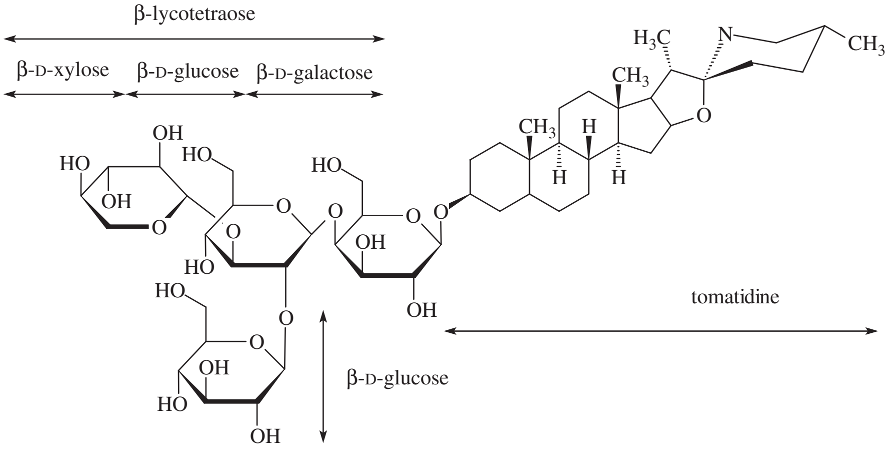
Leptine II	23-Acetylleptinidine	β-Solatriose	β-D-Glc*p*-(1→3)-[α-L-Rha*p*-(1→2)]-β-D-Gal*p*

The β-glycoside of tomatidenol in tomatoes, called dehydrotomatine, accompanies α-tomatine in tomatoes. Dehydrotomatine and α-tomatine contain bound lycotetraose. The (25*S*)-stereoisomer tomatidine (**10-48**), also known as 5,6-dihydrotomatidenol, is an aglycone of the main tomato glycoalkaloid α-tomatine (**10-52**). α-Tomatine also occurs in small amounts in some potato species and some other species of the genus *Solanum*. In the wild potatoes (*S. acaule*) its content ranges from to 74 to 497 mg/kg fresh weight.

The distribution of glycoalkaloids differs in the various parts of plants. α-Solanine and α-chaconine occur in roughly equal amounts. The largest amount of solanine in potato is present in the flowers (5000 mg/kg) and germ (1950–4360 mg/kg). The highest concentrations in tubers are in the surface layers. Towards the



10-52, α-tomatine

Table 10.7 Distribution and content of glycoalkaloids in potatoes.

Part of tuber	Content (mg/kg) (fresh weight)
Unpeeled	75
Peel (2-3% of tuber weight)	300-600
Peel (10-15% of tuber weight)	150-300
Peel with germ (3 mm)	300-500
Peeled	12-50

centre of the tubers, the solanine content decreases (Table 10.7). Higher amounts of solanine generally contain small tubers. Usually, the amount of solanine in potato tubers does not exceed 200 mg/kg, except for the wild species. Potatoes containing more than 140 mg/kg of glycoalkaloids exhibit bitter taste, potatoes containing more than 220 mg/kg have a hot taste. The amount of alkaloids is strongly dependent on soil and climatic conditions. In tubers exposed to light and in injured tubers the alkaloid biosynthesis increases by up to 400%. The stimulating effect mainly comes from light of shorter wavelengths; the light of longer wavelengths primarily stimulates the biosynthesis of chlorophyll.

Tomatine is practically the only glycoalkaloid of tomatoes. Tomatine is accompanied in small amounts by glycoalkaloids containing as sugar components the products of partial hydrolysis of lycotetraose (β_1-tomatine with trisaccharide produced by hydrolysis of xylose from lycotetraose, β_2-tomatine with trisaccharide without glucose and γ-tomatine with disaccharide without xylose and glucose). Tomatine is present in all parts of the plant, with the highest amount located in the leaves, flowers and small green fruits. The biosynthesis of tomatine in fruits is temporary and during their maturation the tomatine content in fruits decreases. Tomatine concentrations in mature red fruits are very small (Table 10.8).

The amount of α-solasonine and α-solamargine in various species, hybrids and varieties of eggplants ranged from 36 to 691 mg/kg dry matter and from 140 to 7700 mg/kg dry matter, respectively, with current eggplant genotypes in the range of 92–125 mg/kg dry matter and 229–299 mg/kg dry matter, respectively.

Table 10.8 Tomatine content in tomatoes. Kozukue, Han, Lee and Friedman, 2004, table 1. Reproduced by permission of the American Chemical Society.

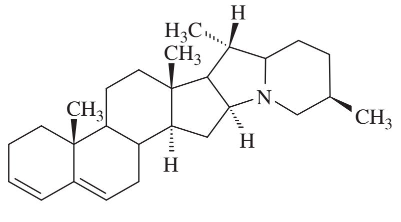
State of ripeness (days after flowering)	Content (mg/kg) (fresh weight)	
	Tomatine	Dehydrotomatine
Small and green (10)	795	60
Large and green (20)	49	2.6
Pink (30)	20	trace
Light red (40)	1.5	0
Red and ripe (50)	3.7	0

Reactions and changes

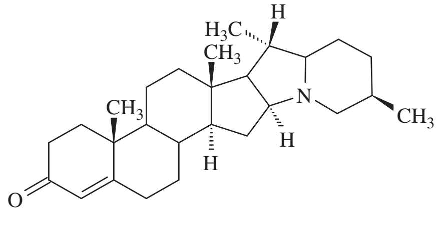
Alkaloids in potatoes are mainly removed by peeling (60–90%), but they are relatively stable during technological and culinary processing. The degradation of alkaloids does not occur even during the production of potato crisps and French fries, but their relative content increases due to loss of water during frying. When cooking potatoes, some loss of alkaloids occurs due to leaching into water. Adding acetic acid can increase this loss. The addition of 0.3% of acetic acid reduces the solanine content in cooked potatoes by about 84%.

Opinions on changes of alkaloids during potato storage vary. Some studies have shown an increase in alkaloid content at lower temperatures. Higher temperature and lower relative humidity are the optimal conditions for preventing the formation of glycoalkaloids during potato storage.

The activity of hydrolases or hydrolysis in acidic media leads to the hydrolysis of glycoalkaloids, but the released aglycones are practically stable. For example, α-chaconine in germinating potatoes is gradually hydrolysed to β_2-chaconine, but the α-solanine content is unchanged. Partial acid hydrolysis of α-chaconine and α-solanine leads gradually to approximately equimolar quantities of β_1-glycosides, β_2-glycosides and γ-glycosides and the final product is aglycone solanidine. The same products may also arise in the digestive tract. Upon heating in mineral acids, solanidine partially dehydrates to solanthrene (**10-53**) and other minor products, such as the oxidation product solanid-4-en-3-one (**10-54**). These reactions can be expected to a lesser extent during thermal processing of potatoes.



10-53, solanthrene



10-54, solanid-4-en-3-one

Tomatine is relatively stable under normal storage and processing conditions. In acid media partial hydrolysis of lycotetraose can be expected. Freezing of unripe tomatoes (unpeeled, green–yellow tomatoes) results in approximately 8% loss of tomatine, freezing of peeled tomatoes leads to an 18% loss of alkaloids, which may be attributed to tissue damage and action of hydrolytic enzymes.

Biological effects

Levels of α-solanine and α-chaconine normally found in potatoes (20–100 mg/kg) are not of toxicological concern. Typical manifestations of higher levels, the so-called solanine poisoning, are vomiting, diarrhea, stomach cramps, headaches and dizziness. α-Solanine toxicity is attributable either to the inhibition of cholinesterase or damage to the digestive tract membranes and some organs. An even more effective inhibitor of cholinesterase is α-chaconine. High doses of α-chaconine have teratogenic effects. In some countries, and formerly also in the EU, the permissible concentrations of α-solanine and α-chaconine were set to 200 mg/kg.

Tomatine has antifungal and teratogenic effects. Toxic effects are often associated with the ability of 3β-hydroxysterols to bind tomatine in membranes, which destabilises the lipid bilayer. For tomato alkaloids (α-solanine, α-chaconine and α-tomatine) the same maximum amount has therefore been set as for potato alkaloids.

10.3.3.2 Saponins

10.3.3.2.1 Structure, nomenclature and occurrence

Saponins are a diverse group of surface-active heteroglycosides occurring mainly in plants. Hydrophobic aglycones of saponins, which are called sapogenols (formerly sapogenins) are compounds derived from:

- C_{30} triterpenoids, also known as triterpenic alcohols
- C_{27} steroids.

The aglycone is bound to one or more sugar residues. In **monodesmosides**, one sugar residue (mono- or oligosaccharide) is bound to the aglycone (sugar is normally bound to the C-3 hydroxyl), **bisdesmosides** have sugar residues bound in different positions and three sugar residues bound in different positions are found in **trisdesmosides**. Common sugars are usually L-arabinose, D-glucose, D-mannose, D-galactose, L-rhamnose, D-glucuronic acid and D-galacturonic acid, less frequently D-xylose and D-apiose, but some other sugars may also be present. Sugars can also be acylated with organic acids, such as acetic acid. The amount of saponins depends mainly on the plant species and climatic conditions. The largest concentration of saponins is located in the roots, bark and fast-growing parts of the plant (Table 10.9). At low concentrations, saponins are also present in certain marine organisms and bacteria.

The physiological role of saponins in plants is not yet fully understood; nevertheless it is assumed that they represent a part of plants' defence systems of protective molecules named phytoprotectants, chemical agents that interacts with a pathogen on the plant surface to prevent infection, either phytoanticipins or phytoalexins (see Section 10.3.3.6).

Triterpenoid saponins

Triterpenoid saponins are common components of many plants. Their structure is mainly derived from pentacyclic triterpenoids, such as lupeol, α-amyrine and β-amyrine (see Section 3.7.4.1.1). In positions C-4 (C-23 methyl), C-17 (C-28 methyl) and C-20 (C-30 methyl) of the aglycone system C_6–C_6–C_6–C_6–C_6 a carboxyl group formed by oxidation of a methyl group may occur. Methyl groups of some saponins are only partially oxidised to hydroxymethyl and formyl groups and some aglycones contain other hydroxyl groups at C-21 and C-22. Positions C-11 and C-16 may also be oxidised. Sugar moieties (1–6) are bound to the C-3 hydroxyl and some hydroxyl groups may be esterified with carboxylic acids, for example with acetic acid (C-22 hydroxyl) or angelic acid (C-21 hydroxyl).

The best known saponins are soyasaponins, aglycones of which are soyasapogenol A (oleane-12-en-3β,22β,24-triol), soyasapogenol B (olean-12-en-3β,22β,24-triol, **10-55**), soyasapogenol E (oleane-12-en-3β,24-diol-22-one, **10-56**), hederagenin (**10-57**), medicagenic acid (**10-58**) and bayogenin (**10-59**). The content of saponins in seeds of the soybean ranges from 0.6% to as much as 6.5% dry matter, depending on the variety, cultivation year, location grown and degree of maturity.

Table 10.9 Saponins content in legumes and other plants.

Plant	Latin name	Content (%)	Plant	Latin name	Content (%)
Fabaceae			Lentil	*Lens culinaris*	0.11–0,51

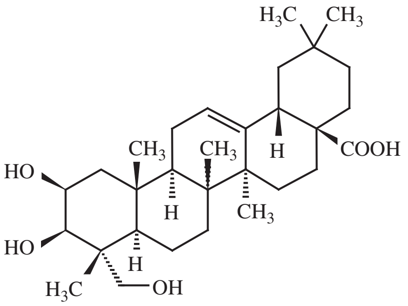
Saponins derived from soyasapogenol A are bisdesmosides containing sugars bound to C-3 and C-22. Some of the sugars can be acetylated. Acetylated derivatives have a bitter and astringent taste. Most varieties of soya contain soyasaponin A_a and A_b (**10-55**) as the main representative of the acetylated compounds. Glycosides of soyasapogenol B, such as soyasaponin B_a and soyasaponin B_b, still often referred to as soyasaponin I (**10-55**), lack the C-22 hydroxyl group; they belong to monodesmosides, and the sugar moiety is attached to C-3 hydroxyl. Additional soyasaponins are derived from soyasapogenol E, for example, saponin B_d and saponin B_e (**10-56**). A recently identified group of soyasaponins B_aA and B_bA (also known as soyasaponin βg, soyasaponin VI or chromosaponin I) are conjugates of soyasaponin B_b with γ-pyrone (2,3-dihydro-2,5-dihydroxy-6-methyl-4*H*-pyran-4-one, which is bound to carbon

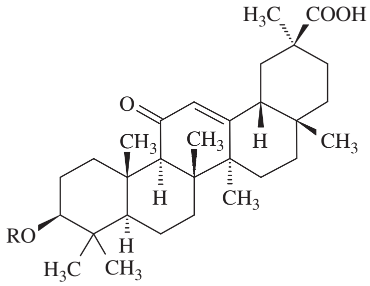


10-59, bayogenin

C-22 (**10-60**). These saponins are thus actually bisdesmosides. Soyasaponin B_b and its conjugates with γ-pyrane occur as the main saponins in some other legumes, for example, in common beans and lima beans, pea, lentils and chickpeas.

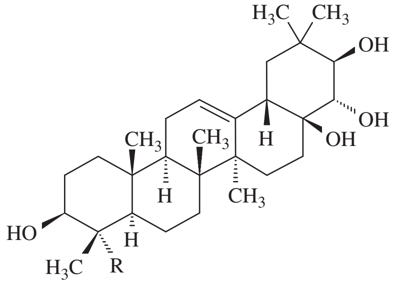
Plants of the Amaranthaceae (formerly Chenopodiaceae) family, for example sugar beet (*Beta vulgaris* group *Altissima*), contain about 5.8% saponins. The main sapogenin is oleanolic acid. Spinach contains about 4.7% saponins, derived from oleanolic acid and hederagenin (**10-57**). The edible grain quinoa of the same plant family (*Chenopodium quinoa*), originating in South America, contains as aglycones phytolaccagenic acid (**10-57**), hederagenin and oleanolic acid (**10-57**). Aglycones of soap tree bark (*Quillaja saponaria*, Quillajaceae) saponins, which are used industrially for pharmaceutical and cosmetic products, are guillajic and gypsogenic acids (**10-57**). Their content in soap tree bark is around 10%. Similar structures are seen in medicagenic (**10-58**) and zanhic acids (**10-58**), which are bis- and trisdesmosides, respectively, found in alfalfa (*Medicago sativa*, Fabaceae) together with saponins, whose aglycone is soyasapogenol B. The main saponin is trisdesmoside of zanhic acid, where R = β-D-Glc*p*-(1→2)-β-D-Glc*p*-(1→2)-β-D-Glc*p*-(1→, R^1=α-L-Ara*p*-(1→, R^2=β-D-Api*f*-(1→3)-β-D-Xyl*p*-(1→4)-α-L-Rha*p*-(1→2)-α-L-Ara*p*-(1→. Related bayogenin (**10-59**) occurs in soya beans.

The rhizome of liquorice (*Glycyrrhiza glabra*) of the same plant family contains 2.2–15.0% of saponins and has an intensely sweet taste. It is used in the production of various pharmaceutical and confectionery products. The primary representative of liquorice saponins is glycyrrhizin, which is a mixture of potassium and calcium salts of monodesmoside known as glycyrrhizic acid. The glycyrrhizin aglycone is glycyrrhetic (glycyrrhetinic) acid (**10-61**), to which are bound two β-D-glucuronic acid units. The sweetness of glycyrrhizin is between 50 and 150 times higher than the sweetness of sucrose.



10-61, glycyrrhetic acid, R = H
glycyrrhizic acid, R = β-D-Glc*p*A-(1→2)-β-D-Glc*p*A-(1→

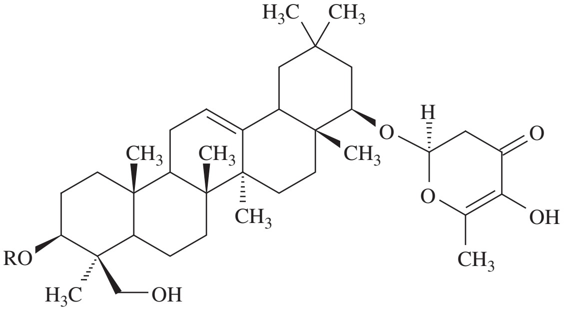
Saponins of tea leaves (*Camellia sinensis*, Theaceae) contain as the main components theasapogenol A and theasapogenol B (**10-62**). Other related compounds include theasapogenols C, D and E, assamsapogenols (A, B, C and D).



10-62, theasapogenol A, R = CH_2OH
theasapogenol B, R = CH=O

Steroid saponins

Saponins that have in the molecule steroids as aglycones (steroid saponins) contain aglycones based on C_{27} structures of spirostanol or furostanol formed by modifications of the cholesterol side chain.

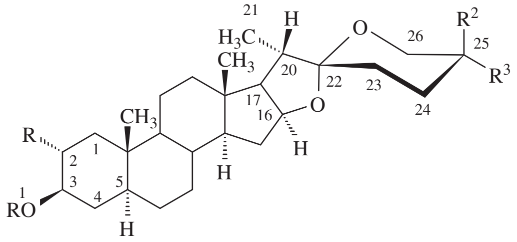


10-60, soyasaponin B_aA, R = β-D-Glc*p*-(1→2)-β-D-Gal*p*-(1→2)-β-D-Glc*p*A-(1→,
soyasaponin B_bA, R = α-L-Rha*p*-(1→2)-β-D-Gal*p*-(1→2)-β-D-Glc*p*A-(1→

Sugars (2–5 residues of hexoses or pentoses) are attached to the C-3 hydroxyl group of aglycones. Other conjugates of this type also include other triterpenes with sugars attached at different positions.

Steroidal saponins are less widespread in comparison with triterpenoid saponins. They typically occur in monocotyledonous plants of the families Agavaceae, Amaryllidaceae, Asparagaceae, Dioscoreaceae and Poaceae, but are also present in some dicotyledonous plants, for example in legumes of the family Fabaceae. Both types of saponins are often present in the same plant material.

Plants of the Allioideae subfamily (the old Alliaceae family), for example, onion (*Allium cepa*), contain saponins derived from oleanolic acid, β-amyrin (see **3-99**), gitogenin (**10-63**), diosgenin (**10-64**), β-chlorogenin (**10-65**) and cepagenin (**10-66**). Recently identified were spirostane-type saponins with trivial names alliospirosides A to D (**10-67**), tropeosides A1, A2, B1, B2 and ascalonicosides A1, A2, B. For example, the sugar bound in allispiroside A is a disaccharide α-L-Ara*f*-(1→2)-6-deoxy-α-L-Man*p*-, tropeoside A1 (**10-68**) contains two monosaccharides,



10-63, tigogenin, R = H, R^1 = H, R^2 = CH_3, R^3 = H
neotigogenin, R = H, R^1 = H, R^2 = H, R^3 = CH_3
gitogenin, R = OH, R^1 = H, R^2 = CH_3, R^3 = H
neogitogenin, R = OH, R^1 = H, R^2 = H, R^3 = CH_3

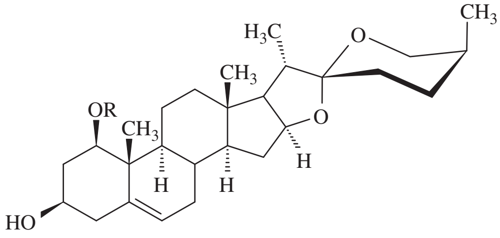
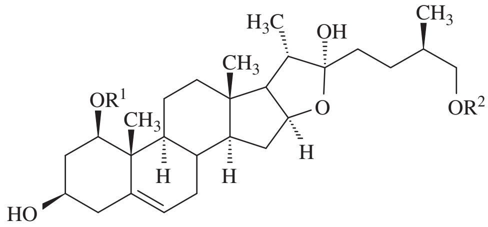
10-66, cepagenin



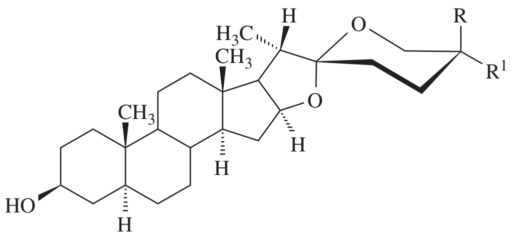
10-67, alliospiroside A

R^1 = β-D-Gal*p*, R^2 = α-L-Rha*p*, and ascalonicoside A1 (**10-68**) contains one monosaccharide (R^1 = β-D-Gal*p*) and one disaccharide (R^2 = α-L-Rha*p*-(1→2)-β-D-Glc*p*-). Saponins of garlic (*Allium sativum*) are derived from phytosterol sitosterol (see **3-119**) and saponins of leek (*Allium ampeloprasum*) contain oleanolic acid and gitogenin (**10-63**) as aglycones.



10-68, tropeoside A1/ascalonicoside A1

Saponins of asparagus (*Asparagus officinalis*, Asparagaceae) are trivially called officinalisins and asparagosins. For example, officinalisins contain 5β-furostan-3β,22α,26-triol as aglycone, aglycone of asparagosins is (25*S*)-spirost-5-en-3β-ol trivially called yamogenin (**10-64**). Saponins are located in larger quantities at the bottom of the stalks, to which they give a bitter taste. Present as a minor aglycone is sarsapogenin derived from spirostane (**10-69**).



10-69, smilagenin, R = CH_3, R^1 = H
sarsapogenin, R = H, R^1 = CH_3

At least nine compounds known as asparagosides (asparagosides A to I) have been characterised.

Yamogenin and yamogenin isomer diosgenin, (25*R*)-spirost-5-en-3β-ol (**10-64**) are the aglycones of saponins in yams (*Dioscorea* spp., Dioscoraceae) whose starchy tubers are eaten in Africa, South-east Asia and the Pacific region (*D. alata* and *D. esculenta* in South-east Asia, *D. trifida* in South America, *D. rotundata* and *D. cayenensis* in West Africa). Yams typically contain 4–8% saponins, which are also a source of steroids for the pharmaceutical industry.

A number of steroid saponins called fenugrins and grecunins are found in the legume plant fenugreek (*Trigonella foenum-graecum*, Fabaceae), which is used as a spice and fodder plant. In India, for example, fenugreek leaves are eaten as a salad and in European countries the seeds are used as a spice. The main aglycone of the seeds is diosgenin; in smaller quantities are present yamogenin (**10-64**), gitogenin, neotigogenin (**10-63**), smilagenin, sarsapogenin (**10-69**) and their 3α-epimers, known as epismilagenin and episarsapogenin. Minor fenugreek components are dihydroxy derivatives yuccagenin, lilagenin (**10-64**), gitogenin and neogitogenin (**10-63**).

A similar structure is seen in steroid bisdesmosides of oats (*Avena sativa*, Poaceae), which are called avenacosides (**10-70**). Specific β-glucosidase present in oat leaves hydrolyses avenacosides (splits-off glucose bound at C-26) to monodesmosides called deglucoavenacosides, which are less bitter, but exhibit higher antimicrobial and haemolytic effects.

10.3.3.2.2 Reactions and changes

Saponins are relatively stable during common technological and culinary operations. Their amount can be reduced by adequate washing, maceration or removing the surface layer (peeling). Sugar beet saponins are removed during the sugar refining, soya bean saponins are removed by debittering using various technological processes, such as peeling, acid hydrolysis and fermentation processes (using suitable microorganisms such as moulds *Aspergillus oryzae* and *A. niger*), in which bitter saponins are enzymatically hydrolysed to non-bitter aglycones.

The content of saponins may be decreased by dipping in water and cooking (or sterilisation). When cooking legumes, bitter glycosides are partly dissolved and partly hydrolysed to aglycones and sugars. For example, losses of saponins during cooking lentils may reach 6–14% of the original amount, which is about 700–1100 mg/kg dry weight. The highest reduction of saponins in legumes can be achieved by soaking, followed by germination for about 40 hours and boiling. Under these circumstances, the content of saponins may be reduced by up to 75%.

Triterpenic saponins derived from soyasapogenol E (B_d and B_e saponins) are highly unstable and during processing of legumes, they are reduced to B_a and B_b saponins, respectively. During the thermal processing of legumes, soyasaponin B_eA is partially degraded to soyasaponins B_b and B_e, which yields the respective aglycone soyasapogenol E. Glucose at position C-26 of steroid furostane type saponins can be split-off by enzymatic hydrolysis or the activity of microorganisms, and furostane derivatives are transformed into spirostane derivatives (Figure 10.2). Similarly to the case of sterols, also saponin aglycones may partially eliminate the hydroxyl group at C-3 as water, with the formation of corresponding unsaturated hydrocarbons.

10.3.3.2.3 Biological effects

In the past, practically all saponins were considered antinutritional or toxic substances as they negatively influence organoleptic properties of food causing unwanted bitterness and astringency in soybeans and other legumes and also animal nutritionists have generally considered saponins to be deleterious compounds that negatively affect growth, feed intake and reproduction in animals.

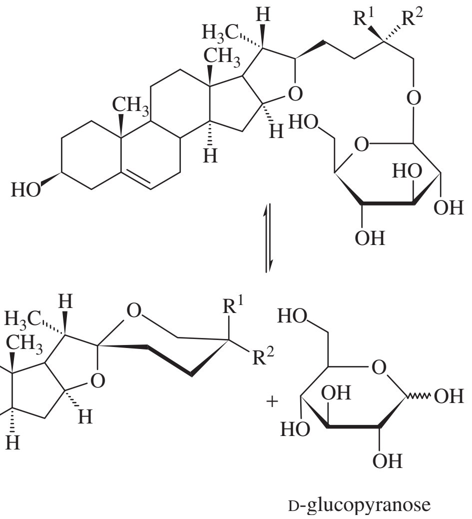


Figure 10.2 Interconversion of furostane and spirostane structures.

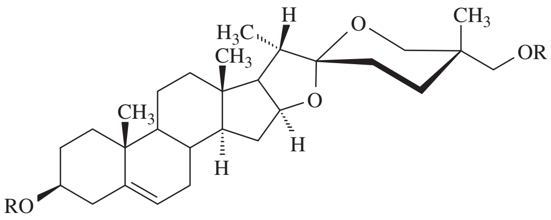


10-70, avenacoside A, R =β-D-Glc*p*-(1→2)-[α-L-Rha*p*-(1→4)]-β-D-Glc*p*-(1→, R^1=β-D-Glc*p*-(1→
avenacoside B, R=β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-[α-L-Rha*p*-(1→4)]-β-D-Glc*p*-(1→, R^1=β-D-Glc*p*-(1→

Saponins are also highly toxic to cold-blooded organisms (such as insects and fish). Toxic saponins are often called **sapotoxins**. Their toxic effect is manifested by haemolysis of erythrocyte cells and damage of intestinal mucosa. The main reason is the interaction of saponins with cholesterol in the cell walls. High doses of toxic saponins may damage the liver, which can lead to respiratory failure. In retrospect, however, only some saponins are really toxic.

Analogously as with cholesterol, saponins react with other sterols and bile acids (under micelle formation) and thereby inhibit their absorption, which is related to the metabolism of cholesterol and prevention of cardiovascular diseases. Recently, a number of studies have reported both beneficial and adverse effects of these compounds in a variety of animals. Extensive research carried out into the membrane-permeabilising, immunostimulant, hypocholesterolaemic, hypoglycaemic, antioxidative (e.g. conjugates of saponin B_b with γ-pyrone) and anticarcinogenic properties of saponins has shown that they may also impair the digestion of proteins, the uptake of vitamins and minerals in the gut, to act as antifungal (such as some asparagus saponins) and antiviral agents. For example, the ability of ginseng (*Panax ginseng*, Araliaceae) to slow down the aging of organism is attributed to antioxidant activity of ginsenosides, which represent a class of steroid glycosides and triterpene saponins.

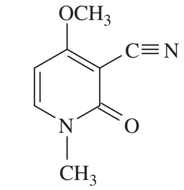
In the form of concentrates, some saponins are used as foaming agents, emulsifiers and antioxidants; glycyrrhizin from liquorice is used as a sweetener in the manufacture of confectionery and tobacco. In the manufacture of some soft drinks, as well as in the production of the famous English ginger beer, saponins from the soap tree bark (*Quillaja saponaria*, Quillajaceae) are used as foaming agents. Saponins are commonly used also in cosmetic products (shampoos and other hair preparations).

10.3.3.3 Cyanogens

Cyanogenesis is the ability of plants and some other organisms to produce hydrogen cyanide by decomposition of cyanogenic compounds. Cyanogenic compounds or cyanogens have been detected in various parts of the roughly 3000 species of plants indexed to 110 families. It is assumed that cyanogens in plants repel predators by their bitter taste and odour and the toxicity of their breakdown products. They possibly also participate in nitrogen metabolism as nitrogen storage forms during seed germination and early stages of plant development. Cyanogens are divided into three basic groups:

- cyanogenic glycosides (β-glycosides of 2-hydroxynitriles or β-glycosides of cyanohydrins)
- pseudocyanogenic glycosides (glycosides or methylazoxymethanol or azoxyglycosides)
- cyanogenic lipids (cyanolipids or fatty acid esters of cyanohydrins).

In addition to these cyanogens, some higher plants also accumulate different nitriles during the assimilation of hydrogen cyanide. Examples of these nitriles are β-cyano-L-alanine and β-aminopropionitrile in vetches (*Vicia* spp.) and sweet peas or vetchlings (*Lathyrus* spp.) of the legume family (Fabaceae) or alkaloid ricinine (**10-71**) of castor oil plant (*Ricinus communis*, Euphorbiaceae). Many plants also produce cyanides as byproducts of the biosynthesis of plant hormone ethylene (Figure 2.1).

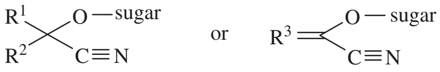


10-71, ricinine

10.3.3.3.1 Cyanogenic glycosides

Structure, nomenclature and occurrence

The approximately 75 documented cyanogenic glycosides are all *O*-β-glycosides of 2-hydroxynitriles (formerly called cyanohydrins) that are glycosides of nitriles of 2-hydroxycarboxylic acids (**10-72**). Cyanogenic glycosides are the most important and most widely occurring cyanogens of many plants consumed as human food or used as livestock feed. They are located mainly in dicotyledonous plants belonging to the families Fabaceae, Asteraceae, Euphorbiaceae and Passifloraceae and in monocotyledonous plants of the families Poaceae and Araceae. Generally, a certain cyanogenic glycoside occurs in only one or two families of plants and one or two cyanogenic glycosides occur in one plant.

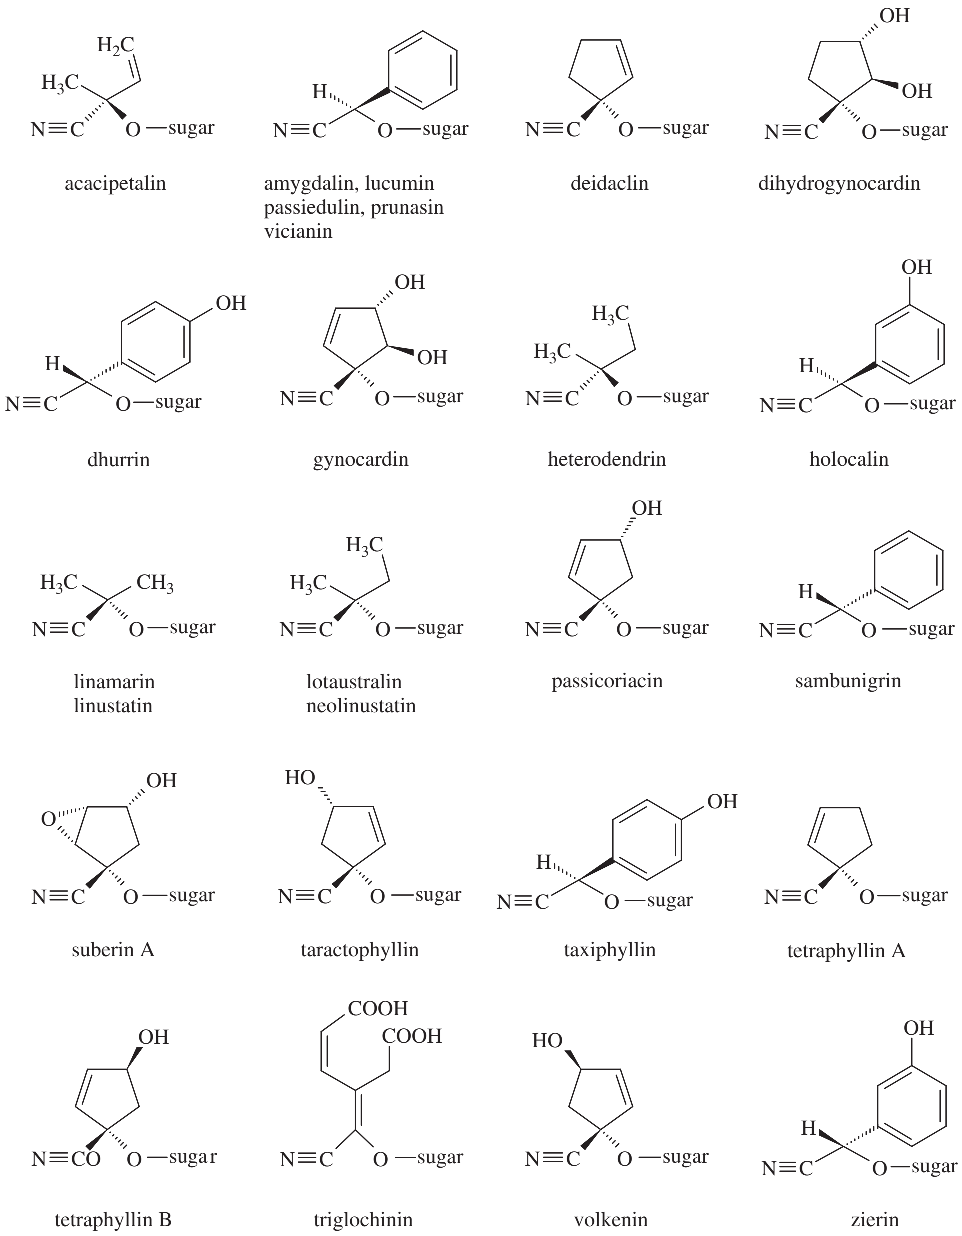


10-72, general structure of cyanogenic glycosides

Cyanogenic glycosides differ in:

- type of bound sugar
- substituents R^1, R^2 (or R^3)
- chirality of carbinol carbon atom.

With some exceptions, the sugar commonly bound in cyanogenic glycosides is monosaccharide β-D-glucose. The exceptions are disaccharides β-vicianose, α-L-Ara*p*-(1→6)-β-D-Glc*p*, β-primeverose, β-D-Xyl*p*-(1→6)-β-D-Glc*p*, β-gentiobiose, β-D-Glc*p*-(1→6)-β-D-Glc*p* and some other disaccharides. In most cyanogenic glycosides, the substituent R^1 is an aliphatic or aromatic substituent and R^2 = H. In this case the carbinol carbon atom (C-2 carbon of aglycone) is chiral and epimeric pairs of compounds therefore exist. The structure of the major cyanogenic glycosides is shown in formulae **10-73** and in Table 10.10, which also lists their occurrence.



10-73, cyanogenic glycosides

Cyanogenic glycosides are usually subdivided according to amino acids from which they arise in biosynthesis. Most cyanogenic glycosides are derived from five hydrophobic amino acids valine (linamarin), isoleucine (lotaustralin), leucine (heterodendrin and epiheterodendrin), phenylalanine (amygdalin and prunasin) and tyrosine (dhurrin, taxifyllin and triglochinin). Cyclopentanoid cyanogens (such as gynocardin) arise from cyclopentenylglycine (**2-16**).

The simplest cyanogenic glycoside derived from valine is linamarin (formerly also called phaseolunatin). Its higher homologue is (*R*)-lotaustralin, which is derived from isoleucine. Both cyanogens occur together, because the corresponding enzymes are not specific and transform both amino acids (valine and isoleucine) into cyanogenic glycosides. Of the products containing these cyanogens, the one which is the most important for human nutrition is cassava (*Manihot esculenta*, Euphorbiaceae), sometimes also called yucca or tapioca, which is a major staple food in the developing world, providing a basic diet for around 500 million people. Cassava is native to South America and is now extensively cultivated in tropical and subtropical regions, especially in sub-Saharan Africa but also in Indonesia and other countries. Cassava contains linamarin as the main cyanogenic glycoside, and (*R*)-lotaustralin is also present in an amount about 20 times smaller. Both glycosides occur in the leaves and starchy tubers, especially in the cortex. Linamarin is similarly the cyanogenic glycoside of butter (lima) beans (*Phaseolus lunatus*, Fabaceae), birds foot trefoil (*Lotus corniculatus*), white clover (*Trifolium repens*) and other plants from the same family, which are often a part of forage for livestock.

Table 10.10 Structures and occurrence of cyanogenic glycosides.

Trivial name	Sugar	Isomer	Occurrence (Latin names of plant species)
Acacipetalin (proacacipetalin)	D-Glucose	*S*	*Acacia*
Amygdalin	Gentiobiose	*R*	*Prunus*
Deidaclin	D-Glucose	*R*	*Deidamia*, *Passiflora*
Dhurrin	D-Glucose	*S*	*Sorghum*
Dihydrogynocardin	D-Glucose	1*S*,4*S*,5*R*	*Passiflora*
Gynocardin	D-Glucose	1*S*,4*S*,5*R*	*Gynocardia*, *Pangium*, *Taractogenes*, *Rawsonia*
Heterodendrin (dihydroacacipetalin)	D-Glucose	*S*	*Acacia*
Holocalin	D-Glucose	*R*	*Sambucus*
Linamarin (phaseolunatin)	D-Glucose	–	*Trifolium*, *Lotus*, *Phaseolus*, *Manihot*
Linustatin	Gentiobiose	–	*Linum*
Lotaustralin (methyllinamarin)	D-Glucose	*R*	*Lotus*, *Manihot*
Lucumin	Primeverose	*R*	*Lucuma*
Neolinustatin	Gentiobiose	*R*	*Linum*
Passicoriacin	D-Glucose	*S*	*Passiflora*
Passiedulin	D-Allose	*R*	*Passiflora*
Prunasin	D-Glucose	*R*	*Prunus*, *Malus*, *Pyrus*, *Sorbus*, *Cydonia*, *Carica*
Sambunigrin	D-Glucose	*S*	*Prunus*, *Sambucus*
Taractophyllin	D-Glucose	1*R*,4*S*	*Passiflora*
Suberin A	D-Glucose	1*R*,2*R*,3*R*,4*R*	*Passiflora*
Taxiphyllin	D-Glucose	*R*	*Taxus*, *Triglochin*, *Bambusa*
Tetraphyllin A	D-Glucose	*S*	*Tetrapathaea*, *Passiflora*
Tetraphyllin B	D-Glucose	1*S*,4*S*	*Tetrapathaea*, *Passiflora*, *Mathurina*, *Carica*
Triglochinin	D-Glucose	–	*Triglochin*, *Glyceria*, *Melica*
Vicianin	Vicianose	*R*	*Vicia*
Volkenin	D-Glucose	1*R*,4*R*	*Passiflora*, *Mathurina*
Zierin	D-Glucose	*S*	*Sambucus*

The main cyanogen in butter beans and birds foot trefoil is (*R*)-lotaustralin. Linustatin has the same aglycone as linamarin and the same aglycone as in (*R*)-lotaustralin is found in (*R*)-neolinustatin. These glycosides, containing disaccharide gentiobiose, occur as the major cyanogenic glycosides in the seeds of linseed (*Linum usitatissimum*, Linaceae). From leucine β-glucosides (*S*)-heterodendrin (dihydroacacipetalin) and (*S*)-acacipetalin (proacacipetalin) are derived, occurring in many acacias (*Acacia* spp.), shrubs and trees belonging to the subfamily Mimosoideae of the family Fabaceae.

A number of cyanogenic glycosides are derived from the aromatic amino acids phenylalanine and tyrosine. From phenylalanine is derived the epimeric pair of β-glucosides known as (*R*)-prunasin and (*S*)-sambunigrin. (*R*)-Passiedulin of purple passion fruit, also known as purple granadilla (*Passiflora edulis*, Passifloraceae), originating in tropical South America, contains a rare hexose D-allose instead of D-glucose. Prunasin is a cyanogenic β-glucoside occurring in seeds of many plants of the rose family (Rosaceae), such as plums (*Prunus* spp.), apricots (*Armeniaca* spp.), peaches (*Persica* spp.), apples (*Malus* spp.), pears (*Pirus* spp.), quinces (*Cydonia* spp.) cranberries (*Sorbus* spp.), cotoneaster berries (*Cotonoaster* spp.), many acacia species and is also present in passion fruits accompanied by other cyanogens. Sambunigrin, accompanied by prunasin and other glycosides, is the main cyanogenic β-glucoside of elderberries (*Sambucus nigra*, Adoxaceae). It is found in all parts of the plant, especially in leaves and immature fruits. During maturation, its content decreases and at the time of maturity sambunigrin is not even present in the fruits. Juice made from unripe elderberries does not contain sambunigrin at concentrations that represent a health risk, but can be sensorially unacceptable for

its bitterness. (*R*)-Epiheterodendrin occurs in some varieties of malting barley (*Hordeum* spp., Poaceae) and in malt.

The same aglycone as prunasin (D-mandelic acid nitrile) contains (*R*)-amygdalin, which is β-gentiobioside, (*R*)-vicianin, containing β-vicianose, and (*R*)-lucumin, which contains β-primeverose. The most important cyanogenic glycoside of this group of cyanogens is amygdalin, since it is present in plants of the rose family (Rosaceae), together with prunasin and sambunigrin. Significant resources are bitter almonds and apricot, peach, plum and cherry pits. In small amounts, amygdalin also occurs in apple, pear and quince seeds. The precursor of amygdalin is prunasin, which is also present in the flesh of immature fruits. The amount of amygdalin is not high, and is not life threatening. Poisoning usually occurs only accidentally, for example when children consume large quantities of bitter almonds.

From phenylalanine is derived the cyanogenic β-glucoside vicianin found in vetches, such as the common vetch (*Vicia sativa*, Fabaceae). Lucumin is present in tropical plants of the genus *Lucuma* of the same plant family. Other cyanogenic β-glucosides are (*R*)-holocalin and its epimer (*S*)-zierin, which occur in small amounts in elder leaves and unripe berries.

Tyrosine yields β-glucoside (*R*)-taxiphyllin and epimeric (*S*)-dhurrin. Taxiphyllin is present in bamboo shoots (*Bambusa* spp., Poaceae), needles of yew (*Taxus baccata*, Taxaceae) and juniper (*Juniperus* spp., Cupressaceae). Dhurrin occurs in grasses (Gramineae), such as sorghum (*Sorghum bicolor*), especially in young green parts of the plants. Tyrosine is also the precursor of β-glucoside triglochinin, which occurs in some grasses, for example, in melic grasses (*Melica* spp.), reed manna grass (*Glyceria maxima*) and wetland plants, such as marsh arrow grass (*Triglochin palustris*, Junkaginaceae), which may become a part of forage for livestock.

An unusual cyanogenic glycoside is (1*S*,4*S*,5*R*)-gynocardin. It occurs along with other β-glucosides and fatty acids with cyclopentene ring (see Section 3.3.3.3.3) in the seeds of chaulmoogra trees of the genus *Hydnocarpos* (syn. *Taraktogenos*, Achariaceae, formerly Flacourtiaceae), native to Indonesia, Malaysia and the Philippines.

The content of cyanogenic glucosides in certain foods, expressed in the amount of bound hydrogen cyanide (cyanogenic potential), is given in Table 10.11. Content depends on the degree of maturity and many other factors.

Reactions and changes

Cleavage of cyanogenic glycosides may occur either enzymatically or chemically. Glycosides containing β-D-glucose are more or less hydrolysed by specific β-glucosidases that are often referred to by common names according to origin. For example, the bitter almond enzyme is called amygdalase (amygdalinase, formerly also emulsin) and the cassava enzyme is known as linamarase. The enzyme hydrolyses the glycosidic bond to produce sugar and cyanohydrin. Glycosides containing disaccharides are broken down in two stages, in the first stage the corresponding glycoside (containing bound monosaccharide) reults and in the second stage the monosaccharide and aglycone (cyanohydrin) is released. For example, prunasin arises as an intermediate from amygdalin, and is further hydrolysed to glucose and 2-hydroxynitrile. Another enzyme involved in the decomposition of cyanogenic glycosides is aldehyde lyase, which catalyses the cleavage of a cyanohydrin to aldehyde or ketone and hydrogen cyanide (Figure 10.3). Such enzymes are cyanohydrin lyase, which catalyses the cleavage of acetone cyanohydrins, mandelonitril lyase, also known as (*R*)-oxynitrilase, which cleaves a number of aromatic and aliphatic cyanohydrins,

Table 10.11 HCN content in some plant cyanogenic glycosides.

Origin	HCN (mg/kg of fresh material)	Origin	HCN (mg/kg of fresh material)
Cassava		***Stone fruits***	
Leaves	650–1 040	Bitter (sweet) almonds	2800–4110 (0–100)
Whole tubers	550	Apricot stones	3200
Tuber bark	840–2 450	Sour cherry stones	3540
Tuber flesh	100–330	Sour cherry flesh	10
Bamboo		***Sorghum***[a]	
Unripe shoots	3000	Germinating plants	2400
Tops of unripe shoots	8000	Young leaves	600
Purple passion fruit		***Legumes***	
Unripe fruit	700	Butter beans	100-4000
Ripe fruit	100	Common beans	20
Linseeds	200–380	Peas	23

[a] *Sorghum bicolor* (Poaceae).

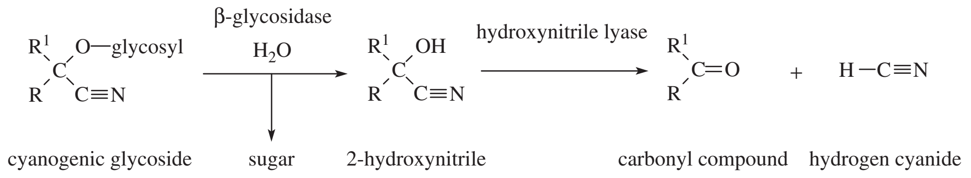


Figure 10.3 Enzymatic hydrolysis of cyanogenic glycosides.

and hydroxymandelonitril lyase that cleaves (*S*)-4-hydroxymandelo nitriles. The final product of triglochinin degradation is not the corresponding carbonyl compound, but a product of its hydration, which is (*E*)-but-2-ene-1,2,4-tricarboxylic acid.

The hydrolysis products of major cyanogenic glycosides are summarised in Table 10.12. In all cases, other products are sugars and hydrogen cyanide. The enzymatic degradation of amygdalin is shown in Figure 10.4 as an example. Hydrogen cyanide released from stone fruit cyanogens is a precursor of toxic ethyl carbamate, which occurs mainly in stone fruit distillates (see Section 12.2.8).

Cyanogenic glycosides are hydrolysed also by diluted acids at elevated temperatures, producing sugars and 2-hydroxy nitriles. For example, amygdalin hydrolysis produces D-mandelic acid nitrile. In concentrated acids, the hydrolysis of nitriles yields 2-hydroxycarboxylic acids and ammonium salts. Amygdalin thus yields D-mandelic acid. In slightly alkaline solutions, epimerisation of cyanogenic glycosides occurs. For example (*R*)-amygdalin yields a mixture of epimers known as isoamygdalin. The epimer of amygdalin derived from L-mandelic acid, called (*S*)-neoamygdalin, does not occur in nature. The epimeric pair of prunasin and sambunigrin was formerly called prulaurasin. In strongly alkaline media, both epimers yield glycosides of 2-hydroxycarboxylic acids. For example, the product of amygdalin alkaline hydrolysis is an epimeric mixture of mandelic acid gentiobioside, which is called amygdalinic acid (Figure 10.5). (*S*)-Epilucumin, which arises from (*R*)-lucumin, also does not occur in nature.

Detoxication of cassava in culinary practice is done by sun drying, crushing and grinding, soaking in water, boiling and fermentation. During fermentation, about 90% of cyanogens are removed and simultaneously formed substances carry the favourable organoleptic properties of the products. After 30 min of cooking, the content of cyanogens decreases by about 8–30% of the original amount.

Table 10.12 Hydrolysis products of cyanogenic glycosides.

Glycoside	Carbonyl compound	Glycoside	Carbonyl compound
Linamarin, linustatin	Acetone	Vicianin	Benzaldehyde
Lotaustralin, neolinustatin	Butan-2-one	Holocalin	3-Hydroxybenzaldehyde
Prunasin	Benzaldehyde	Zierin	3-Hydroxybenzaldehyde
Sambunigrin	Benzaldehyde	Taxiphyllin	4-Hydroxybenzaldehyde
Amygdalin	Benzaldehyde	Dhurrin	4-Hydroxybenzaldehyde

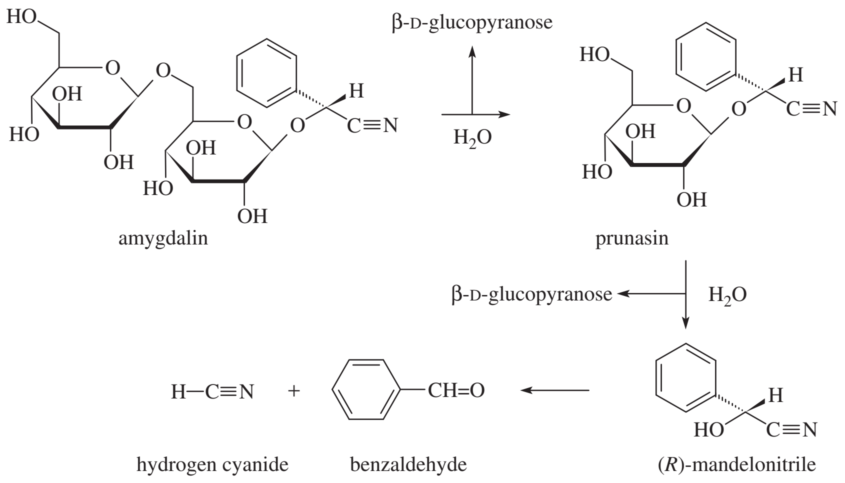

Figure 10.4 Enzymatic hydrolysis of amygdalin.

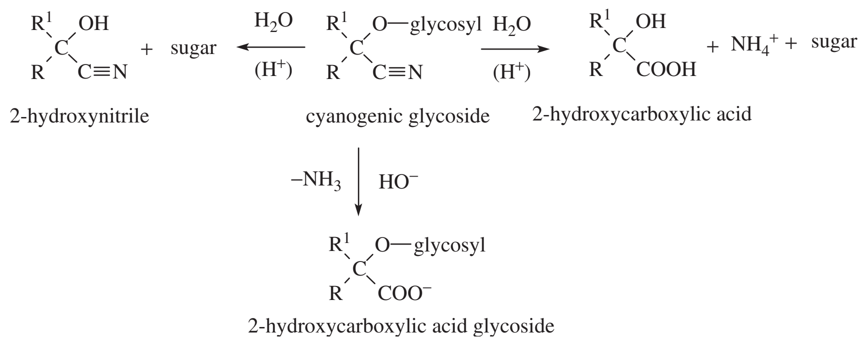

Figure 10.5 Degradation of cyanogenic glycoside in acidic and alkaline media.

Research on developing cassava with lower cyanogenic glucoside content is another way to solve the problem of cassava detoxication. The main cyanogen of bamboo shoots, taxiphyllin, is labile and decomposes during cooking.

The most common source of cyanogens in the European diet is stone fruits. Cyanogens are mainly present in the inedible part of the fruit, the stones. When whole fruit is processed, cyanogens may gradually pass from the stones into the edible part of the fruit. For example, fruit juices obtained from unstoned fruit may contain up to 15 mg/kg of hydrogen cyanide. Higher concentrations also occur in compotes made of unstoned fruit. For example, apricot compotes may contain up to 33 mg/kg of hydrogen cyanide. The amount of released hydrogen cyanide depends on the technological conditions, especially the temperature. The enzymatic degradation can occur only if there is thermal damage of cell membranes and enzymes have not been inhibited. The higher the inactivation effect, the lower the concentration of hydrogen cyanide in the finished product. Benzaldehyde arising from the enzymatic degradation of stone fruit cyanogens is often the bearer of flavour in the stone fruit products. Benzoic acid formed by partial oxidation of benzaldehyde has antimicrobial properties.

Kernels of some stone fruits (such as bitter almonds) are used to make marzipan, almond jelly and other confectionery products. Again, even in this case enzymatic hydrolysis of cyanogenic glycosides releases hydrogen cyanide, which is, however, released in the subsequent technological operations. Similar changes of cyanogens occur in the production of fruit spirits, as the major quantity of hydrogen cyanide formed in the fermentation process is vaporised during fermentation and subsequent distillation. Stone fruit distillates usually contain 0.3–3 mg/kg of hydrogen cyanide (cyanides).

Biological effects

Cyanogenic glycosides are not toxic; only their decomposition product, hydrogen cyanide, is toxic. Acute toxicity is due to inhibition of cytochrome oxidase in the respiratory chain by cyanide (reaction with copper ions) and reaction with haemoglobin (formation of cyanohaemoglobin). The lethal dose of cyanide for humans is from 0.5 to 3.5 mg/kg body weight, which corresponds to 35–245 mg for an adult weighing 70 kg. Symptoms of ingestion of a lethal dose are manifested by stiffness of limbs, dazed consciousness, cyanosis (bluish discoloration of the skin), convulsions and coma. Ingestion of lower cyanide concentrations leads to headaches, anxiety and uneasiness in the throat and chest, heartbeat and muscle weakness. Chronic symptoms of poisoning (manifested by disease of the peripheral nerves) are called degenerative tropical neuropathy.

In cases where fresh cyanogenic plants containing intact glycosides are eaten, there is only a small amount of hydrogen cyanide released, since glycosidases hydrolysing cyanogenic glycosides are inhibited in the stomachs of humans and other monogastric animals. In ruminants (polygastric animals), the plant enzymes are not inhibited and cyanogenic glycosides are partly decomposed by the rumen microflora, which can lead to poisoning.

Detoxification products of cyanides in the human body are thiocyanate (rhodanide) ions. The conversion of cyanides to thiocyanates in the presence of thiosulfates as sulfur donors is catalysed by mitochondrial rhodanese (thiosulfate : cyanide sulfurtranferase). Certain anticarcinogenic effects of cyanogenic glycosides (named vitamin B_{17}) described in the past, have not been demonstrated (see Section 5.15). It was assumed that cyanides attack cancer cells in the tissue with reduced activity of rhodanese. Another enzyme is 3-mercaptopyruvate sulfurtransferase that uses mercaptopyruvic acid as a sulfur donor. Plants have different detoxification mechanisms from animals. Cysteine (or serine) reacts with hydrogen cyanide in a reaction catalysed by β-cyanoalanine synthase with the formation of β-cyanoalanine, which is transformed by β-cyanoalanine hydratase into asparagine, an amino acid important for nitrogen storage (Figure 2.2). Asparagine can be further metabolised to aspartic acid and ammonia by the action of asparaginase. Pathogenic fungi that attack plants, such as *Gloecercospora sorghi* and *Colletotrichum graminicola* infecting sorghum, contain the enzyme cyanide hydratase catalysing the addition of water to hydrogen cyanide, which yields formamide ($H–CONH_2$).

10.3.3.3.2 Pseudocyanogenic glycosides

Toxic pseudocyanogenic glycosides (azoxyglycosides) are found in many plants of the cycad family Cycadaceae found across the subtropical and tropical parts of the world. The pseudocyanogenic glycoside cycasin occurs in seeds of some cycad species used as a source of starch. Depending on the type of plants, starchy dishes made from cycad seeds may contain up to 0.22 mg/kg of azoxyglycosides.

For example, sago cycad (*Cycas revoluta*), the only native cycad in Japan, has been used as a starch source on Amami Oshima, an island in the Amami Islands, for centuries. The stems are mashed into a pulp and then fermented, thus slowly removing the toxins. Likewise, seeds have been used to make a cycad cake called *sotetsu mochi*. Moreover, crushed seeds are made into *sotetsu miso*, a paste much like the normal *miso* made from soya beans. All of these practices are considered dangerous, but to this day, these traditions persist in local areas. If eaten, cycad products containing azoxyglycosides may lead to gastrointestinal distress and liver failure. Cycasin and other azoxyglycosides are not mutagenic or carcinogenic, but the main metabolite methylazoxymethanol is. Incidence of neurological disorders resembling Parkinson's disease has been reported in various areas of the Pacific (e.g. in the United States island territory of Guam), but these neurological disorders might also be caused by the presence of lathyrogenic 2,4-diaminobutyric acid (see **2-41**).

Pseudocyanogenic glycosides are decomposed by pathways other than cyanogenic glycosides. In a weakly alkaline medium they release cyanides, formates and elemental nitrogen; in an acidic medium they yield formaldehyde, methanol and elemental nitrogen. Their enzymatic degradation produces methylazoxymethanol (Figure 10.6).

10.3.3.3.3 Cyanogenic lipids

Cyanogenic lipids (cyanolipids) occur together with conventional triacylglycerols in the seeds of many plants of the soapberry family (Sapindaceae); in certain cases they represent more than 50% of the seed oil. Members of this family have been widely studied for their pharmacological (antioxidant, anti-inflammatory and anti-diabetic properties) and anti-insect activities, and many species have economically valuable tropical fruits and wood. Some cyanogenic lipids also occur in plants of the Hippocastaneaceae and Boraginaceae families, which are not used for human consumption.

The five carbon skeletons of all cyanolipids, derived from leucine, have the cyano group and one or two hydroxyl groups esterified by fatty acids. Type I cyanolipids are diesters of 1-cyano-2-hydroxymethylprop-2-en-1-ol (**10-74**), type II cyanolipids are diesters of 1-cyano-2-hydroxy-methylprop-1-en-3-ol (**10-75**), type III cyanolipids are esters of 1-cyano-3-hydroxyprop-1-ene (**10-76**) and type IV cyanolipids are esters of 1-cyano-2-methylprop-2-en-1-ol (Figure 10.7). In seeds of some

plants, these basic skeletons are not esterified with fatty acids, but exist as glucosides. The most common compounds are type I cyanolipids, which are often accompanied by type II cyanolipids. Compounds of type III are only found together with type II compounds. Cyanolipids of type IV are relatively rare. Compounds of types I and IV are cyanohydrins with a chiral centre, compounds of types II and III are α,β-unsaturated nitriles that are not optically active. The cyanohydrins released by acid or base hydrolysis of types I and IV cyanolipids spontaneously decompose to form hydrogen cyanide (Figure 10.7), parent carbonyl compounds and fatty acids.

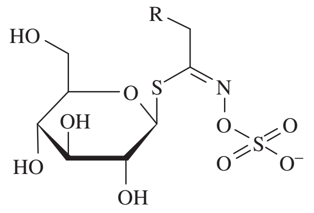
10.3.3.4 Glucosinolates

Glucosinolates, formerly called thioglucosides or mustard oil glycosides, are an important group of more than 150 secondary metabolites found exclusively in flowering dicotyledonous plants belonging to the order Brassicales. In terms of their importance, the dominant position is occupied by the crucifers (mustards or cabbage) family (Brassicaceae), which includes economically important crops (oilseeds, vegetables and condiments). For example, glucosinolates are responsible for the typical pungent taste and odour of rapeseed, mustard, horseradish and other types of vegetables and some spices.

Considerable attention was given to glucosinolates in the 1960s, mainly in connection with strumigenic (goitrogenic) effects of rapeseed meal used as feed for livestock. Glucosinolates were therefore classified as antinutritional factors that interfere with iodine metabolism. Current research is focused primarily on the biological properties of glucosinolate degradation products and their positive effects, but they also have some negative effects on human health.

10.3.3.4.1 Structure, nomenclature and occurrence

The glucosinolate molecule (**10-77**) is formed by the sugar component (in most cases β-D-glucose or β-D-thioglucose, respectively, which may be esterified by sinapic or some other carboxylic acid) and the aglycone, which is a sulfonated oxime anion in the (*E*)-position to the side chain R and in the (*Z*)-position to thioglucose residue. Generally, glucosinolates are found in nature as potassium salts. A vast number of glucosinolates occurring in nature is due to the chemical diversity of the side chain, which is derived from a few amino acids (methionine and its higher homologues, phenylalanine, tyrosine and tryptophan). An overview of main glucosinolates is given in Table 10.13.



10-77, general structures of glucosinolates

Semisystematic names of glucosinolates are formed from the chemical names of the variable part of the molecule (the side chain R) and extension glucosinolate (e.g. 2-hydroxybut-3-en-1-ylglucosinolate). However, trivial names are used more often, derived mostly from the Latin names of plants, from which glucosinolates were first isolated. For example, 4-hydroxybenzylglucosinolate was first isolated from white mustard seeds (*Leucosinapis alba*, syn. *Brassica alba*) and was therefore termed sinalbin. Prop-2-en-1-ylglucosinolate, isolated from seeds of black mustard (Brassica nigra, syn. *Sinapis nigra*), was called sinigrin. 2-Hydroxybut-3-en-1-ylglucosinolate, which is a common constituent of cruciferous vegetables and rapeseeds, is called progoitrin as it is the precursor of goitrin, showing significant antithyroid (strumigenic) effects.

The side chain R determines the chemical, physical and biological properties of the individual glucosinolates and the type of their degradation products. According to the structure of the side chain, glucosinolates can be divided into several groups:

- aliphatic or alk(en)ylglucosinolates (No. 1-6 in Table 10.13) or aliphatic hydroxy substituted glucosinolates (No. 7–9);
- sulfur-containing with a methylthio group in the side chain (No. 10–13) or their oxidised forms (No. 14–19);
- aromatic with unsubstituted or substituted benzene rings (No. 20–26);
- indole (with a substituted indole skeleton, No. 26–30).

An overview of significant plants of the Brassicaceae family that contain glucosinolates is given in Table 10.14. Some plants belonging to other families are also occasionally consumed, such as the caper bush (*Capparis spinosa*, Capparidaceae) with edible flower buds known as capers used as a seasoning, which contain

Table 10.13 Names and structure of most widespread glucosinolates.

No.	Trivial name	Substituent R	No.	Trivial name	Substituent R
1	Glucocapparin	Methyl	16	Glucoraphanin	4-Methylsulfinylbutyl
2	Sinigrin	Prop-2-en-1-yl (allyl)	17	Glucoalyssin	5-Methylsulfinylpentyl

Table 10.14 Overview of dominant glucosinolates of selected vegetables and oilseeds.

Vegetable	Latin name	Typical glucosinolates (names of substances are given in Table 10.13)
Cabbage	*Brassica oleracea* convar. *capitata*	2, 14, 26, 28
Brussels sprouts	*Brassica oleracea* convar. *oleracea* var. *gemmifera*	2, 14, 26, 28, 29
Cauliflower	*Brassica oleracea* var. *botrytis*	2, 4, 7, 18, 26, 27, 29
Cale	*Brassica oleracea* var. *sabellica*	2, 7, 26
Kohlrabi	*Brassica oleracea* var. *gongylodes*	2, 14, 26, 28
Broccoli	*Brassica oleracea* var. *italica*	4, 7, 10, 12, 14, 16, 17, 27, 28, 29, 30
Chinese cabbage	*Brassica chinensis* var. *chinensis*	23, 26
Turnip rape	*Brassica rapa* subsp. *rapa*	2, 4, 7, 24, 26, 27
Rapeseed[a]	*Brassica napus* var. *napus*	4, 6, 7, 9, 27
Brown mustard	*Brassica juncea*	2, 4
Black mustard	*Brassica nigra*	2
White mustard	*Leucosinapis alba*	21
Radishes	*Raphanus sativus*	11, 15, 16, 24, 27, 28
Horseradish	*Armoracia rusticana*	2, 21
Garden cress	*Lepidium sativum*	20

[a]Crambe (*Crambe abyssinica*), an oilseed crop native to the Mediterranean area, contains glucosinolate epiprogoitrin as the main instead of progoitrin. Rapeseeds contain a number of other minor glucosinolates. For example, the 00 varieties (varieties with low erucic acid and glucosinolate contents) contain, in addition to the above compounds, glucosinolates 1, 8, 14–18, 21, 23–26, 28, 29 (Table 10.13), 2-hydroxy-2-methylpropyl glucosinolate, 2-hydroxybenzyl glucosinolate and glycosides of glucosinolates with sugar bound to the hydroxyl group of the aromatic ring (2-α-L-rhamnopyranoside of 2-hydroxybenzyl glukosinolate), glucosinolate esters with phenolic acids bound to glucose, for example, 6′-sinapoylglucoraphenin and (*Z*)-6′-feruloylglucosibarin.

glucosinolate glucocapparin. The seeds of papaya (*Carica papaya*, Caricaceae), containing glucosinolate glucotropaeolin, are used for their spicy and pungent flavour as a black pepper substitute.

The intake of glucosinolates by farm animals is associated with non-traditional *Brassica* fodder crops (such as fodder kale, fodder rape, swede and turnip) and rapeseed meal, a byproduct from crushing, expelling and extracting oil from oilseed rape. In human food, the income of glucosinolates is almost exclusively associated with the consumption of cruciferous vegetables. The most important source of glucosinolates are cabbage, cauliflower, kale, broccoli and Brussels sprouts, followed by occasionally consumed vegetables, such as radishes, watercress, horseradish and others. Vegetables of the cruciferous family commonly contain approximately 20–30 glucosinolates. In one plant there are usually only a few of them in significant quantities (Table 10.14). While the composition of glucosinolates for each plant (or variety) is typical to a certain extent and is determined mainly by genetic factors, the total glucosinolate content is influenced by a number of external factors during cultivation (such as climate conditions, use of fertilisers, pest attack and other factors). The average glucosinolate content in the vegetative parts of plants (in fresh vegetables) ranges from 100 to 2500 mg/kg, but in seeds may reach values of up to 60 000 mg/kg.

10.3.3.4.2 Reactions and changes

In plant tissue, glucosinolates are accompanied by the enzyme myrosinase (thioglucoside glucohydrolase), which catalyses their decomposition. Myrosinase is a globular glycoprotein with a relative molecular weight of 140 kDa, consisting of several isoenzymes. A special feature is the occurrence of myrosinase in some microorganisms (fungi) and even in some animal tissues. In intact tissue, myrosinase is located separately from glucosinolates, but in mechanically damaged cells (e.g. cells which have been damaged by cutting, biting or freezing) it comes into contact with glucosinolates, which are then hydrolysed relatively rapidly. The rate of glucosinolate hydrolysis is determined by enzyme activity, which is influenced by many factors (temperature, pH value, type and part of the plant or the presence of substances which act as activators or inhibitors).

The actual enzymatic hydrolysis is initiated by myrosinase-catalysed cleavage of the thioglucoside bond of glucosinolate. Hydrolysis yields, in addition to D-glucose, an unstable intermediate (aglycone) thiohydroxamate-*O*-sulfonate, which is spontaneously degraded with the cleavage of bisulfate ion (HSO_4^-) and stabilisation of the remaining part of the molecule yielding one or more stable products (Figure 10.8). The most common glucosinolate decomposition products are isothiocyanates and nitriles: however, depending on glucosinolate structure and some external factors, a number of other products can arise. Isothiocyanates (and partly also nitriles) formed by hydrolysis of aliphatic glucosinolates contribute to the typical spicy flavour of cruciferous vegetables (see Section 8.3.7.5).

For example, degradation of the most common glucosinolate, sinigrin, yields, in addition to allyl isothiocyanate (see Section 8.2.9.1.5) and allyl cyanide (but-3-enenitrile, see Section 8.2.7.1.3), allyl thiocyanate (it is not clear whether this substance arises directly from the unstable aglycone or by isomerisation of isothiocyanate) and 2-(cyanomethyl)thiirane, also known as

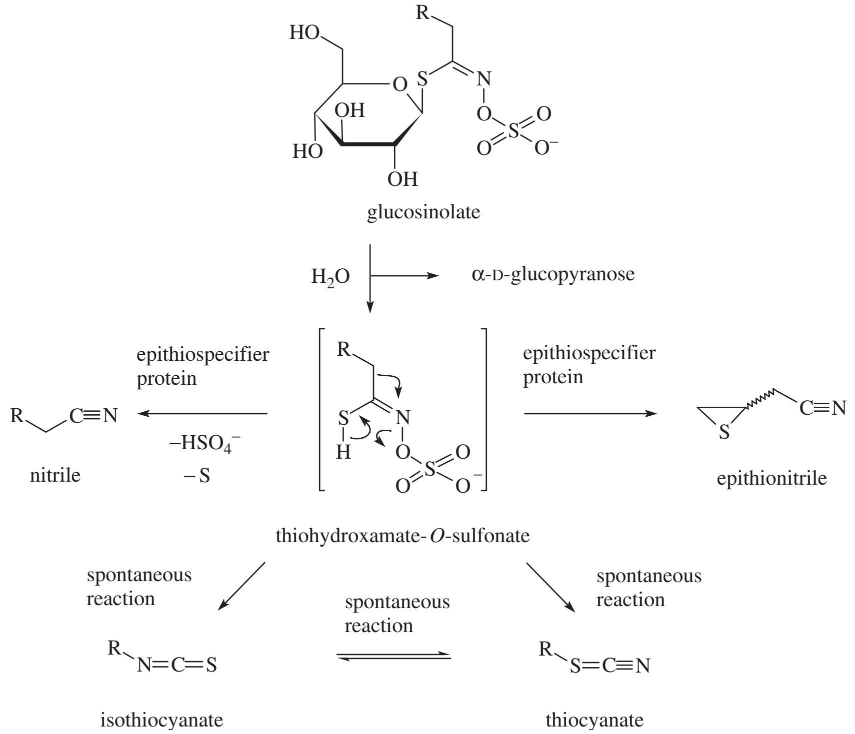

Figure 10.8 General mechanism of glucosinolate degradation.

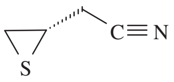
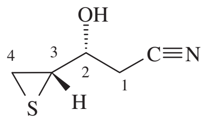
2-(cyanomethyl)episulfide or 1-cyano-2,3-epithiopropane (**10-78** and **10-79**), which arises at the expense of allylcyanide in the presence of a special protein cofactor, called epithiospecifier protein (ESP), whose existence has been demonstrated in many plants. This protein is essential for myrosinase induced formation of (*R*)- and (*S*)-enantiomeric epithionitriles of all glucosinolates with unsaturated side chains. For example, gluconapin yields both enantiomers of 2-(thiiran-2-yl)acetonitrile (1-cyano-3,4-epithiobutane), from glucobrassicanapin arises 1-cyano-4,5-epithiopentane, from progoitrin, except (*R*)-1-cyano-2-hydroxybut-3-ene, arise diastereoisomeric (*R*)-1-cyano-2-hydroxy-3,4-epithiobutanes (3-hydroxy-4,5-epithiopentylnitriles, **10-80** and **10-81**) and from gluconapoleiferin 1-cyano-2-hydroxy-4,5-epithiopentanes. Isothiocyanates resulting from 2-hydroxyalkenylglucosinolates are unstable and spontaneously cyclise (by intramolecular addition of hydroxyl group) to substituted 5-alkenyl-1,3-oxazolidine-2-thiones. Progoitrin, the dominant glucosinolate of rapeseeds, yields toxicologically significant (*R*)-5-vinyl-1,3-oxazolidine-2-thione called goitrin (Figure 10.9), napoleiferin produces 5-allyl-1,3-oxazolidine-2-thione and glucobarbarin gives rise to 5-phenyl-1,3-oxazolidine-2-thione.

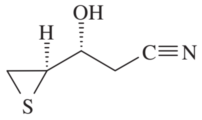
10-78, (*R*)-2-(cyanomethyl)thiirane



10-79, (*S*)-2-(cyanomethyl)thiirane

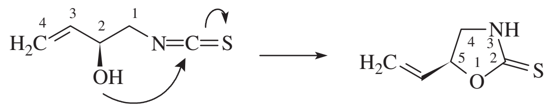


10-80, (2*R*,3*R*)-1-cyano-2-hydroxy-3,4-epithiobutane



10-81, (2*R*,3*S*)-1-cyano-2-hydroxy-3,4-epithiobutane

The situation is somewhat more complicated in the case of the so-called indole glucosinolates (indol-3-ylmethylglucosinolates) called glucobrassicins. In seeds of oilseed rape and other *Brassica* species, the total pool of glucosinolates is most often dominated by 4-hydroxyindol-3-ylmethyl glucosinolate (4-hydroxyglucobrassicin) and methionine-derived glucosinolates. In contrast, vegetative parts of *Brassica* species, including various types of vegetables, have a relatively high content of the indol-3-ylmethyl glucosinolates: glucobrassicin, 4-methoxyglucobrassicin

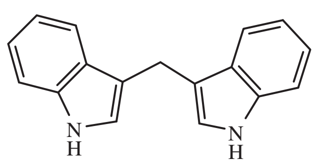


(*R*)-2-hydroxybut-3-en-1-ylisothiocyanate (*R*)-5-vinyloxazolidine-2-thione

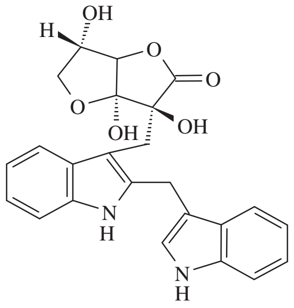
Figure 10.9 Formation of goitrin from 2-hydroxybut-2-en-1-yl isothiocyanate.

and 1-methoxyglucobrassicin (neoglucobrassicin). Under the catalysis of myrosinase, the indol-3-ylmethylglucosinolates (as well as some other arylmethylglucosinolates) are degraded to indol-3-ylacetonitriles and unstable isothiocyanates, with release of the thiocyanate (rhodanide) ion and a reactive carbonium ion, which gives a complex mixture of reaction products, such as 3-hydroxymethylindoles (indol-3-ylmethanols) and ascorbigens, depending on the nucleophiles available and the reaction conditions (Figure 10.10). Their subsequent reactions give various dimers and oligomers.

Ascorbigen derived from glucobrassicin was formerly called ascorbigen A. In vegetables rich in ascorbic acid, ascorbigen is the main transformation product of glucobrassicin. Its contents in cruciferous vegetables can reach 5–60 mg/kg. Depending on various factors, about 20–50% of glucobrassicin can be converted into ascorbigen, which has 15–20% of ascorbic acid activity. Stabilities of 3-hydroxymethylindole and ascorbigen are limited, particularly at higher temperatures, and both compounds provide a wide range of transformation products. Self-condensation of 3-hydroxymethylindole, after cleavage of formaldehyde, yields 3,3′-diindolylmethane (**10-82**) and other di- and polyindolylmethanes. At higher temperatures, ascorbigen splits off ascorbic acid and the remaining residue can bind as a cation to another molecule of ascorbigen to form a dimer (**10-83**) and a trimer (**10-84**). Binding to other nucleophilic compounds is also possible. A mixture of the dimer and trimer was previously called ascorbigen B.



10-82, 3,3′-diindolylmethane



10-83, ascorbigen dimer

Thermal degradation of glucobrassicin produces 3-indolylacetonitrile as the main product (Figure 10.10), 3-indolylacetic acid, 3-indolylacetamide, 3-formylindole (**10-85**), 3-methylindole (skatole, see Section 2.5.1.1.3) and other compounds.

In relation to the biological effects of glucosinolates, particular attention is paid to the influence of external conditions (particularly

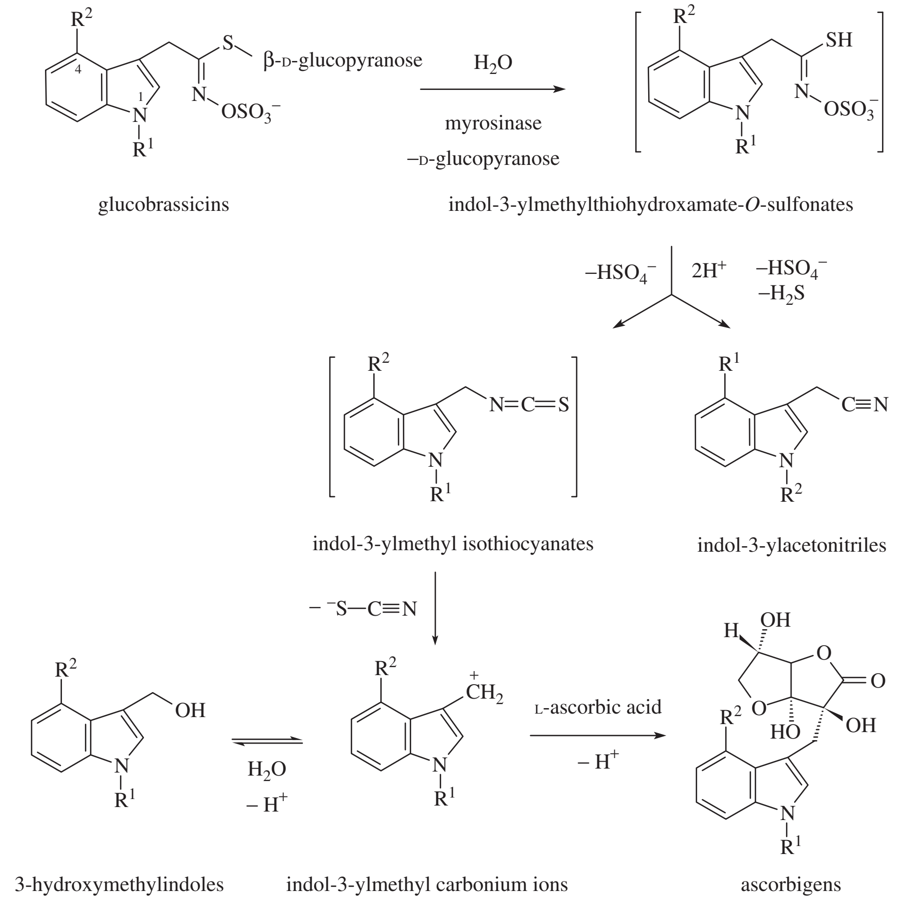


Figure 10.10 Degradation of indol-3-ylmethylglucosinolates:
Glucobrassicins: glucobrassicin ($R^1 = R^2 = H$), 4-hydroxyglucobrassicin ($R^1 = H$, $R^2 = OH$), 4-methoxyglucobrassicin ($R^1 = H$, $R^2 = OCH_3$), neoglucobrassicin ($R^1 = OCH_3$, $R^2 = H$)
Ascorbigens: ascorbigen ($R^1 = R^2 = H$), 4-hydroxyascorbigen ($R^1 = H$, $R^2 = OH$), 4-methoxyascorbigen ($R^1 = H$, $R^2 = OCH_3$), neoascorbigen ($R^1 = OCH_3$, $R^2 = H$).

pH, temperature and concentration of metal ions) to the mechanism of their hydrolysis. These effects should be taken into account when assessing the potential toxicity and the positive effects of glucosinolates, because they are significantly involved in the formation of physiologically active products. The pH value of the reaction medium has an effect on the rate of enzymatic hydrolysis as myrosinases of various plants usually have several pH-optima, which lie in the interval of between pH 5 and 8, due to the presence of several isoenzymes and the degradation mechanism of unstable aglycone (Figure 10.8). Generally, under acidic conditions (pH < 4) nitriles predominantly arise, while at higher pH values larger amounts of isothiocyanates are formed. Another factor affecting the decomposition of glucosinolates is temperature. Thermal processing of vegetables (such as cooking, blanching and sterilisation) leads

to inactivation of enzymatic systems, including myrosinase and epithiospecifier protein. Depending on the temperature and duration of heat treatment, glucosinolates are also partially decomposed (the main cause of losses is leakage into water) along with some other thermolabile products (such as 3-hydroxymethylindole and ascorbigen). In addition, a number of volatile substances are evaporated, in particular low molecular weight isothiocyanates, which significantly changes the flavour characteristics of processed vegetables. The disruption of plant tissue, which was preceded by a sufficiently effective thermal intervention, no longer results in enzymatic degradation of glucosinolates and the remaining amount of glucosinolates stays in the food. Glucosinolate hydrolysis may be affected by the presence of various chemicals, of which the most significant is ascorbic acid, which occurs in cruciferous vegetables in amounts of about 100–1200 mg/kg. In addition to the formation of ascorbigen, ascorbic acid also participates in the myrosinase activation, thus speeding up the whole process of enzymatic degradation of glucosinolates. Changes in the content of glucosinolates in selected cruciferous vegetables during cooking are summarised in Table 10.15.

Generally, blanching and cooking of vegetables results in a considerable leakage of glucosinolates into water, on average, 30–40% of glucosinolates are extracted, and in cabbage 28% during 10 min of boiling. Losses of glucosinolates by leakage and degradation are lowest for sinigrin (about 30%) and highest for neoglucobrassicin (about 60%). Approximately one-third to half of the original content of glucosinolates remains unchanged during cooking. In frozen vegetables, as a result of myrosinase activity in damaged tissues, about 50% of the originally present glucosinolates decomposes. Virtually complete degradation of glucosinolates occurs during the first week of cabbage fermentation.

10.3.3.4.3 Biological effects

The mean daily intake of glucosinolates is difficult to evaluate as there are large variations between countries, income groups (e.g. it is likely that certain individuals, such as vegetarians, will consume more than 300 mg total glucosinolates per day) and over the year (the amount consumed is approximately doubled in the winter months). The nutritional and toxicological consequences of such an intake are largely unknown at present. For example, the mean total glucosinolate intake in Germany (in 2009) was 14.2 mg/day for men and 14.8 mg/day for women, and increased with age and education. Quantitatively, the most important individual glucosinolates were glucobrassicin and sinigrin, with mean daily intakes of 3.5 and 1.7 mg/day for men and 4.2 and 2.5 mg/day for women, respectively. Broccoli, Brussels sprouts and cauliflower contributed most to the total glucosinolate intake.

Glucosinolates as such are in practice indifferent compounds and thus are probably neither harmful nor beneficial. Only products of their degradation show biological effects. Degradation of glucosinolates leads to a wide variety of substances. The situation is aggravated by the fact that one substance often exhibits several biological effects. When evaluating the consequences of their presence in a particular crop, attention should therefore be paid to:

- which glucosinolates are present and in what quantities
- which products will arise by their degradation and under what conditions
- biological activity of resulting products.

Table 10.15 Glucosinolates content in fresh and cooked cruciferous vegetables.

Toxic effects

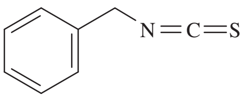
Decomposition of aliphatic glucosinolate leads to slightly strumigenic isothiocyanates, some of which exhibit strong antimicrobial and insecticidal effects (such as allyl isothiocyanate formed from sinigrin). Other products include nitriles and cyanoepithioalkanes that may be hepatotoxic and nephrotoxic. Strumigenic (*R*)-5-vinyl-1,3-oxazolidine-2-thione (goitrin), formed by progoitrin hydrolysis, inhibits the synthesis of thyroid hormones (thyroxine and triiodothyronine) and transmission of iodine in the thyroid gland. Thiocyanate anions, arising from unstable indole and aromatic isothiocyanates, exhibit moderate strumigenic activities, but unlike goitrin and isothiocyanates, they act competitively with respect to iodine. Both mechanisms can lead to an enlarged thyroid gland (goitre) and disturbances of its function. In humans, the strumigenous effects of these compounds have not been demonstrated.

The presence of glucosinolates may be a problem in fodder production. Major deleterious effects of glucosinolates ingestion in animals are reduced palatability, decreased growth and reproduction. Progoitrin and epiprogoitrin impair palatability at a level of between 2.3 and 4.7 mol/g diet, while at higher levels feed intake decreases. Nitriles are known to affect liver and kidney functions. The thiocyanates interfere with iodine availability, whereas goitrin is responsible for the morphological and physiological changes of thyroid. Rapeseed meal feeding (containing 36–40% of protein) does not impair the carcass quality, but increases erucic and elaidic acids contents in carcass and milk fat. However, the newly introduced rapeseed cultivars of canola quality (commonly known as double-low or 00) have, in addition to the low content of erucic acid (0.2%, which corresponds to about 0.5% in the oil), also reduced glucosinolate content (20 mmol/kg). Ruminants are less sensitive to dietary glucosinolates. Pigs are more severely affected by dietary glucosinolate compared with rabbits, poultry and fish. The tolerance level of glucosinolates in ruminants, pig, rabbits, poultry and fish is 1.5–4.2, 0.78, 7.0, 5.4 and 3.6 mol/g of diet, respectively. Results using techniques based on detoxification, such as removal of glucosinolates and their breakdown products by alkali extraction, exposure to water vapour at higher temperatures (toasting) are not satisfactory, especially with regard to their economic demands. Iodine supplementation in the diet of pigs and ruminants seems to be promising.

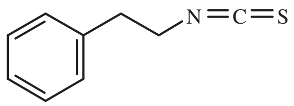
Beneficial effects

Experimental studies with laboratory animals and the results of epidemiological studies have confirmed that increased consumption of cruciferous vegetables reduces the risk of chemically induced cancer, which is cancer induced by intake of carcinogens. The active principles are some glucosinolate degradation products, although the presence of ascorbic acid, α-tocopherol, β-carotene, dimethylthiosulfinate, phenolic antioxidants (e.g. flavonoids) and fibre cannot be ignored.

Benzyl isothiocyanate (**10-86**) and 2-(phenylethyl) isothiocyanate (**10-87**), which arise by hydrolysis of gluconasturtiin and glucotropaeolin, respectively, have the ability to activate some important enzymatic system deactivating carcinogens.

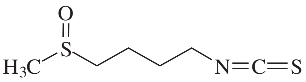


10-86, benzyl isothiocyanate



10-87, 2-(phenylethyl) isothiocyanate

Also worth mentioning is sulforaphane, 4-(methylsulfinyl)butyl isothiocyanate, also known as 4-(methanesulfinyl)butyl isothiocyanate (**10-88**), whose beneficial effects have been appreciated only recently. Its precursor is glucosinolate glucoraphanin occurring, for example, in broccoli or radishes. Another product of glucoraphanin degradation is the corresponding nitrile, which is called sulforaphane nitrile. In broccoli, glucoraphanin is the main glucosinolate. It is present at a level of about 1600 mg/kg fresh weight (approximately 55% of the total glucosinolate content). The other broccoli glucosinolates (in descending order of quantity) are glucoiberin, glucobrassicin, glucoerucin, progoitrin, 4-hydroxyglucobrassicin, glucoibervirin, 4-methoxyglucobrassicin, gluconapin, glucoalyssin and 1-methoxyglucobrassisin. The main glucosinolate of radishes is glucoraphasatin (178–2230 mg/kg fresh weight), which is followed by glucobrassicin, glucoraphenin and glucoraphanin (0–24 mg/kg fresh weight, 0–7% of the total glucosinolate content).



10-88, 4-(methylsulfinyl)butyl isothiocyanate

Much attention has recently been devoted to degradation products of indole glucosinolates, as they are found in virtually all commonly consumed vegetables, and sometimes form a significant proportion of glucosinolates present (e.g. they account for 95% of glucosinolate content in Chinese cabbage). One of the major degradation products of glucobrassicin is 3-hydroxymethylindole, a compound possessing an unusual ability to induce enzymes of the first and second phases of detoxification. Ascorbigen, resulting from the reaction of 3-hydroxymethylindole with ascorbic acid, is partially degraded in the stomach, ascorbic acid splits off and the molecule residue is transformed into products with antimutagenic and anticarcinogenic properties, such as 5,11-dihydroindolo[3,2-*b*]carbazole (**10-89**), which is able to inhibit certain DNA-damaging carcinogens. In neutral media, ascorbigen is converted into indole sugars (**10-90** and **10-91**), the toxicological evaluations of which, as well as the evaluation of the effects of other ascorbigen metabolites and 3-hydroxymethylindole, are not yet sufficiently developed.

10.3.3.5 Phenolic compounds

Phenolic compounds found in foods exhibit a wide range of biological effects. Their antimicrobial and antioxidant properties are particularly appreciated, but some phenolic compounds also show toxic effects. Some coumarins have carcinogenic effects related to their phototoxicity; oestrogenic properties are shown by some lignans, isoflavonoids (isoflavones and related pterocarpans) and prenylflavonoids, which also display anticarcinogenic effects. Other phenolic compounds such as phenolic acids (see Section 8.2.6.1.6), lignans, tannins (see Section 8.3.5), stilbenes (see Section 10.3.3.6.3), flavonoids (see Section 9.4), and many other phenolic compounds, exhibit a wide range of other biological effects.

10.3.3.5.1 Oestrogenic substances

Sex hormones are steroid compounds regulating normal development and function of reproductive human organs and organs of other animals. Male hormones are androgens, but very little is known about the plant **androgens** (testosterone and androsterone) found, for example, in the pollen of pines (*Pinus silvestris*, Pinaceae). Androgenic activity is also seen in the sweetener stevioside (see Section 11.3.2.1.3). Women (female) sex hormones are called **gynecogens** that include:

- **oestrogens** produced by the ovarian follicles
- **gestagens**, hormones with progestational activity, produced by *corpus luteum*, a temporary endocrine structure.

The most active women's oestrogen derived from hydrocarbon 5β-oestrane (**10-92**) is 3,17β-oestradiol (abbreviated E_2, **10-93**), which is supplied to the tissues by blood circulation, where it binds to specific receptors (proteins). In the body, it is transformed into oestrone (**10-94**) and oestriol (**10-93**).

Structure, nomenclature and occurrence

Oestrogenic activity is not limited to mammalian steroid hormones. In addition to endogenous oestrogens (hormones), a number of exogenous compounds present in foods of plant origin as natural components or substances that get into the food as contaminants (mould metabolites, pesticides and some other substances), also possess oestrogenic activity. These substances resemble the effect of sex hormones and induce oestrus as seen in experimental animals.

According to the origin, exogenous oestrogenic compounds include:

- **phytooestrogens**
- **mycooestrogens**
- **xenooestrogens** also known as anthropogenic oestrogens.

Phytooestrogens

Substances with oestrogenic effects (several dozens of substances are known) occur in about 300 plant species. The main phytooestrogens belong to the following groups of phytochemicals:

- isoflavones
- prenylflavonoids
- pterocarpans
- lignans.

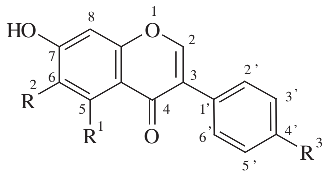
The first phytooestrogen identified in plants was oestrone, found in small quantities in palm and palm kernel oils (obtained from oil palm, *Elaeis guineensis*, Arecaceae) and pomegranate seeds (*Punica granatum*, Punicaceae).

Isoflavones

Isoflavonoids are a group of flavonoid compounds exhibiting different biological effects. The occurrence of about 200 known

isoflavonoids is essentially limited to legumes, to which, for example, soya (*Glycine max*, Fabaceae) belongs. Isoflavones are also found in smaller quantities in some other plant families, such as Amaranthaceae, Iridaceae, Moraceae and Rosaceae. The main representatives of isoflavonoid substances exhibiting oestrogenic effects are isoflavones, compounds isomeric with flavones. Some isoflavones also exhibit antimicrobial and other biological effects.

Soya beans contain isoflavone daidzein (7,4′-dihydroxyisoflavone), which is the most active oestrogenic isoflavone, accompanied by genistein (5,7,4′-trihydroxyisoflavone), formononetin (7-hydroxy-4′-methoxyisoflavone), glycitein (7,4′-dihydroxy-6-methoxyisoflavone) and biochanin A (5,7-dihydroxy-4′-methoxyisoflavone, **10-95**). The biochemical precursor of daidzein, formononetin and glycitein is flavanone liquiritigenin (7,4′-dihydroxyflavanone), the precursor of genistein and biochanin A is naringenin (5,7,4′-trihydroxyflavanone).



10-95, isoflavones
daidzein, $R^1 = H$, $R^2 = H$, $R^3 = OH$
genistein, $R^1 = OH$, $R^2 = H$, $R^3 = OH$
formononetin, $R^1 = H$, $R^2 = H$, $R^3 = OCH_3$
glycitein, $R^1 = H$, $R^2 = OCH_3$, $R^3 = OH$
biochanin A, $R^1 = OH$, $R^2 = H$, $R^3 = OCH_3$

Isoflavones occur predominantly as 7-β-D-glucosides. The glucoside of daidzein is daidzin, the glucoside of genistein is genistin, that of formononetin is ononin, and the glucoside of glycitein is glycitin (**10-96**). The main components of soya beans are glycosides genistin, daidzin and glycitin and their malonic acid esters. In addition to these compounds, free isoflavones and acetyl derivatives of glycosides occur in small amounts, which are products of decarboxylation of malonyl esters (**10-96**). Sprouting beans contain formononetin as one of the major isoflavones. Contents of the individual compounds are given in Table 10.16. The isoflavones concentrations in soya beans vary over a wide range, from about 0.13 to 0.42%, their content in soya bean flour is about 0.2%, in soya isolates 0.06–0.10%, and 0.07% in soya concentrates. Free aglycones even occur in acid hydrolysate of soybean meal, which is used as a food seasoning.

glycitin, $R = H$, $R^1 = H$, $R^2 = OCH_3$, $R^3 = OH$
6″-acetylgenistin, $R = COCH_3$, $R^1 = OH$, $R^2 = H$, $R^3 = OH$
6″-malonylgenistin, $R = COCH_2COOH$, $R^1 = OH$, $R^2 = H$, $R^3 = OH$

In addition to soya beans, oestrogenic isoflavones also occur in other plants, but in much smaller quantities. For example, peanuts contain about 0.50 mg/kg of daidzein and 0.83 mg/kg of genistein (free and bound as glycosides and their derivatives). Sunflower seeds contain 0.08 mg/kg of daidzein and 0.14 mg/kg of genistein, poppy seeds contain 0.18 and 0.07 mg/kg of daidzein and genistein, respectively. Formononetin is also the main isoflavone of some forage plants. For example, red clover (*Trifolium pratense*) of the legume family (Fabaceae) contains 1–30 g/kg of formononetin in dry matter. Minority forage isoflavones are also genistein, daidzein and biochanin A. Daidzein-8-*C*-glucoside called puerarin is found in a number of plants and herbs such as the root of kudzu plant

Table 10.16 Isoflavones and their derivatives content in soya beans and soya bean products (mg/kg).

[a]Tr = traces.
[b]Tofu (also known as bean curd), originating in ancient China, is made by coagulating soy milk with a coagulant, such as calcium sulfate.
[c]Tempeh is an Indonesian cake-like food prepared by fermentation of soya beans.
[d]Miso is traditional Japanese seasoning produced by fermenting rice and soybeans.

(Pueraria lobata, Fabaceae) native to southern Japan and south east China and possibly other species in the genus *Pueraria*. In traditional Chinese medicine, kudzu is considered one of the 50 fundamental herbs. It is used to treat tinnitus, vertigo and Wei syndrome (superficial heat close to the surface).

Prenylflavonoids

Legume plants also contain many lipophilic prenylated isoflavones (**10-97**), which are, in comparison with the original isoflavones, more efficient defence substances against pathogenic ilicitors (microorganisms) and animal pests (phytoalexins). They arise by prenylation of isoflavone precursors by dimethylallyl diphosphate.

Prenylated isoflavones are related to prenylated flavonoids (chalcones and flavanones or dihydroflavones) located in mature female cones of hops (*Humulus lupulus*, Cannabinaceae), which exhibit oestrogenic and anticarcinogenic effects. Their amount depends on the weather conditions and the hops variety. The most common compound is a chalcone xanthohumol (**10-98**), which does not exhibit oestrogenic activity. Its content in hop cones is around 1%. Xanthohumol is accompanied by the flavanone isoxanthohumol, which arises from xanthohumol by conversion in an acidic media during heating. Isoxanthohumol is therefore the main prenylated flavonoid in beer. At concentrations of about 10 to 100 times lower, prenylated flavonoids are accompanied by chalcone demethylxanthohumol, which is a precursor of most hop prenylflavonoids. The main oestrogen is flavanone 8-prenylnaringenin accompanied by 6-prenylnaringenin (**10-98**) and other compounds. Concentrations of 8- prenylnaringenin in various beer brands range from <1.6 μg/l in non-alcoholic beers to 138.5 μg/l in stouts. 8-Prenylnaringenin also results from isoxanthohumol by the action of bacteria in the colon or liver (cytochrome P450 enzymes). Chalcone xanthogalenol (**10-98**) has only been detected in the US and East Asian hops varieties.

Pterocarpans

Pterocarpans are a group of modified isoflavonoids occurring in small amounts in legume plants (Fabaceae) and in several other families. They typically act as phytoalexins, protecting plants against pathogens. Unlike most of the isoflavones, pterocarpans are synthesised in response to biotic and abiotic stress factors. Their important precursors are the isoflavones daidzein and formononetin.

In germinated soybeans and other legumes occurs, together with isoflavone formononetin, as the major oestrogen coumestrol (**10-99**), which is present in an amount ranging from 0.05 to 0.2 mg/kg. During germination, its concentration increases about 70–150 times. The highest amount of coumestrol occurs in hulls

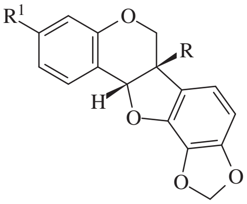
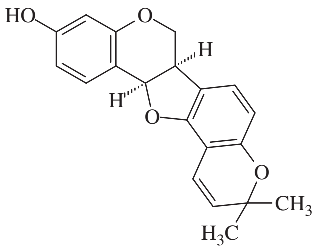
10-99, coumoestrol

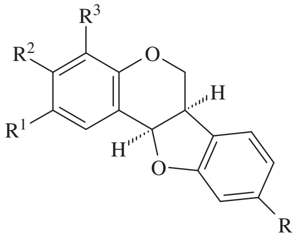


10-101, (+)-maackiain, R = H, R^1 = OH
(+)-pisatin, R = OH, R^1 = OCH_3

of beans. Oestrogenic activity of coumestrol is 30–40 times higher than activities of isoflavones. Small quantities of other related compounds are present, such as medicarpin, lucernol, sativol (**10-100**) and other pterocarpans. Coumestrol is the main oestrogen of most forage crops (legumes), such as alfalfa (*Medicago sativa*), where it is accompanied by medicarpin (**10-100**). Maackiain (**10-101**) occurs in chickpea (*Cicer arietinum*), pisatin (**10-101**) in pea (*Pisum sativum*), phaseolin (**10-102**) in common beans (*Phaseolus vulgaris*) and glyceollins (**10-103**) in soya beans (*Glycine max*).



10-102, (−)-phaseolin

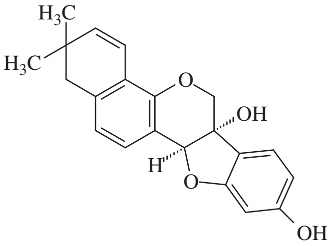


10-100, (−)-medicarpin, R = OCH_3, R^1 = H, R^2 = OH, R^3 = H
(−)-lucernol, R = OH, R^1 = OH, R^2 = OH, R^3 = H
(−)-sativol, R = OH, R^1 = H, R^2 = OCH_3, R^3 = OH

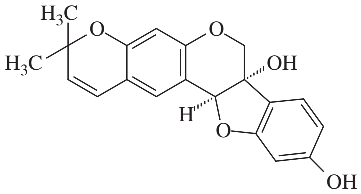
According to the structure, pterocarpans are divided into simple pterocarpans (an example is medicarpin with a methoxyl group and maackiain with a methylenedioxy group), pterocarpens (such as coumestrol) and 6-hydroxypterocarpans (such as pisatin), some of which, such as glyceollin III (**10-103**) with a prenylated substituent on the furan ring, have a more complex structure.

Lignans

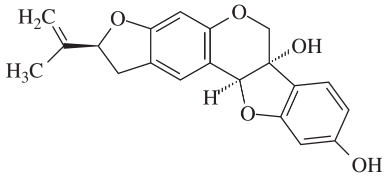
Lignans are a group of plant phenolic compounds, classified as phenylpropanoids, which are derived from coniferyl alcohol and



glyceollin I



glyceollin II



glyceollin III

10-103, glyceollins

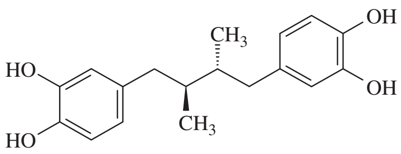
other cinnamyl alcohols. Lignans are dimers of type $(C_6–C_3)_2$ formed by association of two phenylpropane units on the central carbon atom of the side chain by bond C-8/C-8′ with the formation of a $C_6–C_3–C_3–C_6$ skeleton. The polymer of phenylpropane units known as lignin (see Section 4.5.1.7.1) has an analogous structure. Dimers of type $C_6–C_3–C_6–C_3$ are called **neolignans**. Together with the polymeric lignin, lignans are the most widespread plant components, which have a function in protecting the plant against pathogens. They also have a variety of other biological effects, as they additionally act as phytooestrogens, antioxidants and anticarcinogenic agents.

Several hundred lignans have been identified. Depending on the degree of skeleton oxidation, several types of lignans are distinguished, of which four types of linear lignans are of the greatest importance in food materials (**10-104**):

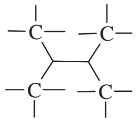
- lignans, butane derivatives also called **diarylbutanoids**,
- derivatives of butanolide called **lignanolides**,
- derivatives of tetrahydrofuran called **monoepoxylignans**,
- furofuran lignans called **bisepoxylignans**, which are derivatives of 3,7-dioxabicyclo[3.3.0]octane.

Another cyclisation providing a new bond C-7/C-6′′ yields **cyclolignans** (cyclic lignans), which can be considered derivatives of naphthalene or tetrahydronaphthalene (**10-104**).

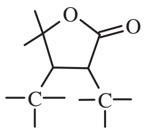
The longest known lignan of diarylbutanoid type is nordihydroguaiaretic acid, 4,4’-(2,3-dimethylbutane-1,4-diyl)dibenzene-1,2-diol, abbreviated NDGA (**10-105**), the biosynthesis of which is based on caffeoyl alcohol. In the 1950s and 1960s NDGA was used as an antioxidant, initially in the form of a resinous product obtained from the North American evergreen creosote bush (*Larrea tridentata*, Zygophyllaceae) and later as a synthetic substance.



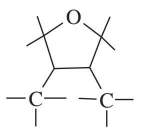
10-105, nordihydroguaiaretic acid



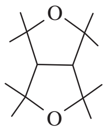
diarylbutanoids



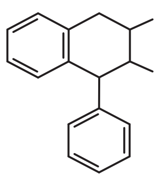
lignanolides



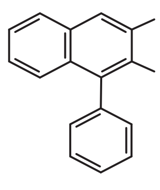
monoepoxylignans



bisepoxylignans



tetrahydronaphthalene structure

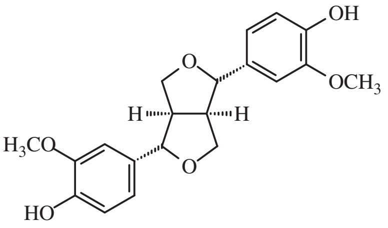


naphthalene structure

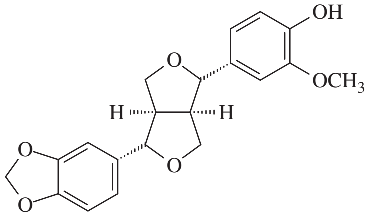
10-104, basic structures of lignans and cyclolignans

The antioxidant properties of NDGA are similar to the properties of gallates, but because of its adverse toxicological effects it has no practical significance.

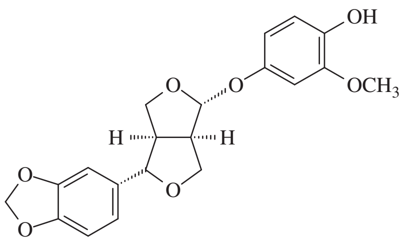
Based on coniferyl alcohol, the bisepoxylignan (+)-pinoresinol (**10-106**) is a precursor of many other bisepoxylignans, such as (+)-piperitol (**10-107**), (+)-sesamolinol (**10-108**), (+)-sesamin (**10-109**) and (+)-sesamolin (Figure 10.11). Sesamin is a fairly widespread compound in higher plants, found in large quantities in sesame oil obtained from the seeds of Indian sesame (*Sesamum indicum*, Pedaliaceae), which is highly resistant to oxidation. The main components of sesame seed are sesamin (0.1–10 g/kg) and sesamolin (0–10 g/kg). In addition to abundant sesamin and sesamolin, several minor furofuran lignans are also found in sesame seeds, such as (+)-pinoresinol, (+)-piperitol, (+)-sesamolinol, (−)-episesamin, also known as (−)-asarinin (**10-110**), along with other substances. Hydroxysubstituted lignans and compounds with an opened 1,3-dioxol ring are present as glycosides (β-gentiobiosides, β-sophorosides, di- and tri-β-glucosides). Water-soluble lignan glycosides are, for example sesaminol diglucoside, sesaminol-2′-*O*-β-D-glucopyranosyl-(1→6)-β-D-glucopyranoside, and sesaminol triglucoside, sesaminol-2′-*O*-β-D-glucopyranosyl-(1→2)-*O*-[β-D-glucopyranosyl-(1→6)]-β-D-glucopyranoside) (**10-111**).



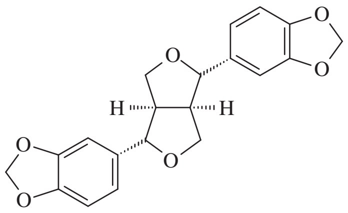
10-106, (+)-pinoresinol



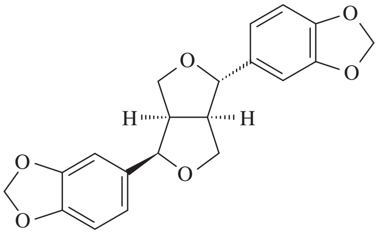
10-107, (+)-piperitol



10-108, (+)-sesamolinol



10-109, (+)-sesamin



10-110, (−)-asarinin

Sesamin, in addition to a significant antioxidant effect, also shows an insecticidal effect. The actual antioxidant (having an effect comparable to BHA and BHT) is sesamol (Figure 10.11), which is present in small amounts in seeds, but which arises in larger quantities by hydrolysis of sesamoline during sesame oil refining (especially in bleaching) and during thermal operations (such as frying). Sesamol is very easily oxidised in the presence of Fe ions and produces cytotoxic oxidation products, which are structurally oligomeric compounds of sesamol (**10-112**). Oestrogenic bisepoxylignan (a precursor of enterolactone) is (−)-asarinin (**10-110**), occurring also in some medicinal plants, for example in *Asiasarum sieboldi* (syn. *Asarum sieboldi*) of the birthwort family

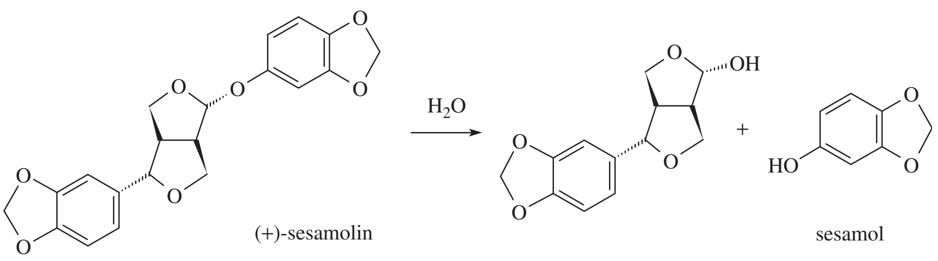


Figure 10.11 Formation of sesamol from sesamolin.

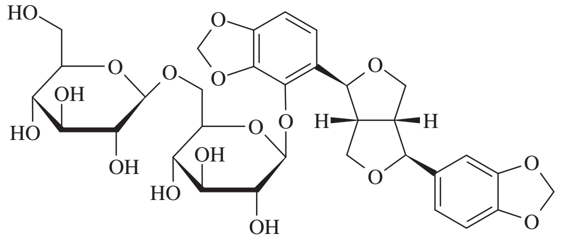
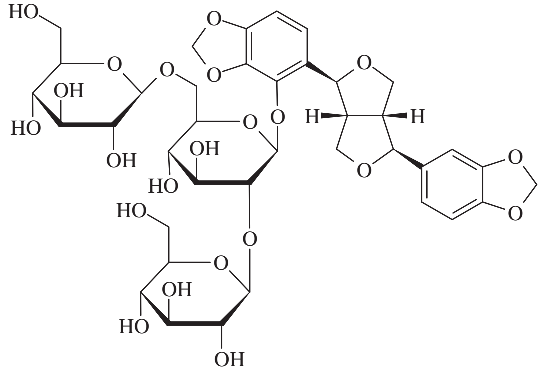


sesaminol diglucoside



sesaminol triglucoside

10-111, sesaminol glucosides

Aristolochiaceae, which is used in cosmetic skin conditioning preparations.

(+)-Pinoresinol (furofuran) is also a precursor of (+)-lariciresinol (benzylaryltetrahydrofuran, **10-113**), (−)-seco-isolariciresinol (dibenzylbutane, **10-114**) and (−)-matairesinol (dibenzylbutyrolactone, **10-115**), which are intermediates in the biosynthesis of cyclolignans derived from aryltetrahydronaphthalene. Isomerisation of (+)-pinoresinol gives (−)-pinoresinol (**10-116**), which is analogously the precursor of (−)-lariciresinol (**10-117**) and (+)-secoisolariciresinol (**10-118**).

The most important oestrogenic compounds are (−)-matairesinol, (3*R*,4*R*)-3,4-bis[(4-hydroxy-3-methoxyphenyl)methyl] oxolan-2-one, and (−)-secoisolariciresinol, (2*R*,3*R*)-2,3-bis[(4-hydroxy-3-methoxyphenyl)methyl]butane-1,4-diol, which are found in plant materials in the form of glycosides. For example, (−)-mataresinol may occur as 4-*O*-β-D-glucoside or 4,4′-di-*O*-β-D-glucoside (**10-119**), while the principal lignan precursor found in flaxseed is (−)-secoisolariciresinol 2,3-di-*O*-β-D-glucoside (**10-120**). In foods, these lignans occur as the main components of whole grain cereal products, in rice, legumes, nuts and various other seeds, and also in vegetables and fruits (Table 10.17).

Related to lignans are **flavonolignans**, which do not exhibit oestrogenic activity. Their biosynthesis is based on flavonoids (such as dihydroflavonol taxifolin or dihydroquercetin) and phenylpropanoids, usually coniferyl alcohol. Examples of flavonolignans are components of the pericarp of milk thistle (*Silybum marianum*, Asteraceae) called silymarin, of which 70–80% are structurally related flavonolignans. The main component of the silymarin complex is silybin (also known as silibinin), which is a mixture of diastereoisomers A (**10-121**) and B (**10-122**) occurring in the ratio of 1 : 1. Milk thistle is recommended for indigestion, as a

supportive agent in chronic hepatitis therapy and liver cirrhosis, and in gallbladder problems and for loss of appetite.

Other phytooestrogens

Many cereals accumulate hydroxamic acids derived from the lactam 2-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one that are one of the most important chemical barriers against herbivores and have been shown to be inhibitory to several plant pathogenic fungi and bacteria. For example, these benzoxazinoid hydroxamic acids are involved in the defense of maize against various lepidopteran pests, most notably the European corn borer, in the defense of cereals against various aphid species and in allelopathy affecting the growth of weeds associated with rye and wheat crops. The biosynthetic pathway to benzoxazinoid hydroxamic acids differs from tryptophan biosynthesis at indole-3-glycerol phosphate, which is converted into indole and indolin-2-one (Figure 10.12). Subsequently four oxygen atoms are enzymatically introduced into the indolin-2-one moiety via 3-hydroxyindolin-2-one, (*R*)-2-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (known under the acronym HBOA) and (*R*)-2,4-dihydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIBOA). After glucosylation, the glucoside is further modified by hydroxylation to (*R*)-2,4,7-trihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (TRIBOA glucoside) and *O*-methylation at C-7 to form (*R*)-2,4-dihydroxy-7-methoxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIMBOA glucoside). The predominant benzoxazinoids are DIBOA and its 7-methoxy derivative DIMBOA, which are stored as glucosides in vacuoles. Upon tissue damage, specific glucosidases present in the plastids come into contact with the glucosides and bioactive aglycones, 3*H*-benzoxazol-2-ones (2,3-dihydro-1,3-benzoxazol-2-ones), are produced. Young plants of wheat, maize, rice and other cereals contain mainly 3*H*-1,3-benzoxazol-2-one (BOA) and 7-methoxy-3*H*-benzoxazol-2-one (MBOA) that do not have oestrogenic activities, but stimulate the secretion of oestradiol from ovarian follicles, showing signs of oestrogen activities. Lactams, the corresponding hydroxamic acids and derived benzoxazolones are collectively known as **benzoxazinoids**. Various benzoxazinoids also occur in bread, where the main components are DIBOA and MBOA.

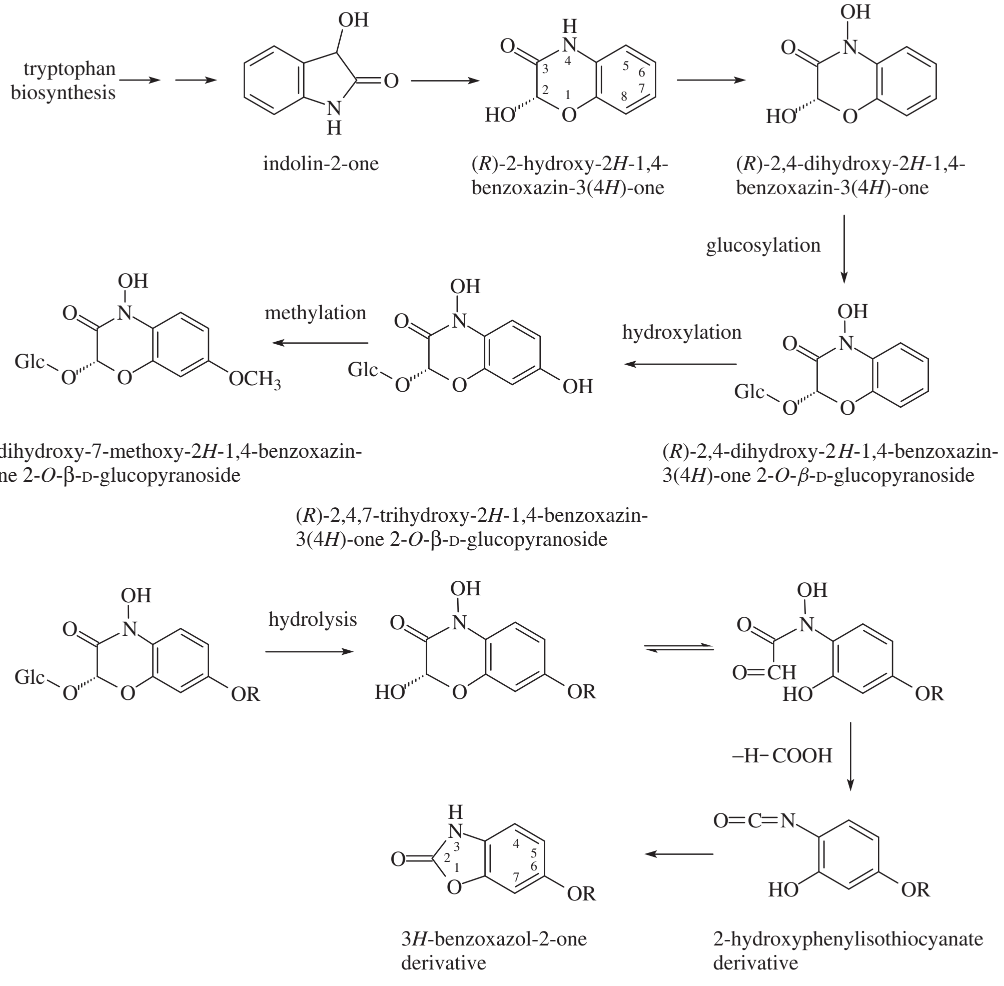

Figure 10.12 Biosynthesis and transformation of benzoxazinoid hydroxamic acids.

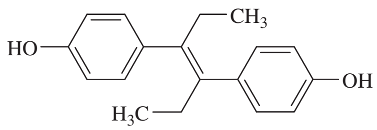
Mycooestrogens

The most effective mycooestrogen from the group of resorcinic acid lactones is (*E*)-6-(10-hydroxy-6-oxoundec-1-en-1-yl)-2,4-dihydroxybenzoic acid lactone, trivially known as zearalenone or F-2 toxin. Zearalenone is produced by fungi of the genus *Fusarium* (see Section 12.3.1.2.1).

Xenooestrogens

Comparable, or even higher, oestrogenic activity than oestradiol is exhibited by synthetic stilbene (*E*)-stilboestrol (*trans*-diethylstilboestrol, **10-123**), which was originally used in the fattening of cattle and other livestock, because it accelerated their growth. In human medicine, *trans*-diethylstilbestrol was used to prevent miscarriages, but because of its carcinogenic effects, the compound is no longer used.



10-123, (*E*)-diethylstilboestrol

Oestrogenic activity has been demonstrated in a number of other anthropogenic substances. An example is bisphenol A (see Section 12.9.2), a monomer of polycarbonate and epoxy resins, which can be leached from lacquered plates for cans or dental compositions and seals. Oestrogenic activity is also exhibited by some halogenated pesticides, polychlorinated biphenyls and certain of their hydroxylated metabolites, phthalates (used as plastic softeners), veterinary pharmaceuticals and some other xenobiotics, which are referred to in Chapter 12.

Reactions and changes

Isoflavones are transferred virtually unchanged from soya beans into flour. The loss caused by leaching during soaking of soya beans is about 11%. Cooking results in about a 50% loss of the original content. About 40% of isoflavones are lost during extraction with alkaline agents during production of protein isolates. Acid hydrolysates of soybean meal contain only isoflavone aglycones formed by hydrolysis of glycosides.

Biological effects

Oestrogens are both useful and harmful for the organism. An endogenous oestrogen of mammals is oestradiol, which is essential for normal development and reproduction of the organism, and also affects other important processes related to the immune system and central nervous system. At the same time, however, oestradiol is associated with cancers of the mammary glands, rectum and probably also the prostate.

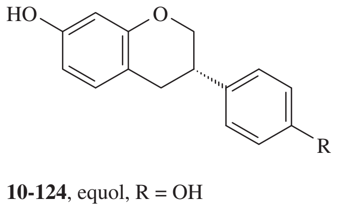
The effects of other oestrogens are still under discussion. Phytooestrogens show several orders of magnitude lower oestrogenic activity than oestradiol (Table 10.18), but given the quantities in which they are consumed, they may cause male cattle infertility and abortions in female cattle.

Table 10.18 Relative activity of selected oestrogens.

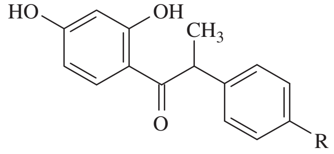
Oestrogen	Relative activity (%)
(*E*)-Diethylstiboestrol	100
Oestron	6.9
Coumoestrol	0.035
Genistein	0.001
Daidzein	0.000 75
Biochanin A	0.000 46
Formononetin	0.000 26

In women consuming food rich in phytooestrogens, irregularities of the menstrual cycle were observed. On the other hand, in a population with a high intake of soy isoflavones (such as in some Asian countries), lower incidence of breast cancer in women and of prostate cancer in men was reported. The activity of phytooestrogens is generally an additive property. If the level of endogenous (steroid) oestrogens is low (typically in animals), phytooestrogens bind together with them to the receptors. If the level of steroid oestrogens is high (usually in women), phytooestrogens act antagonistically (as antioestrogens).

Some isoflavones do not exhibit oestrogenic activity themselves. Formononetin is not an oestrogenic substance; however, in the rumen of ruminant animals (as well as in silage feed and the digestive tract of humans, as it also occurs in the urine of women after consumption of soya products) it is transformed by bacteria after the hydrolysis of sugar to aglycone and further, via daidzein, to the oestrogenic compound equol (7,4′-dihydroxyisoflavan, **10-124**), which is the main product of this transformation. Byproducts of formononetin (**10-125**) transformations are angolensin and 4′-*O*-methylequol (**10-124**), from which equol arises by a side-path reaction. Equol is partially transformed into *O*-demethylangolensin



10-124, equol, R = OH
4′-*O*-methylequol, R = OCH_3

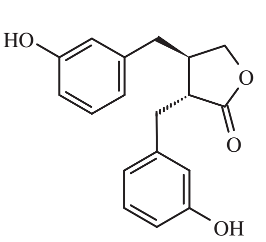


10-125, *O*-demethylangolensin, R = OH
angolensin, R = OCH_3

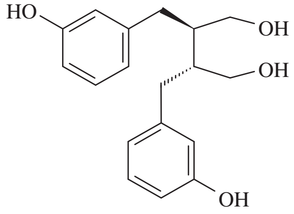
(**10-125**). Equol represents about 70% of formononetin degradation products, *O*-demethylangolensin 5–20% and minor products are of 4′-*O*-methylequol and angolensin.

For example, the infertility syndrome called clover disease of sheep, occurring in the 1940s in Western Australia, was caused by equol. The disease was manifested by a decrease of sheep gestation, frequent abortions and postnatal complications. Similar syndromes have been found in other animals.

Biochanin A is degraded to genistein and further to dihydrogenistein, from which 4-ethylphenol and other simple products arise. The bacterial degradation products of matairesinol in the digestive tract are enterolactone (**10-126**) and lariciresinol. Secoisolariciresinol gives rise to enterodiol (**10-127**), which can be oxidised to the enterolactone. These compounds are excreted in the urine.



10-126, enterolactone



10-127, enterodiol

The result of exposure to anthropogenic oestrogens in men is believed to be lower sperm quality, and in women there is a higher incidence of lung cancer. Oestrogens may also cause anomalies in wildlife (such as feminisation of male fish). These findings are still mainly speculative due to the small amounts of consumed xenooestrogens, compared with the much higher amount of oestrogens produced endogenously and with the amount of consumed phytooestrogens.

In addition to oestrogenic activity, isoflavones also exhibit relatively high antioxidant activity, which requires the presence of two hydroxyl groups (at C-7 and C-4′) in the molecule, as found in daidzein, which is therefore the most active antioxidant. The activity of aglycones is higher than the activity of glycosides, but, generally, isoflavones have lower antioxidant activity than the corresponding flavones. Isoflavones are also major contributors to the astringent and bitter taste of soya beans.

10.3.3.5.2 Phototoxic compounds

Phototoxicity and other toxic effects are exhibited by a group of phenolic compounds called **coumarins**. The primary photosensitisers are furanocoumarins and some plant pigments, such as hypericin of St. John's wort (*Hypericum perforatum*, Hypericaceae) and fagopyrin (**9-174**) of common buckwheat (*Fagopyrum esculentum*, Polygonaceae).

Structure, nomenclature and occurrence

Coumarins More than 1000 coumarins occur in nature, of which about 300 compounds are simple coumarins. Coumarins occur most often as a mixture of 10–20 related compounds in about 100 families of plants, but especially in plants of the Rutaceae family, which includes various citruses, Moraceae, to which mulberries (*Morus* spp.) and figs (*Ficus* spp.) belong, Apiaceae, including many species of aromatic vegetables (carrots, parsley, parsnips and celery) and spices (caraway, cumin, coriander, dill, anise and fennel) and Asteraceae, which includes some medicinal herbs. Simple coumarins (including 2*H*-1-benzopyran-2-ones and 5,6-benzo-2-pyrones) are derived from γ-lactones of 2-hydroxycinnamic acids. The basic member of the homologous series of coumarins (**10-128**) is coumarin. Almost all other simple coumarins are non-volatile compounds hydroxylated at C-7. Other skeletal positions may also be hydroxylated and some hydroxyl groups are protected by methylation or isoprenylation. Coumarins also often occur as glycosides, which are accompanied by respective aglycones. Some coumarins act as blastocolins (inhibiting seed germination). Relatively widespread are different **furanocoumarins**, which are linear (6,7-furanocoumarins, also known as psoralen type furanocoumarins or psoralens) or angular compounds (7,8-furanocoumarins, angelicin type furanocoumarins or angelicins). Linear and angular **pyranocoumarins** are relatively rare. They are found mainly in plants of the Rutaceae family. I**socoumarins** (3,4-benzo-2-pyrones) are also rare, and 3-phenylcoumarins (**isoflavonoids**) and 4-phenylcoumarins (**neoflavonoids**) are less common.

Typical representatives of simple coumarins substituted at position C-6 or at positions C-6 and C-7 are umbelliferon (7-hydroxycoumarin), derived from 4-coumaric acid, and its 7-*O*-β-D-glucopyranoside skimmin, aesculetin (6,7-dihydroxycoumarin, formerly also known as cichorigenin), its 6-*O*-β-D-glucopyranoside aesculin (or aesculoside) and 7-*O*-β-D-glucopyranoside cichoriin, scopoletin (7-hydroxy-6-methoxycoumarin) and its 7-*O*-β-D-glucopyranoside scopolin and scoparon (6,7-dimethoxycoumarin, **10-129**).

These coumarins are present in small amounts in some fruits and vegetables as phytoalexins. Aesculetin and scopoletin were found at a level of about 1 mg/kg in carrots, celery and other root vegetables and some fruits (such as apricots). The same compounds, aesculetin-6-*O*-β-D-glucoside (aesculin) and aesculetin 7-*O*-β-D-glucoside (cichoriin) also occur in the roots and buds of chicory, and together with other substances contribute to the bitter taste of this vegetable. The bark of horse chestnut (*Aesculus* spp., Hippocastanaceae) contains a large amount of aesculin. Scoparone occurs in citrus fruits exposed to UV radiation or significant temperature fluctuations. Hemiarin (7-methoxycoumarin) and ajapin (6,7-methylenedioxycoumarin, **10-130**) are found in tubers of Jerusalem artichokes (*Helianthus tuberosus*, Asteraceae).

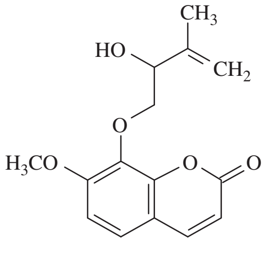
10-132, isoprenoid coumarins
osthenol, R = OH
osthol, R = OCH_3



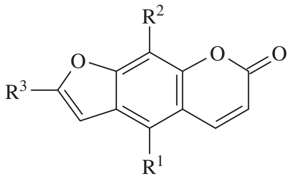
auraptenol

Examples of coumarins substituted at other positions of the benzene ring are daphnetin (7,8-dihydroxycoumarin), limettin (5,7-dimethoxycoumarin) and fraxidin (6,7-dimethoxy-8-hydroxycoumarin, **10-131**). Limettin, for example, occurs in citrus fruits, dafnetin-8-*O*-β-ᴅ-glucoside, known as daphnin, is present in higher quantities in the bark of daphne (*Daphne mezereum*, Thymelaeaceae), commonly known as mezereon, and fraxidin-8-*O*-β-ᴅ-glucoside or fraxin occurs together with related coumarins in the bark of common ash (*Fraxinus excelsior*, Oleaceae).

An example of coumarins with isoprenoid substituents is osthenol, 7-hydroxy-8-(2-hydroxy-3-methyl-3-en-1-yl)coumarin (**10-132**), which together with osthol, 7-methoxy-8-(3-methyl-2-en-1-yl)coumarin and auraptenol, 7-methoxy-8-(2-hydroxy-3-methyl-3-en-1-yl)coumarin, occurs in citrus fruits. In common with many other coumarins, it is found in garden angelica (*Angelica archangelica*, Apiaceae) and other plants.

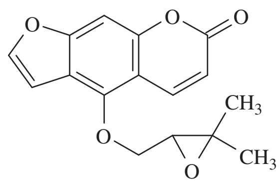
Furanocoumarins These are frequently found in plants and are synthesised from umbelliferon. There are two basic types of furoanocoumarins:

- linear coumarins or 6,7-furanocoumarins, or psoralen type coumarins or psoralens
- angular coumarins or 7,8-furanocoumarins or angelicin type coumarins or angelicins.



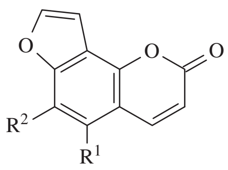
10-133, main psoralen type furanocoumarins
psoralen, $R^1 = R^2 = R^3 = H$
bergaptol, $R^1 = OH$, $R^2 = R^3 = H$
bergapten, $R^1 = OCH_3$, $R^2 = R^3 = H$
xanthotoxin, $R^1 = R^3 = H$, $R^2 = OCH_3$
isopimpinellin, $R^1 = R^2 = OCH_3$, $R^3 = H$
trioxsalen, $R^1 = R^2 = R^3 = CH_3$
imperatorin, $R^1 = R^3 =$, $R^2 = OCH_2CH{=}C(CH_3)_2$
isoimperatorin, $R^1 = OCH_2CH{=}C(CH_3)_2$, $R^2 = R^3 = H$
fellopterin, $R = OCH_3$, $R = OCH_2CH{=}C(CH_3)_2$, $R^3 = H$
bergamottin, $R^1 = OCH_2CH{=}C(CH_3)(CH_2)_2CH{=}C(CH_3)_2$, $R^2 = R^3 = H$

Common linear hydroxy and methoxyl substituted furanocoumarins (**10-133**) include psoralen, bergaptol (5-hydroxypsoralen), bergapten (5-methoxypsoralen), xanthotoxin (8-methoxypsoralen) and isopimpinellin (5,8-dimethoxypsoralen). Some other linear furanocoumarins, such 8-(3-methyl-2-en-1-yloxy)psoralen (imperatorin), 5-(3-methyl-2-en-1-yloxy)psoralen (isoimperatorin), 5-methoxy-8-(3-methyl-2-en-1-yloxy)psoralen (fellopterin) and 5-(3,7-dimethyl-2,6-dien-1-yloxy)psoralen or 5-geranoxypsoralen (bergamottin) have an alkenoxyl isoprenoid chain as do the simple coumarins osthol and auraptenol. These compounds are found mainly in citrus essential oils and root vegetables. Psoralen and bergapten are also the main coumarins of fig tree leaves. A more complex structure is oxypeucedanin, 5-(3,3-dimethyloxiranylmethoxy)psoralen (**10-134**), which occurs as (*R*)- and (*S*)-isomers in parsley and garden angelica, for example.



10-134, oxypeucedanin

Angular type furanocoumarins (**10-135**) include angelicin, isobergapten (5-methoxyangelicin) sphondin (6-methoxyangelicin) and pimpinellin (5,6-dimethoxyangelicin). In small amounts, these compounds accompany linear furanocoumarins. An example of a complex furanocoumarin of the angelicin type is archangelicin (**10-136**), which occurs in garden angelica.



10-135, angelicin type furanocoumarins

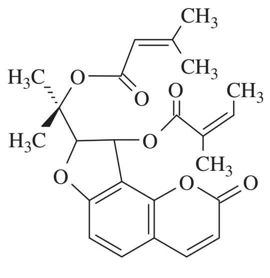
isobergapten, $R^1 = OCH_3$, $R^2 = H$
sphondin, $R^1 = H$, $R^2 = OCH_3$
pimpinellin, $R^1 = OCH_3$, $R^2 = OCH_3$



10-136, archangelicin

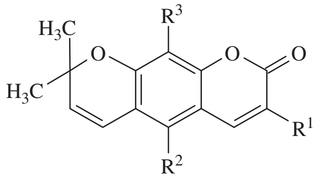
From a hygienic–toxicological point of view, psoralen type furanocoumarins are important in foods, and their major sources are mainly citrus fruits and root vegetables. Juice from the leaves of the common fig tree (*Ficus carica*, Moraceae) contains 2000 mg/l of psoralen and 500 mg/l of bergapten., These compounds are found in some spices in a small amount (Table 10.19).

The concentration of coumarins in plants is dependent on a number of factors. In healthy plants, their content varies in their different parts and greatly depends on climatic conditions. For example, in celery (*Apium graveolens* var. *dulce*, Apiaceae), whose leaves are eaten raw as a salad and cooked as a vegetable, the content of furanocoumarins in older outer leaves is 50 mg/kg, in the inner leaves 8 mg/kg and in the small central leaves 4 mg/kg fresh matter. The content in leaf petioles is about 0.2 mg/kg fresh matter. The amount of furanocoumarins is also low in the root, where it reaches only 1.1 mg/kg. A similar amount of furanocoumarins is found in the tuberous thick base of stems of celeriac (*A. graviolens*, var. *rapaceum*), which is cooked and eaten as a salad vegetable. High levels of furanocoumarins, however, appear as a result of different stress factors, such as attacks of microorganisms, exposure to UV radiation, storage at low temperatures, mechanical damage and other stress factors. For example, the attack of the fungus *Sclerotinia sclerotiorum* on the celery root results in a significant increase in the concentrations of these compounds (up to 44 mg/kg from about 2 mg/kg).

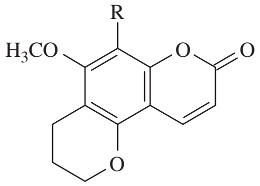
Pyranocoumarins Also found in plants, but in small amounts, are pyranocoumarins, of both linear (**10-137**) and angular types (**10-138**). Common linear pyranocoumarins are present mainly in plants of the Rutaceae family, and thus also in citrus fruits and,

Table 10.19 Furanocoumarins and pyranocoumarins in major food materials.

Material	Content of furanocoumarins (mg/kg)
Orange essentials oil	Bergaptol (0.5)
Lemon essentials oil	Bergapten (33)
Grapefruit essentials oil	Bergapten (120)
Carrot (root)	Bergapten (0.01), xanthotoxin (0.01)
Parsley (root)	Oxypeucedanin (26), bergapten (12), isoimperatorin (5.6), psoralen (1.4), Imperatorin (1.4), xanthotoxin (0.1), graveolon
Parsnips (root)	Xanthotoxin (48), angelicin (47), bergapten (7), psoralen (7)
Celery (root)	Bergapten (0.6), xanthotoxin (0.5), psoralen (0.04)
Celery (stalks)	Xanthotoxin (7.2), psoralen (1.0), bergapten (0.6)
Anise, coriander, caraway (seeds)	Xanthotoxin (0.01), bergapten (0.01)

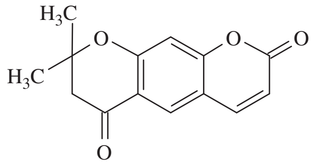


10-137, important linear pyranocoumarins
xanthiletin, $R^1 = H$, $R^2 = H$, $R^3 = H$
xanthoxylethin, $R^1 = OCH_3$, $R^2 = H$, $R^3 = H$
lugangetin, $R^1 = OCH_3$, $R^2 = H$, $R^3 = H$
trachyphyllin, $R^1 = OH$, $R^2 = CH{=}CHCH(CH_3)_2$, $R^3 = H$



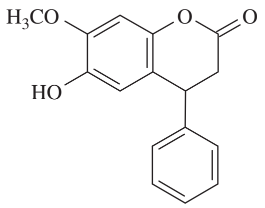
10-138, important angular pyranocoumarins
alloxanthoxyletin, R = H
dipetalin, $R = CH{=}CHCH(CH_3)_2$
aviceunin, $R = CH{=}CHC(CH_3){=}CH_2$

especially, in citrus essential oils extracted from the peel. A similar pyranocoumarin is graveolon (**10-139**), which is present in small amounts in the leaves and roots of parsley.



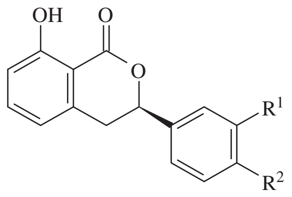
10-139, graveolon

3-Phenylcoumarins, 4-phenylcoumarins and isocoumarins A coumarin substituted at the C-3 phenyl group (having anisoflavone skeleton), known as santalin AC (6,7,3′-trihydroxy-2′,4′-dimethoxy-3-phenylcoumarin), is a minor component of red sandalwood colour (see Section 9.4.2.9). 4-Phenylcoumarins (also known as neoflavonoids), are found in trees of the genus *Dalbergia* (Fabaceae) grown in tropical regions of Asia and America. A typical representative is dalbergin (**10-140**).



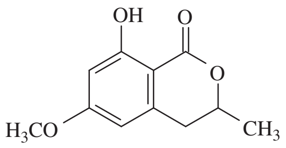
10-140, dalbergin

Furthermore, rarely found in plant materials are also isocoumarins (3,4-benzo-2-pyrones or 1*H*-2-benzopyran-1-ones), which are polyketides together with related stilbenes and coloured chalcones, but which are unlike other coumarins. Examples of dihydroisocoumarins are hydrangenol and phyllodulcin (**10-141**) located in the leaves of the large leaf hydrangea (*Hydrangea macrophylla*, Hydrangeaceae) and similar species. Phyllodulcin



10-141, hydrangenol, $R^1 = H$, $R^2 = OH$
phyllodulcin, $R^1 = OH$, $R^2 = OCH_3$

is used locally as a sweetener (see Section 11.3.2.1.3). A compound with oestrogenic activity is methoxymellein 6-(8-hydroxy-6-methoxy-3-methyl-3,4-dihydroisocoumarin, **10-142**). It occurs in carrots infected by a fungus and plant pathogen, *Ceratocystis fimbriata*, which gives the root a bitter taste.



10-142, 6-methoxymellein

Biological effects

Coumarins exhibit a wide variety of biological effects. They mainly act as vasodilatant agents and anticoagulants. For example, the synthetic dicoumarol warfarin is used in human medicine and as a rhodenticide (see Section 5.5.3). Furanocoumarins exhibit spasmolytic and vasodilatory effects, and coumarins and furanocoumarins have antibacterial and antifungal properties. For example, umbelliferon, scopoletin and furanocoumarins act as molluscocides (bergapten and isopimpinellin), they may have oestrogenic effects (some isocoumarins) and furanocoumarins can act as photosensitisers and thus exhibit phototoxic effects.

Photosensitisation caused by furanocoumarins is manifested by an increased sensitivity of unpigmented skin to sunlight (near-UV radiation of wavelength 400–300 nm, 3.10–4.13 eV, visible to birds, insects and fishes) and is associated with a higher incidence of skin cancer. The primary cause is binding of furanocoumarins to DNA (cycloaddition reactions with pyrimidine bases) and other macromolecular components of cells (such as fatty acids in lipoproteins) and the formation of free radicals activated by UV radiation. This disease is different from photo-dermatitis or sunburn, which is damage to the skin without the photosensitiser. Photosensitising diseases are, according to the origin of the photosensitiser and the way it gets into the peripheral circulation, distinguished into primary photosensitisation (the photosensitiser is an exogenous substance) and several others. Furanocoumarins and toxic pigments hypericin and phagopyrin (see Section 9.8.1.3.2) cause primary photosensitisation.

The toxicity of furanocoumarins occurring in foods (such as vegetables of the carrot family and citrus oils consumed in soft drinks, including flavoured teas) may be displayed in humans if the consumed amount ranges from 0.14 to 0.38 mg/kg body weight, which is out of the question in normal consumption of root vegetables. The total daily intake is estimated to be 1.3 mg. Photosensitisation caused by furanocoumarins may be a problem for workers handling celery or parsley leaves or coming into contact with the juice of fresh figs. It is reported that this so-called acute contact dermatitis appears after contact with celery leaves containing at least 18 mg/kg furancoumarins. Chronic dermatitis may appear in repeated contact with celery leaves even if the material contains about 7 mg/kg of furanocoumarins in fresh matter. In this respect, particularly infamous is the giant hogweed (*Heracleum mantegazzianum*, Apiaceae), native to Central Asia and introduced to some European countries, the United States and Canada as an ornamental plant, the sap of which causes severe dermatitis resulting in blisters, long-lasting scars, and blindness, if it comes in contact with the eyes.

Properties of furanocoumarins are also used therapeutically. Bergapten and xanthotoxin are used to treat psoriasis and the idiopathic depigmentation called vitiligo, which is caused by the formation of melanin pigment disorders associated with the activity of tyrosinase. After irradiation, psoralens act on the surrounding undamaged melanocytes, which are bigger, produce more melanin, and thus give the skin its normal colour.

10.3.3.6 Other natural antimicrobial compounds

Antimicrobial compounds, often showing many other biological effects, are synthesised and accumulated in plant tissues in response to an external stimulus. The external stimulae may be viruses or phytopathogenic organisms (bacteria and fungi), but may also include a variety of stress factors (such as UV radiation, cold, heavy metal ions, treatment with fungicides, herbicides and others). Compounds that are a permanent part of the plant tissues, synthesised by the plant at a constant rate and therefore always present in the tissues of the plant, are called **phytoanticipins**. They are produced by healthy plants from the beginning of growth and serve only as a passive defence against potential harmful factors. **Phytoalexins** are antimicrobial substances synthesised *de novo* by plants from phytoanticipins to combat infection by pathogens. Phytoalexins are also called **phytoncides**, **plant antibiotics** or **plant pesticides**, as they are toxic to pathogenic ilicitors (viruses and microorganisms) and animal pests (insects and higher animals). The distinction between phytoalexins and phytoanticipins is not always clear, as some compounds may be phytoalexins in one species and phytoanticipins in another species. In addition, the same substance may often serve as both phytoalexin and phytoanticipin. In general, the distinction between the two compounds depends on when they are produced, either before or after infection. The ability to synthesise and accumulate phytoalexins is documented in more than 200 species of plants belonging to about 40 genera and 20 families.

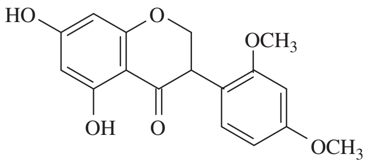
Examples of anticipins are glucosinolates in cruciferous (Brassicaceae) plants (see Section 10.3.3.4), which are enzymatically hydrolysed in disrupted tissue to form the antimicrobially active isothiocyanates. Another example is allicin in garlic, which is formed from the indifferent amino acid alliin by the activity of alliinase (see Section 8.2.9.2.2). Numerous phenolic compounds also exhibit antimicrobial activity in plant food materials, as do terpenoid substances, acetylene derivatives, heterocyclic nitrogen compounds and many others. For example, most antimicrobial compounds produced by the legume family plants (Fabaceae) are isoflavones, isoflavanes, related pterocarpans and stilbenes. For the nightshade family (Solanaceae) terpenic compounds are characteristic, for plants of the family of crucifers (Brassicaceae) indole derivatives are typical, and the representative compounds for the carrots family (Apiaceae) are polyacetylenes. This section gives only a short overview of the major antimicrobial compounds occurring

in food raw materials and foods, and aims to demonstrate the chemical diversity of these compounds. Antimicrobial effects are also exhibited by many other compounds described in previous chapters.

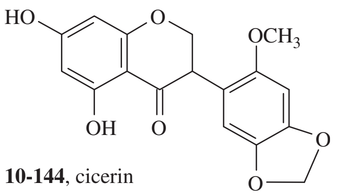
10.3.3.6.1 Isoflavones and isoflavanones

A number of isoflavones exhibit, in addition to oestrogenic activity, antimicrobial activity and other toxic effects. Examples of isoflavones exhibiting antimicrobial properties are prenylated isoflavones of legumes listed in Section 10.3.3.5.1, which occur mainly on the surface of leaves and other aboveground plant parts. Examples of such compounds are wighteon and luteon, which occur in lupines (*Lupinus* spp.) together with other related compounds.

Isoflavanones occur predominantly in legumes as 6′′-malonylglucosides. Examples of isoflavanones are homoferreirin (**10-143**) and cicerin (**10-144**), which occur in chickpea (*Cicer arietinum*).



10-143, homoferreirin



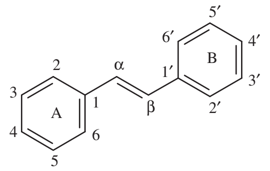
10-144, cicerin

10.3.3.6.2 Pterocarpans

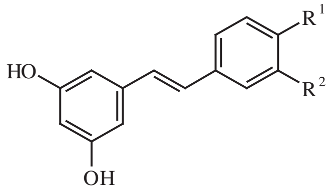
Pterocarpans of legume plants with the properties of phytoalexins are glyceollins in soya beans (*Glycine max*), medicarpin and maackiain in chickpeas (*Cicer arietinum*), pisatin in pea seeds (*Pisum sativum*) and phaseolin in common beans (*Phaseolus vulgaris*). Pterocarpans occur preferentially as 6′′-malonylglucosids. In addition to antimicrobial effects they also exhibit other biological effects (see Section 10.3.3.5.1).

10.3.3.6.3 Stilbenes

Stilbenes (also called diarylethanoids) are a group of substituted plant secondary metabolites with the structure of C_6–C_2–C_6. Stilbenes are hypothetically derived from the hydrocarbon (*E*)-1,2-diphenylethylene, which is known as (*E*)-stilbene or *trans*-stilbene (**10-145**). Ring A usually carries two hydroxy groups in the *m*-position, whereas ring B is replaced by hydroxy and methoxy groups in the *o*-, *m*- or *p*-position. Free stilbenes accompanied by the corresponding glycosides are found in small quantities in several plant species. Their biosynthesis is closely related with biosynthesis of isocoumarins (see Section 10.3.3.5.2). The basic member of a number of common stilbenes is (*E*)-pinosylvin (stilbene-3,5-diol). It occurs along with other stilbenes (**10-146**) especially in conifers, for example in pines (*Pinus* spp., Pinaceae).



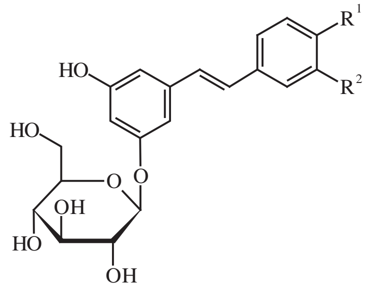
10-145, (*E*)-stilbene



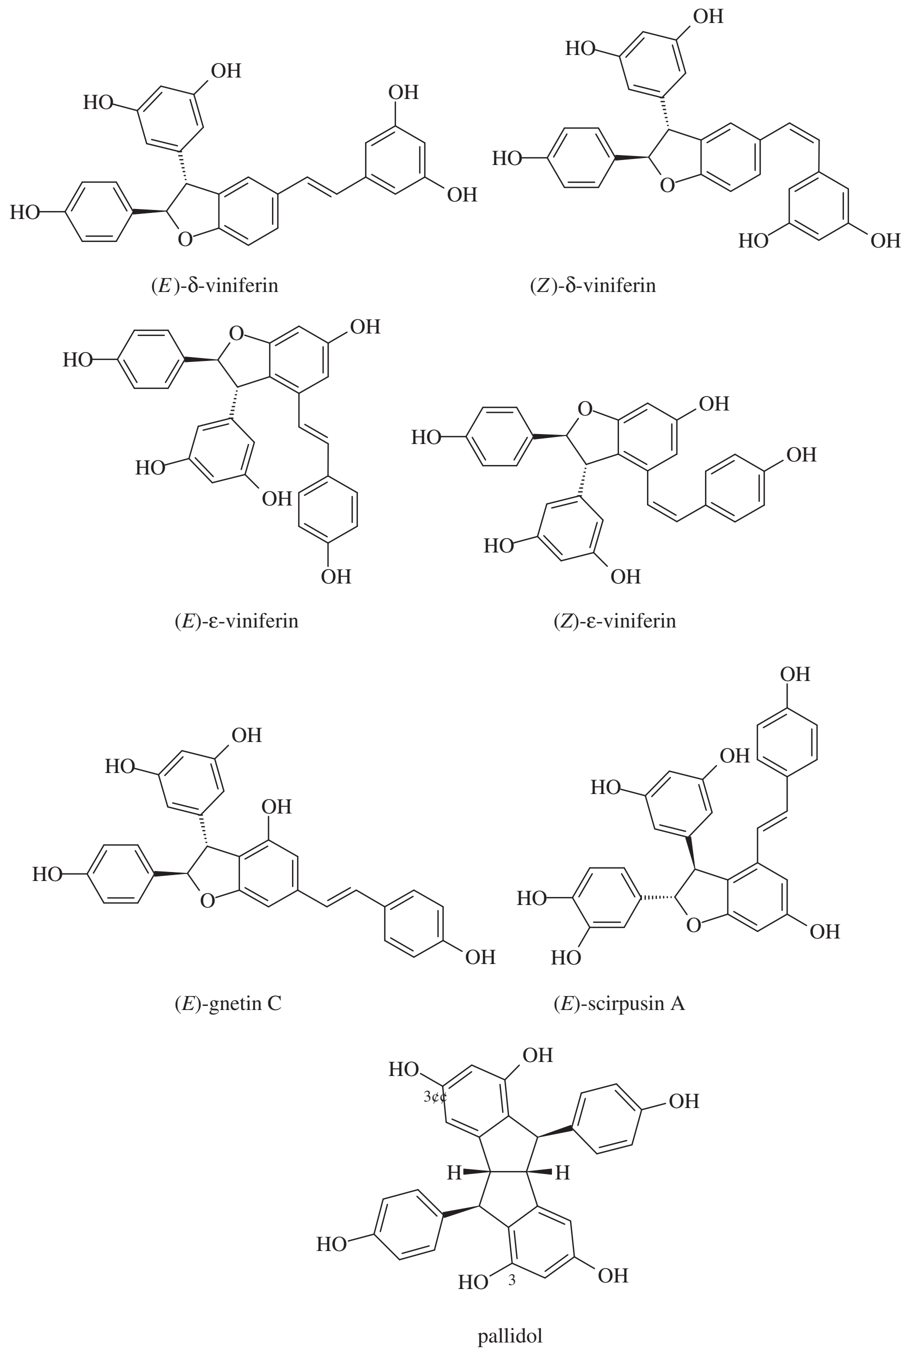
10-146, (*E*)-pinosylvin, $R^1 = R^2 = H$
(*E*)-resveratrol, $R^1 = OH, R^2 = H$
(*E*)-piceatannol, $R^1 = R^2 = OH$

The representative of stilbenes with antimicrobial and antioxidant effects is (*E*)-resveratrol (3,4′,5-trihydroxystilbene, **10-146**), an antifungal substance produced by a relatively limited number of plant species in response to biotic and abiotic stress and UV light irradiation. Resveratrol is synthesised by common grape vine (*Vitis vinifera*, Vitaceae), some legumes, such as peanuts (*Arachis hypogea*, Fabaceae), conifers and some other plants.

Resveratrol in grapes is mainly present in the skins of red grape varieties. From here it passes into the wine in amounts of about 1–5 mg/l. It is accompanied by (*Z*)-resveratrol and some oxidation products, such as (*E*)- and (*Z*)-piceatannol, (*E*)- and (*Z*)-3,3′,4′,5,-tetrahydroxystilbene. Larger amounts of resveratrol and piceatannol are bound in the form of β-D-glucopyranosides. The glucopyranoside of (*E*)-resveratrol is called (*E*)-piceid and the glucopyranoside of (*E*)-piceatannol is known as (*E*)-astringin (**10-147**). Resveratrol, its dimer ε-viniferin, dehydrodimer δ-viniferin, also known as viniferifuran, analogues of some other dimers (**10-148**), trimeric products, such as α-viniferin (**10-149**), resveratrol tetramer β-viniferin, tetramer hopeaphenol and a more



10-147, (*E*)-piceid, $R^1 = OH, R^2 = H$
(*E*)-astringin, $R^1 = R^2 = OH$



10-148, resveratrol dimers and analogues

highly polymerised oligomer of resveratrol referred to as γ-viniferin are found in wine grapes. They show even higher antioxidant and fungicidal activity than resveratrol. In recent years the anticarcinogenic and cardioprotective effects of resveratrol have been intensively studied. The plants of the genus *Vitis* (Vitaceae) contain many other stilbenoids that are of chemotaxonomic interest.

The stilbenes that have been reported for several varieties from peanuts (*Arachis hypogaea*), in leaves, roots and seeds, seem to be derived mainly from (*E*)-resveratrol (**10-146**). Examples of peanut stilbenes are (*E*)-piceatannol (**10-146**), (*E*)-piceid (**10-147**), prenylated stilbenes arachidins, (*E*)-4′-deoxyarachidin-2 (chiricanine A), (*E*)-4′-deoxyarachidin-3 (arahypin-1), (*E*)-3′-(2″,3″-dihydroxy-3″-methylbutyl)resveratrol (arahypin-2), (*E*)-4-(2″,3″-dihydroxy-3″-methylbutyl)resveratrol (arahypin-3), (*E*)-4-(2″,3″-dihydroxy-3″-methylbutyl)-4′-deoxyresveratrol (arahypin-4) and arahypin-5 (**10-150**).

Hydroxysubstituted stilbenes are often methylated. Examples of such compounds are (*E*)-pallidol (**10-148**), which occurs in Riesling wine as 3-*O*-glucopyranoside and 3,3″-di-*O*-glucopyranoside. Another example is 3,3′,5-trihydroxy-4′-methoxystilbene, which

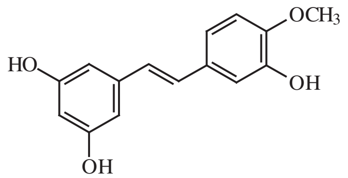
10-150, arachidins, arahypins and related compounds

is called rhapontigenin. It occurs as 3-*O*-β-ᴅ-glucopyranoside called rhapontigenin (**10-151**), for example, in rhubarb (*Rheum undulatum*, Polygonaceae), which is used for its haemostatic effects in Korea and Japan. It also displays antioxidant and antimicrobial properties.

10.3.3.6.4 Terpenoids

Terpenoid phytoalexins are present in economically important solanaceous plants (Solanaceae). Phytuberin (**10-152**), lubimin and 4-hydroxylubimin (**10-153**), along with steroid glycosides, are important representatives of sesquiterpenic phytoalexins of potatoes (*Solanum tuberosum*). Lubimin is also a major phytoalexin of eggplants (*S. melongena*). Another terpenoid is rishitin (**10-154**) occurring in potatoes and tomatoes (*S. lycopersicum*). Capsidiol (**10-155**), a phytoalexin of bell peppers (*Capsicum* spp.) and tobacco (*Nicotiana* spp.) also shows antimicrobial effects, as do the active substances of hot peppers known as capsaicinoids (see Section 10.3.3.1.7), and tobacco alkaloids (see Section 10.3.3.1.1). Several



10-151, rhapontigenin

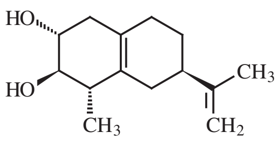
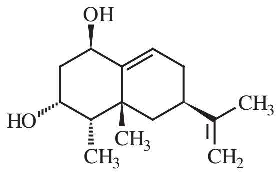
4-hydroxylubimin, R = OH

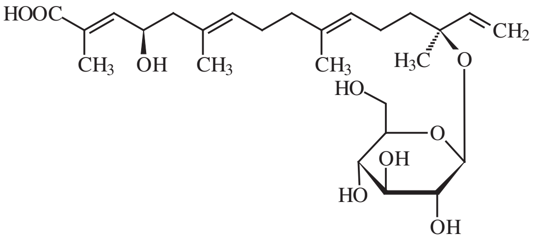


10-154, rishitin



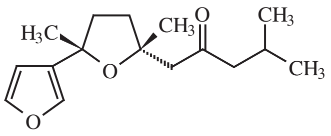
10-155, capsidiol

diterpenoid glycosides, named capsianosides from bell peppers exhibit antihypertensive effects and have been found to be related to the improvement and prevention of hypertension. An example of these diterpenoid glycosides is capsianoside I (**10-156**).

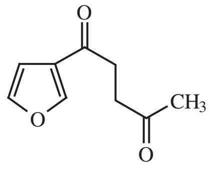


10-156, capsianoside I

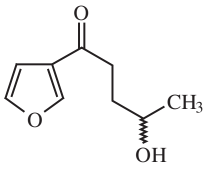
Structurally related to terpenoids are the so-called furanoterpenoids. A number of these derivatives can be found, for example, in sweet potatoes (*Ipomoea batatas*, Convolvulaceae). The first phytoalexin isolated from the crop affected by the mould *Fusarium solani* was hepatotoxic ipomeamarone (**10-157**). Also of toxicological concern are four other related derivatives: ipomeanine (**10-158**), a mixture of enantiomers of ipomean-4-ol (**10-159**) and ipomean-1-ol (**10-160**) and a mixture of diastereomers of ipomea-1,4-diol (**10-161**). The pneumotoxin (a respiratory tract toxicant) ipomean-4-ol is mainly responsible for the toxic effects of sweet potatoes. The use of mechanically damaged and microbially infected sweet potato as feed for cattle represents a significant risk, as in some instances this has led to the death of the livestock due to pulmonary oedema that were incurred. It seems very likely that these substances significantly contribute to the increased incidence of chronic respiratory diseases in the Pacific regions, where sweet potatoes are an important food.



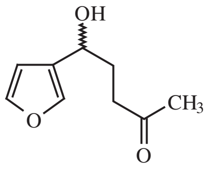
10-157, ipomeamarone



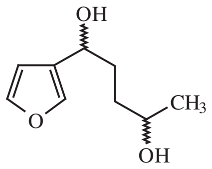
10-158, ipomeanine



10-159, (±)-ipomean-4-ol



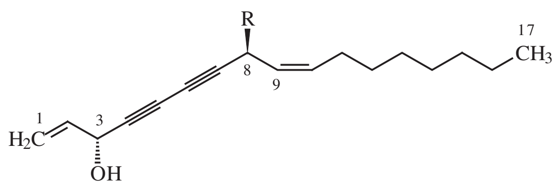
10-160, (±)-ipomean-1-ol



10-161, ipomean-1,4-diol

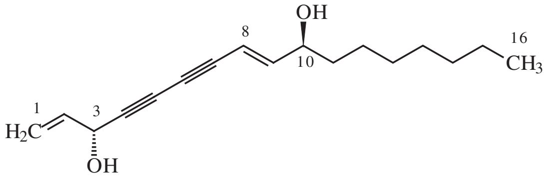
10.3.3.6.5 Polyacetylenes

An example of bitter phytoalexins of this group, found in carrots (*Daucus carota*, Apiaceae), parsley, parsnip, fennel, celery, celeriac and other umbelliferous vegetables, and also in ginseng (*Panax ginseng*, Araliaceae) and ivies (*Hedera* spp., Araliaceae) is (3*R*,9*Z*)-1,9-heptadecadiene-4,6-diyn-3-ol, known as falcarinol or carotatoxin or panaxynol (**10-162**). In carrots, falcarinol may occur in a concentration of about 290 mg/kg dry matter. The corresponding 3-ketone is a constituent of ginseng. Another polyacetylene of carrots is a product of falcarinol oxidation, which is (3*R*,8*S*,9*Z*)-heptadeca-1,9-dien-4,6-diyne-3,8-diol, known as falcarindiol (**10-162**). This diol occurs in about the same concentrations as falcarinol (240 mg/kg dry matter) and is accompanied by the corresponding 3-acetate. Falcarinol and falcarindiol were also found in parsnip in concentrations of 1600 and 5770 mg/kg dry matter, respectively, and in fennel (40 and 240 mg/kg dry matter,



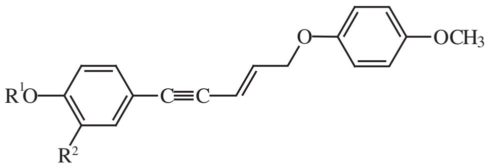
10-162, falcarinol, R = H
falcarindiol, R = OH
8-*O*-methylfalcarindiol, R = OCH_3

respectively). Falcarindiol (2320 mg/kg dry matter), (3*R*,8*S*,9*Z*)-8-*O*-methylfalcarinol (**10-162**) and (3*R*,8*E*,10*S*)-panaxydiol (**10-163**) occur in parsley at concentrations of 2320, 350 and 120 mg/kg, respectively. Celeriac contains up to 1620 mg/kg dry matter falcarinol, 2070 mg/kg dry matter falcarindiol, 170 mg/kg dry matter 8-*O*-methylfalcarinol and 60 mg/kg dry matter falcarindiol. The recognition threshold concentrations of falcarinol, falcarindiol and its acetate are 20, 40 and 60 mg/l.



10-163, panaxydiol

Asparenyn, 1-methoxy-4-[5-(4-methoxyphenoxy)pent-3-en-1-ynyl]benzene, 2-hydroxyasparenyn and asparenyol are examples of acetylenic compounds with cancer chemopreventive properties, which occur in asparagus (*Asparagus officinalis*, Asparagaceae) (**10-164**).

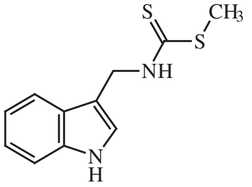


10-164, asparenyol, $R^1 = R^2 = H$
asparenyn, $R^1 = CH_3$, $R^2 = H$
2-hydroxyasparenyn, $R^1 = CH_3$, $R^2 = OH$

Except for antibacterial and antifungal activities, aliphatic polyacetylenes of the falcarinol type have other interesting bioactivities, including anti-inflammatory, anti-platelet-aggregatory, neuritogenic, serotonergic and potential anticancer effects. A medicinal usage of pure polyacetylenes is not feasible, because of their pronounced chemical instability and their ability to induce allergic reactions. However, consumption of food containing polyacetylenes might have a chemopreventive benefit. Adverse effects due to an excessive intake of polyacetylenes with the human diet are not to be expected, because polyacetylenes have a bitter off-taste in higher concentrations and are one of the main group of compounds contributing to the bitter taste of stored carrots.

10.3.3.6.6 Indoles

Interest in phytoalexins of the family Brassicaceae, called brassinins, began in the late 1980s when the first phytoalexin was identified in Chinese cabbage (*Brassica chinensis*). About 20 phytoalexins characteristic for this plant family are known today. Their common feature is the indole ring substituted at C-3 or C-2 by substituents containing nitrogen and sulfur. The structures of these compounds are illustrated in the structures of four commonly occurring indole phytoalexins: brassinin (**10-165**), cyclobrassinin (**10-166**), spirobrassinin (**10-167**) and brassilexin (**10-168**). Phytoalexins of cruciferous vegetables include also glucosinolates (see Section 10.2.3.3).



10-165, brassinin

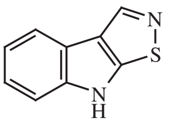
10-167, spirobrassinin



10-168, brassilexin

Biological effects

Biological activity of phytoanticipins and phytoalexins (and natural pesticides in general) is not limited to microorganisms and other pests, but affects virtually all organisms. These materials exhibit a wide spectrum of effects, from the relatively harmless, such as the hallucinogenic and narcotic effects of myristicin (see Section 8.2.13.2), to the toxic effects of carcinogenic furanocoumarins (see Section 10.3.3.5.2). Mechanisms of biological effects of most phytoanticipins and phytoalexins are not known, and practical toxicological data on the effect of long-term exposure (chronic toxicity) do not exist.

10.3.3.7 Other natural antioxidants

The use of antioxidants dates back to ancient times, when herbs and spices were used in food preservation. A number of plant food materials have antioxidant properties. Particularly effective plants are rosemary and sage, but oregano, thyme, cloves, turmeric, oatmeal and other materials are also effective. Natural antioxidants (mainly derived from plant extracts) often have limited use, because they may resemble the odour of the plant or may have a bitter taste. An overview of natural antioxidants occurring in significant food materials is given in Table 10.20. The issue of natural and synthetic antioxidants approved in the EU as food additives is addressed in Section 11.2.2.

10.3.3.7.1 Simple phenols

Antioxidant and antimicrobial effects are found in some simple phenols (especially hydroquinone, guaiacol, isoeugenol and salicylaldehyde) that occur as components of smoke, which has been used for smoking foods since ancient times. Phenols, which are components of some common spices, also have high antioxidant activities. In common thyme (*Thymus vulgaris*, Lamiaceae), for example, thymol and carvacrol occur (see Section 8.2.8.1).

Table 10.20 Natural antioxidants of important food commodities.

Material	Compounds with antioxidative activities
Fruits	
Olives (*Olea europea*)	Phenolic acids (*p*-coumaric and others), their glycosides (verbascoside), phenols (tyrosol, hydroxytyrosol), oleuropein
Spices	
Rosemary (*Rosmarinum officinalis*)	Diterpenes (carnosic acid, carnosol and others), phenolic acid esters (rosmarinic acid)
Sage (*Salvia officinalis*)	Diterpenes (carnosic acid, carnosol and others)
Tyme (*Thymus vulgaris*)	Simple phenols (thymol, carvacrol) and their dimers (diterpenes)
Turmeric (*Curcuma longa*)	Curcuminoids (diarylheptanoids and their lower homologues)
Ginger (*Zingiber officinale*)	Gingerols, shogaols, zingerone, curcuminoidsy
Vegetables	
Onion (*Allium cepa*)	Flavonoids (quercetin), phenolic acids
Peppers (paprika) (*Capsicum annuum, C. frutescens*)	Capsaicinoids and related compounds
Cereals and oilseeds	
Wheat (*Triticum aestivum*)	Phenolic acids (esters, glycosides), tocopherols, flavonoids, phospholipids
Rye (*Secale cereale*)	Phenolic acids (esters, glycosides), tocopherols, flavonoids, phospholipids
Barley (*Hordeum vulgare*)	Tyrosine, tyramine, phenolic acids (esters, glycosides), tocopherols, flavonoids, phospholipids, lignans
Oats (*Avena sativa*)	Avenanthramides, phenolic acids (esters, glycosides), tocopherols, flavonoids, phospholipids
Rice (*Oryza sativa*)	Flavones (isovitexin), phenolic acids (esters, glycosides), tocopherols
Soya (*Glycine max*)	Tocopherols, isoflavones and their glycosides, phenolic acids, phospholipids
Sesame seed (*Sesamum indicum*)	Lignans and their degradation products
Peanuts (*Arachis hypogaea*)	Phenolic acids (*p*-coumaric and others), flavonoids (taxifolin, in hulls eriodictyol and luteolin), tanns, tocopherols
Rapeseed (*Brassica napus*, *B. rapa*)	Phenolic acids (their esters and glycosides), mainly (*E*)-sinapic acid and sinapine, tannins, tocopherols

10.3.3.7.2 Phenolic acids and their derivatives

Phenolic acids, primarily acids with structures C_6–C_1 (benzoic acid and its derivatives) and C_6–C_3 (cinnamic acid and its derivatives) are normal constituents of plant materials (see Section 8.2.6.1.6). Some aromatic carboxylic acids, such as 2-hydroxybenzoic (salicylic) and 4-hydroxybenzoic acids, are components of smoke used for smoking foods.

Phenolic acids and their derivatives exhibit the effects of primary antioxidants. Their activity depends on the number of hydroxyl groups in the molecule. Generally cinnamic acids and *o*-diphenols are more active as antioxidants (e.g. caffeic acid

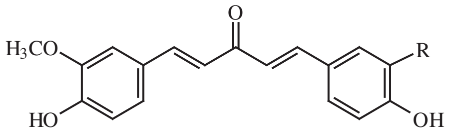
and its ester chlorogenic acid or ester of caffeic acid and 3,4-dihydroxyphenyllactic acid known as rosmarinic acid, see Section 8.2.7.1.1). In addition to these esters (depsides), many other phenolic acid derivatives, such as amides and glycosides, show antioxidant activity.

10.3.3.7.3 Lignans

Simple diarylbutanoids as well as complex bisepoxylignans (see Section 10.3.3.5.1) and other lignans have antioxidant activity and other biological effects. Some lignans are also active as phytooestrogens and anticancerogenic agents.

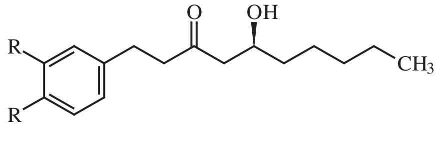
10.3.3.7.4 Curcuminoids and related compounds

Yellow pigments of turmeric (*Curcuma longa*, Zingiberaceae), which are classified as curcuminoids and diarylheptanoids (see Section 9.6), have antioxidant effects. Also potent antioxidants are curcuminoids occurring in other plants of the genus *Curcuma*, such as *C. xanthorrhiza*, originating from Indonesia, which contains the lower homologues of yellow curcuminoids belonging to diarylpentanoids (**10-169**), where R = H or OCH_3.

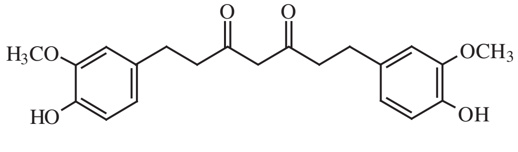


10-169, turmeric diarylpentanoids

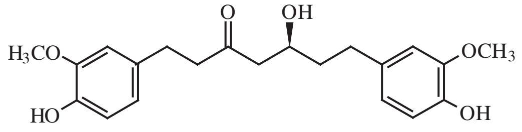
Ginger rhizome (*Zingiber officinale*) contains hot gingerols, shogaols and zingerone (see Section 8.3.7.3) that are highly active antioxidants. In addition to these compounds, several tens of compounds occur in various ginger species, which are structurally related to gingerols, shogaols or curcuminoids. Examples are methoxy-6-gingerol, deoxy-6-gingerol (**10-170**), tetrahydrocurcumin (**10-171**) and hexahydrocurcumin (**10-172**). Ginger rhizome also contains more complex compounds, examples of which are the so-called phenylbutenoids cassumunins A and B (**10-173**). A related species of ginger (*Z. montanum*, syn. *Z. cassumunar*) contains, in addition to curcumin, cassumunins A, B and C (**10-174**), together with kassumunarins A (**10-175**), B and C (**10-176**).



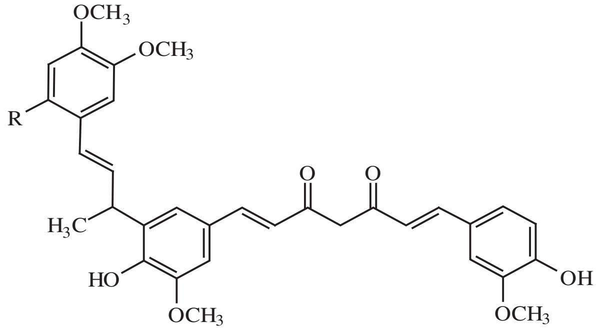
10-170, methoxy-6-gingerol, $R^1 = OCH_3$, $R^2 = OCH_3$
deoxy-6-gingerol, $R^1 = H$, $R^2 = OH$



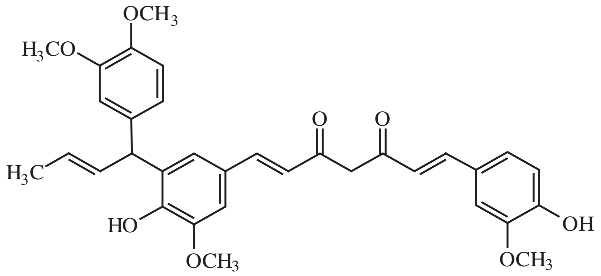
10-171, tetrahydrocurcumin



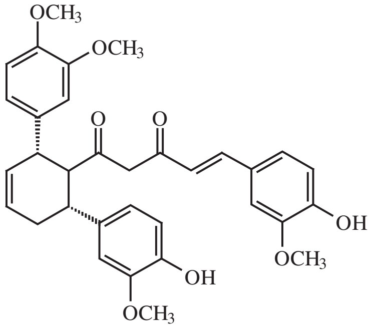
10-172, hexahydrocurcumin



10-173, cassumunin A, R = H
cassumunin B, $R = OCH_3$



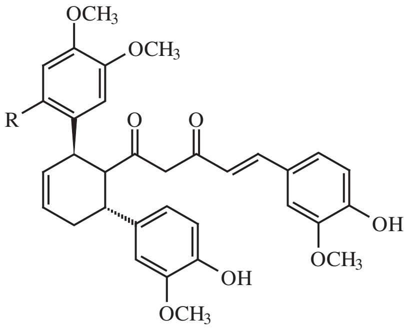
10-174, cassumunin C



10-175, cassumunarin A

An unusual diarylheptanoid (4*E*,6*E*)-1,7-bis(4-hydroxyphenyl) hepta-4,6-dien-3-one (**10-177**) was isolated from fruits of a banana (Musa x paradisiaca, cultivar derived from *M. acuminata* and *M. balbisiana*) together with a bicyclic diarylheptanoid, *rel*-(3*S*,4a*R*,10b*R*)-8-hydroxy-3-(4-hydroxyphenyl)-9-methoxy-4a,5,

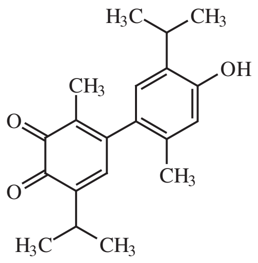
6,10b-tetrahydro-3*H*-naphtho[2,1-*b*]pyran, as well as 1,2-dihydro-1,2,3-trihydroxy-9-(4-methoxyphenyl)phenalene, hydroxyanigorufone with chemopreventive activities and cytotoxic 2-(4-hydroxyphenyl)naphthalic anhydride.



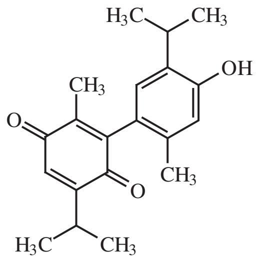
10-176, cassumunarin B, R = H
cassumunarin C, R = OCH_3

10.3.3.7.5 Terpenoids

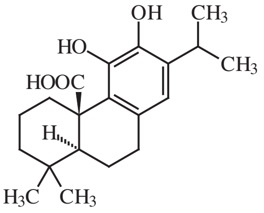
Mint plants (Lamiaceae), for example in common thyme *(Thymus vulgaris*), contain substituted biphenyls derived from monoterpenic alcohol thymol, their *o*-quinones (**10-178**) or *p*-quinones (**10-179**), which exhibit marked antioxidant activities. Among the most active natural antioxidants with anti-inflammatory effects is carnosic acid, also known as rosmaricine (**10-180**), which is accompanied by carnosol (picrosalvin, **10-181**). These two antioxidants represent about 15% by weight of commercial extracts of rosemary (*Rosmarinus officinalis*) and more than 90% of their antioxidative activity. The carnosic acid content in fresh spices is about 1–2%.



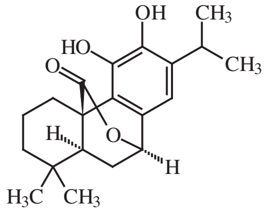
10-178, thyme *o*-quinone



10-179, thyme *p*-quinone

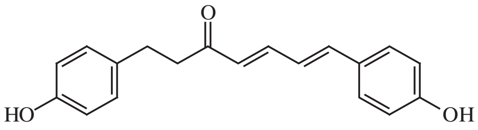


10-180, carnosic acid

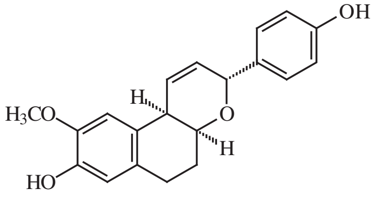


10-181, carnosol

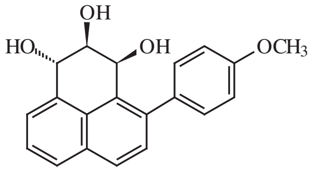
Carnosic acid is unstable and is transformed into carnosol. Other active products are rosmanol (7α-isomer, **10-182**), epirosmanol (7β-isomer) and 7-methylepirosmanol (**10-183**). Other minority compounds of rosemary extracts are isorosmanol (**10-184**), rosmariquinone (**10-185**) and rosmaridiphenol (**10-186**), which



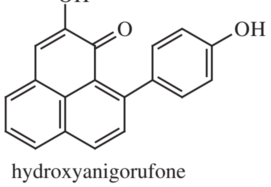
1,7-bis(4-hydroxyphenyl)hepta-4,6-dien-3-one



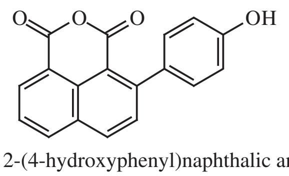
8-hydroxy-3-(4-hydroxyphenyl)-9-methoxy-4a,5,6,10b-tetrahydro-3*H*-naphtho[2,1-*b*]pyran



1,2-dihydro-1,2,3-trihydroxy-9-(4- methoxyphenyl)phenalene



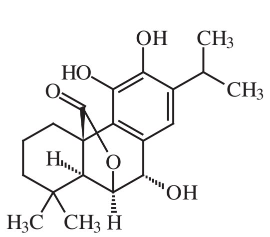
hydroxyanigorufone



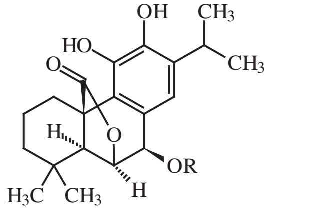
2-(4-hydroxyphenyl)naphthalic anhydride

10-177, banana diarylheptanoids

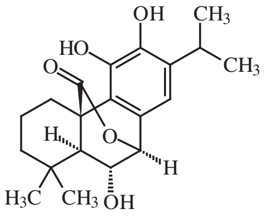
is related to tropones. The same compounds are also found in common (garden) sage (*Salvia officinalis*).



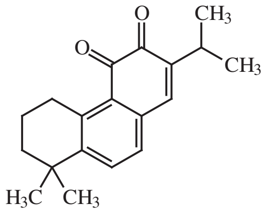
10-182, rosmanol



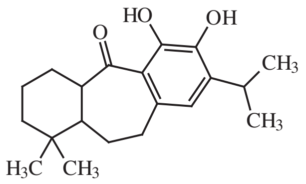
10-183, epirosmanol, R = H
7-methylepirosmanol, R = CH_3



10-184, isorosmanol



10-185, rosmariquinone



10-186, rosmaridiphenol

Extract of rosemary is currently approved in the EU as a natural antioxidant (E392). Carnosic acid has a typical *o*-diphenol structure and is easily oxidised. The antioxidation mechanism is based on a coupling reaction with the peroxyl radical at the 12- or 14-position of carnosic acid and subsequent transformation reactions of intermediates to an *o*-quinone and a hydroxy *p*-quinone (Figure 10.13).

An important group of substances derived from diterpenoids are quinones of red (Chinese) sage (*Salvia miltiorrhiza*). Antioxidative properties are related to their reduced glycosidic forms. The drug is used as a traditional medicine in China and Southeast Asia countries. The active substances can actually be considered as derivatives of phenanthrenequinones, but their biochemical origin is different.

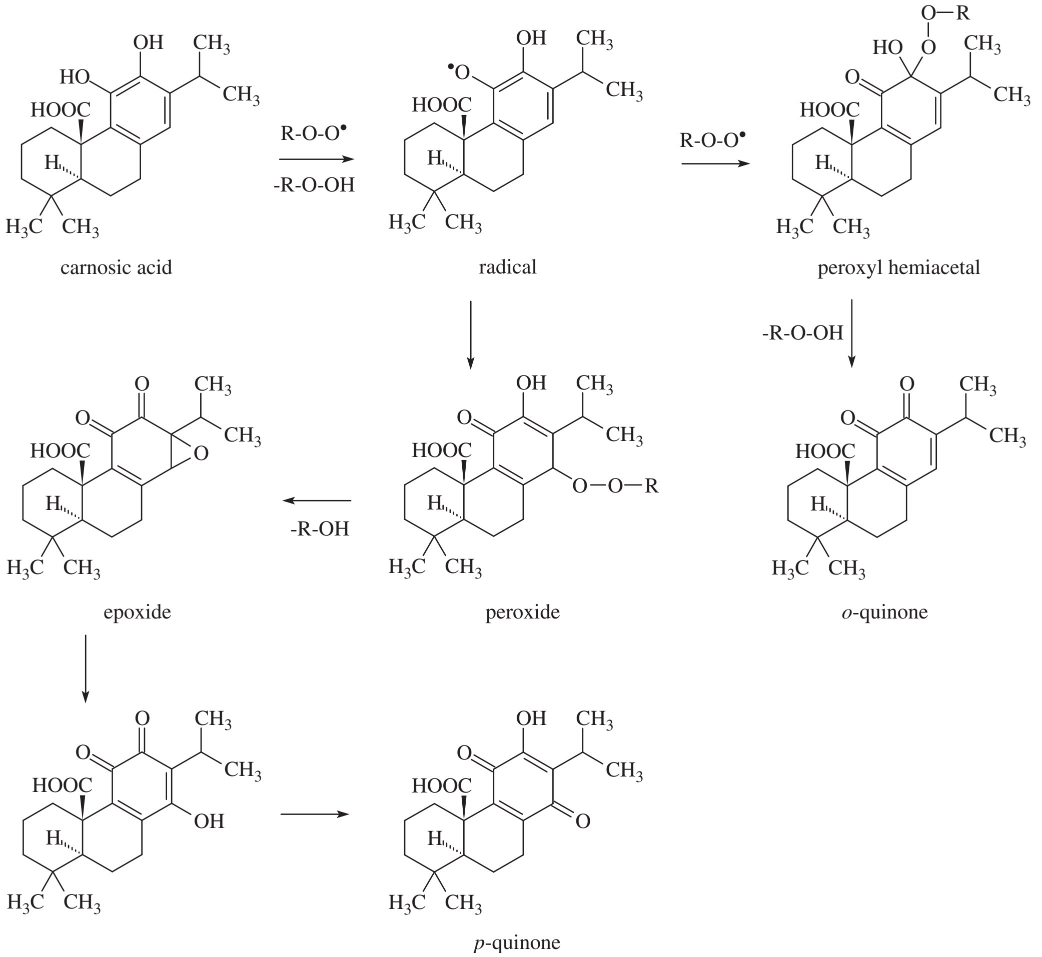


Figure 10.13 Antioxidant mechanism of carnosic acid.

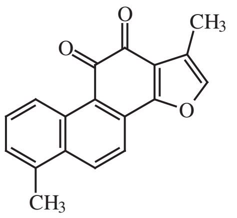
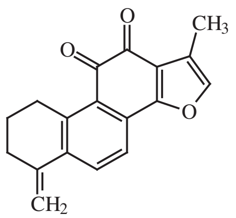
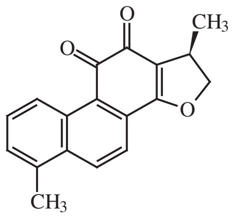
Some furanophenathrenequinones are exemplified in formulae **10-187** to **10-189**. In addition to these compounds, another group of quinones includes their isopropyl derivatives, such as rosmariquinone (**10-185**), which is also found in rosemary, miltirone (**10-190**), dehydrorosmariquinone (**10-191**), danshenxinkuns A (10-190), B and C (**10-192**). In addition to antioxidant activity, these substances also have sedative, antimicrobial, anticoagulant, anti-inflammatory and other effects. In addition to these compounds, other components include rosmarinic acid (**8-83**) and a number of its derivatives.



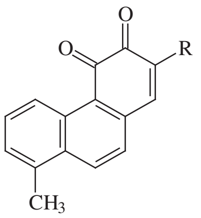
10-187, tanshinone I



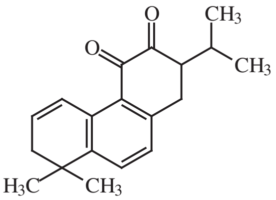
10-188, methylenetanshinone



10-189, (*R*)-dihydrotanshinone

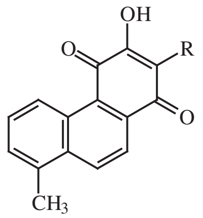


10-190, miltirone I, R = $CH(CH_3)_2$
danshenxinkun A, R = $CH(CH_3)CH_2OH$



10-191, dehydrorosmariquinone

The antioxidant potential of plant materials, such as rosemary, also comes from some triterpenic acids such as betulinic, oleanolic and ursolic acids, triterpenic alcohols (β-amyrin and others, see Section 3.7.4.1.1) and derived saponins (see Section 10.3.2.2). Usually low antioxidant activity (up to temperatures around 180 °C) is



10-192, danshenxinkun B, R = $CH(CH_3)_2$
danshenxinkun C, R = CH_3

exhibited by phytosterols, the most active compound of which is Δ^5-avenasterol (see Section 3.7.4.1.3).

10.3.3.7.6 Flavonoids

Flavonoid substances are primary antioxidants. Flavonols and 5-hydroxysubstituted flavones also bind metals into inactive complexes. Important for the antioxidant activity of flavonoids is the number of hydroxyl groups in the molecule and their positions. Active compounds are all dihydroxy derivatives with hydroxyl groups at positions C-3′ and C-4′. The presence of other hydroxy groups in ring B further increases the antioxidant activity (e.g. robinetin and myricetin with an additional hydroxyl group at C-5′ are more active as antioxidants than quercetin and fisetin). Low antioxidative activity is exhibited by flavonoids with one hydroxy group in ring B (such as flavanones naringenin and hesperetin). Other important functional groups include the carbonyl group at C-4 and free hydroxyl group at C-3 (or C-5). Very efficient antioxidants have two hydroxyl groups in the *o*-position in one ring and two hydroxy groups in the *p*-position in other rings, such as 3,5,8,3′,4′- and 3,7,8,2′,5′-pentahydroxy derivatives.

10.3.3.7.7 Other antioxidants

In biological materials, some vitamins (especially vitamins C and E) and a number of nitrogen and sulfur compounds act *in vivo* as substances with potential antioxidant carotenoids and related polyenes. For example, nitrogen compounds with significant antioxidant activities include certain alkaloids, uric acid and other purines, some peptides, amino acids, biogenic amines and tetrapyrrole pigments. Important sulfur compounds with antioxidant activity are sulfur amino acids (cysteine and methionine), derived peptides (glutathione) and some proteins. An antioxidant of animal and plant tissues also found in microorganisms is lipoic acid and derived sulfides and polysulfides. Some fungi contain as an antioxidant a derivative of histidine known as ergothioneine (**2-16**). In marine animals there is a mercaptohistidine derivative ovothiol A (**2-55**). Dipeptide carnosine also exhibits antioxidant activity in animal tissues.

Biological effects

The evaluation of natural antioxidants is highly problematic, since many of them have different biological activities. Some flavonoids, for example, exhibit spasmolytic, anti-inflammatory and

anticancerogenic effects, some also act as phytoalexins protecting plants against viral and microbial infections, while certain compounds have oestrogenic, carcinogenic and other effects.

10.3.3.8 Lectins

One of the protection mechanisms of plants lies in the accumulation of certain proteins in seeds and vegetative parts related to reproduction. These organs of plants are unacceptable, unpalatable or toxic to parasites and predators. Such proteins are inhibitors of proteases (see Section 10.2.1.1), inhibitors of saccharases (see Section 10.2.1.2) and lectins.

10.3.3.8.1 Structure, nomenclature and occurrence

Lectins, formerly called phytohaemagglutinins, were originally defined as proteins capable of red blood cells (erythrocytes) agglutination in animal organisms. Their activity is due to their interaction with sugars, which are components of glycoproteins or glycolipids in cell membranes. The current definition refers to lectins, as all proteins with at least one centre other than the active (catalytic) centre by which proteins can reversibly bind to specific monosaccharides and oligosaccharides. Many lectins can bind to monosaccharides and their derivatives (such as D-glucose, D-mannose, D-galactose, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine and L-fucose), however they have a higher affinity to oligosaccharides that do not occur in plants, but are typical components of animal glycoproteins. Such compounds are, for example, *N*-acetylneuraminic acid and *N*-acetyl-D-galactosamine located as building units in the chains of complex carbohydrates.

Lectins are a highly heterogeneous group comprising several hundreds of plant proteins, which are divided into three groups:

- **merolectins**
- **hololectins**
- **chimerolectins**.

Merolectins are simple proteins unable to agglutinate cells, which contain only one centre binding sugars and no catalytic centre. Merolectin is, for example, the protein of amaranth (*Amaranthus caudatus*, Amaranthaceae), which binds polysaccharide chitin.

Hololectins are proteins containing at least two centres binding sugars and, like merolectins, have no catalytic functions. They behave as true agglutinins. The majority of plant lectins are hololectins. An example is soya bean lectin (SBA, abbreviation of Soya Bean Agglutinin), a tetrameric glycoprotein (or metalloprotein as it contains one binding site for Mn^{2+} and four sites for binding transition metals), with a relative molecular weight of 120 kDa. It is composed of two structurally slightly different subunits (30 kDa) and contains four centres binding *N*-acetyl-D-galactosamine.

Chimerolectins are complex proteins containing one to two centres binding sugars and an independent centre with catalytic or other biological activity. Depending on the number of sugar binding centres, chimerolectins behave either as merolectins or as hololectins. For example, lectin inactivating ribosomes type 2, such as toxic protein ricin occurring in castor seeds (*Ricinus communis*, Euphorbiaceae), has a catalytically active A chain covalently linked to two chains B by disulfide bridges. Each of these two polypeptide chains B contains one centre, which binds sugars; therefore ricin behaves as a hololectin.

The majority of known lectins belong to one of four major subgroups:

- legume lectins
- mannose-binding lectins (monocot plant lectins)
- chitin-binding lectins
- ribosome type 2-inactivating lectins.

The most important mannose-binding lectins occur in different families of plants, mainly Amarillidaceae, Araceae, Liliaceae and Orchidaceae. Chitin-binding lectins are located in five mutually taxonomically unrelated families of plants, Poaceae, Solanaceae, Urticaceae, Papaveraceae and Amaranthaceae. Some lectins cannot be classified into any of these subgroups, because they appear to belong to other, not yet specified, subgroups.

Lectins are widely distributed in both the plant and animal kingdoms, and are even present in some microorganisms. The maximum amounts are found in the seeds of plants. The most frequently occurring lectins, their content and important properties are shown in Table 10.21. Some lectins traditionally have trivial names, for example the lectin (albumin) of castor seeds is ricin, and the lectin of jack beans (*Canavalia ensiformis*, Fabaceae) is trivially called concavalin A.

10.3.3.8.2 Reactions and changes

Lectins can be denatured by heat and a decrease of their biological activity also occurs during proteolysis. Detoxification procedures of lectins in food materials commonly include soaking and cooking. The efficiency of these operations depends on the time of soaking, temperature and the time of heat treatment. Soaking itself is not sufficient. For example, detoxification of beans by soaking for 16 hours at 22–25 °C decreases the activity of lectins by only 4–5%. Cooking itself is also not appropriate for food detoxification. For example, detoxification of beans by cooking takes about 90 min, while the same material soaked for 16 hours is detoxified during 4–10 min of cooking. Lectins are largely dissolved into the soaking water and the cooking water. It is not recommended to consume this water. Autoclaving, especially at higher pressures, is also a suitable detoxification procedure, but during extrusion, only small losses of lectin activity occur (12–18%).

Cereal products containing soya beans generally show higher residual activity of lectins than other materials. Seed germination leads to a significant decrease in the activity of lectins. The germination time required to substantially reduce the activity of lectins is 4–6 days. Detoxification of common products, such as potatoes, can be done by common manufacturing and culinary practices.

Table 10.21 Main lectins in economically important plants.

Plants	Latin name	Occurrence	Content (g/kg)	Thermal stability[a]	Toxicity in foods	
					Raw	Processed
Legume lectins						
Peanuts	*Arachis hypogaea*	Seeds	0.2–2	Unstable	Yes	Yes
Peas	*Pisum sativum*	Seeds	0.2–2	Unstable	Possibly	No
Common beans	*Phaseolus vulgaris*	Seeds	1–10	Medium	Yes	Possibly
Jack beans	*Phaseolus lunatus*	Seeds	1–10	Medium	Yes	Possibly
Tepary beans	*Phaseolus acutifolius*	Seeds	1–10	Medium	Yes	Possibly
Runner bean	*Phaseolus coccineus*	Seeds	1–10	Medium	Yes	Possibly
Lens	*Lens culinaris*	Seeds	0.1–1	Unstable	Yes	No
Soya beans	*Glycine max*	Seeds	0.2–2	Low	Yes	No
Broad beans	*Vicia faba*	Seeds	0.1–1	Unstable	Possibly	No
Mannose-binding lectins

[b]Highly toxic.

10.3.3.8.3 Biological effects

Lectins applied intravenously are highly toxic and some exhibit toxicity even when applied orally. Acute toxicity is usually low, but long-term exposure to even small amounts of lectins can be harmful. Consuming raw or inadequately cooked beans may cause stomach upset, vomiting and diarrhea. In comparison with the lectins of common beans, soya bean lectins are relatively well digested in the small intestine, but they are still antinutritional or toxic compounds. Approximately 60% of ingested lectins passes through the digestive tract unchanged and bind to the carbohydrate receptors of the small intestine epithelium, which is manifested by reduced viability of epithelial cells and a possible increase of small intestine weight as a result of cell hyperplasia. At concentrations of 0.5–0.6%, the growth of experimental animals is slow; at higher concentrations it leads to weight loss and, in some cases, to the death of affected animals.

Non-toxic lectins are lectins of garlic, onions, leeks, tomatoes and amaranth. Of the common lectins, those of peanuts, lentils, peas, common beans and soya beans are slightly toxic, wheat lectins are moderately toxic, and lectins of some beans (such as Jack beans) are highly toxic, while castor seed lectins are lethal (Table 10.21). Some lectins (such as lectins of garlic) have prebiotic effects and inhibit undesirable intestinal microflora (*Escherichia coli*). Often, lectins are not the only toxic substances of the plant material. For example, lectins of soybean seeds participate in their antinutritional and toxic effects at a level of about 25%, but trypsin inhibitors are about 40% and the rest is covered by saponins and other substances.

10.3.3.9 Toxic amino acids

Common proteinogenic amino acids may show some toxic effects in animals, for example L-tryptophan and L-3,4-dihydroxyphenylalanine (dopa). In plants about 700 aminocarboxylic and iminocarboxylic acids occur (see Section 2.2.1.2), which do not occur in proteins and are classified as secondary metabolites. Many of these compounds are structurally similar to the basic (proteinogenic) amino acids and their toxicity may be manifested in a variety of symptoms. The mechanism of toxicity is usually due to one of the following effects:

- competitive inhibition of enzymes because of resemblance to normal substrates
- interference in the activation and transfer of normal amino acid to transfer RNA
- interference in the assembly of amino acids into protein and interruption of protein synthesis
- incorporation into proteins resulting in the formation of non-functional proteins.

With the exception of the first effect, the other effects are fairly subtle metabolic disorders that can lead to diseases in humans and animals rather than to poisoning. Toxicologically important amino acids that are part of human food or animal feed are usually divided into several groups. They are mainly identified as:

- lathyrogenic amino acids (lathyrogens)
- arginine analogues
- analogues of sulfur and selenium amino acids
- other toxic amino acid.

10.3.3.9.1 Structure, nomenclature and occurrence

Lathyrogens

Lathyrogens are toxic amino acids and their derivatives (peptides, nitriles and other substances) occurring in the seeds of certain vetchlings (*Lathyrus* spp.) and vetches (*Vicia* spp.) belonging to the legume family (Fabaceae). Lathyrism is manifested by deformations of lower limbs (**osteolathyrism**), damage to blood vessels (**angiolathyrism**) and disorders of the nervous system (**neurolathyrism**).

Osteolathyrism appears in livestock fed with seeds of some vetchling species, namely sweet pea (*L. odoratus*), caley pea (*L. hirsutus*), tiny pea (*L. pussilus*) and pink vetchling. (*L. roseus*). Forms of osteolathyrism in poultry fed with sweet pea seeds are sometimes called **odoratism**. Osteolathyrism also occurs in people suffering from chronic neurolathyrism. The toxic substance is β-aminopropionitril (see Section 2.2.1.2.4), occurring as such or as the γ-glutamyl derivative. β-Aminopropionitril arises from 2-cyanoethylisoxazolin-5-one, the precursor of which is 2-(3-amino-3-carboxypropyl)isoxazolin-5-one (see **2-74**). The content of β-aminopropionitril in seeds of sweet pea ranges up to 0.8% of dry matter. In vetches, β-aminopropionitril results probably by decarboxylation of cyanoalanine (see Figure 2.2).

Neurolathyrism accompanies consumption of seeds of some vetchlings and vetches. Neuronal activity is shown by L-2,4-diaminobutanoic (L-α,γ-diaminobutyric) acid (see Section 2.2.1.2.9), which is a lower homologue of L-ornithine. It is present in particular in the seeds of flat pea (*L. sylvestris*) and perennial pea (*L. latifolius*), along with one of the degradation products of 2-(3-amino-3-carboxypropyl)isoxazolin-5-one, but it may arise also from L-3-cyanoalanine. 2,4-Diaminobutanoic acid in seeds occurs in quantities up to 1.5% dry weight and is accompanied by 4-(*N*-oxalyl)-L-2,4-diaminobutanoic acid. The main neurolathyrogen is 3-(*N*-oxalyl)-L-2,3-diaminopropanoic acid, also known as β-(*N*-oxalylamino)-L-alanine, which is produced by the reaction of L-2,3-diaminopropanoic acid with oxalyl-CoA and also from L-3-cyanoalanine. This neurotoxin is found primarily in seeds of grass pea (*L. sativus*), red pea (*L. cicera*), winged vetchling (*L. ochrus*) and crimson pea (*L. clymenum*). Its content in seeds of grass pea ranges from 0.1 to 1.5% and in the seeds of red pea from 0.1 to 0.3%. Diaminopropanoic acid similarly occurs in many rattle pods (*Crotalaria* spp.) and acacias (*Acacia* spp., Fabaceae). At a level of about 5% w/w, diaminopropanoic acid is accompanied by the non-toxic α-isomer, which arises from the β-isomer by intramolecular rearrangement via 2,3-dioxopiperazine-5-carboxylic acid (Figure 10.14). The expected reaction sequences of formation of neurotoxic amino acids and other toxic compounds in vetchlings seeds are illustrated in Figure 10.15 (AdoMet, also known as SAM is *S*-adenosyl-L-methionine).

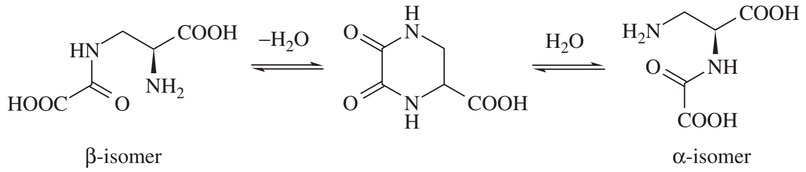

Figure 10.14 Isomerisation of 3-(*N*-oxalyl)-2,3-diaminopropanoic acid.

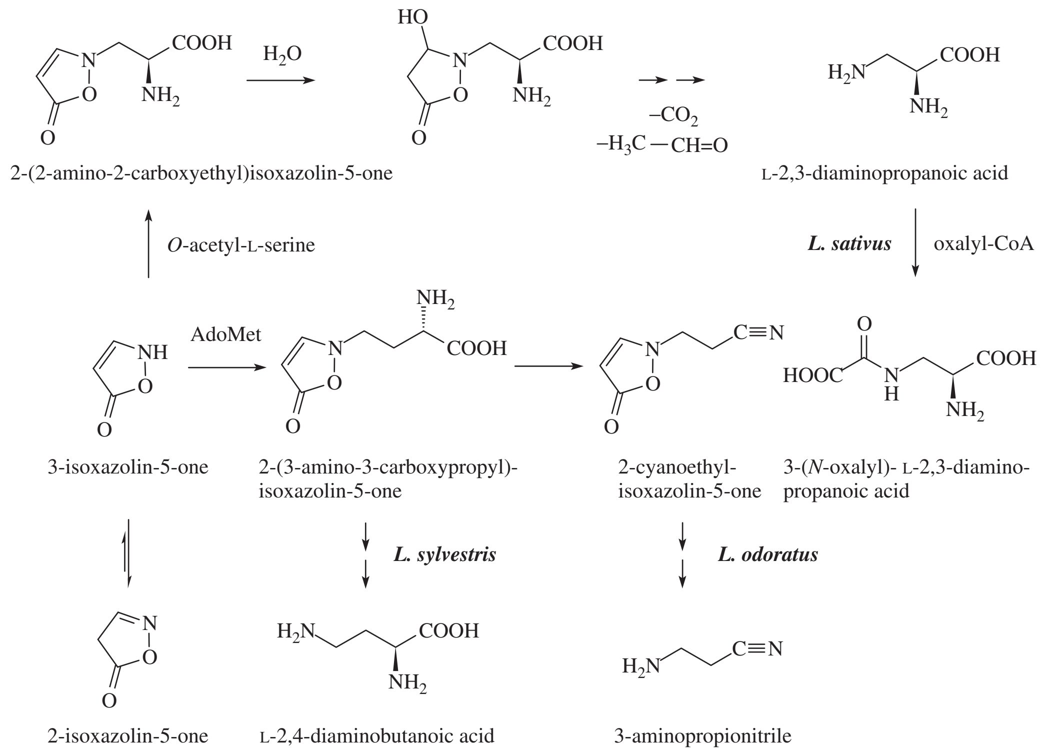

Figure 10.15 Biosynthesis of lathyrogens in vetchings.

Arginine analogues

A number of legume plants, especially seeds of tropical legumes, but also seeds of common vetch species, contain structural analogues of arginine, which may interfere with its metabolism (metabolism of ornithine) in the urea cycle. An example of these amino acids is a unique amino acid L-canavanine (see **2-44**), which was first isolated from Jack beans (*Canavalia ensiformis*), probably native to South America, which is cultivated for its edible pods and seeds, or as a reclamation plant and for green manure. The concentration in jack bean seeds is around 50 g/kg of dry matter. Later, this amino acid was identified in a number of other legumes.

An unusual amino acid is L-indospicine (see **2-45**) occurring in seeds of indigo shrubs (*Indigofera hendecaphylla*, syn. *I. spicata*) of the Fabaceae family. Its amount in these seeds is about 20 g/kg (dry weight). Indospicine is accompanied by canavanine (9 g/kg), which is also toxic. Another analogue of arginine is homoarginine, which occurs in the seeds of vetchlings and vetches together with L-4-hydroxyarginine and homocitrulline (see **2-42**). Seeds of red pea contain homoarginine at a level of about 12 g/kg of dry matter.

Sulfur and selenium amino acid analogues

Some sulfur amino acids or their selenium analogues may also exhibit toxic effects in livestock. An example of a sulfur-containing amino acid that is toxic to cattle, sheep, goats and other ruminants is a derivative of L-cysteine, *S*-methyl-L-cysteine sulfoxide, which is known as methiin (**2-23**). Methiin commonly occurs in forage brassicas, such as forage rape (*Brassica napus*), leaf turnips or forage brassica hybrids (*B. campestris*), kale (*B. oleracea*), turnips (*B. rapa*) and swedes (*B. napobrassica*) (see Section 2.2.1.2.2). The content of methiin in forage brassicas varies over a wide range of about 3–14 g/kg of dry weight, depending on the variety, the time of harvest and other factors. For example, its content in forage rape is commonly around 0.1 g/kg of dry weight, but may also reach 5–7 g/kg. Methiin also occurs in cabbage and broccoli, where its content is about 0.2 g/kg, in Brussels sprouts it is 0.7 g/kg, and is also found in onion and garlic, which contain methiin at concentrations of about 1.6 and 3 g/kg of fresh weight, respectively.

An analogue of L-cystine is 3,3′-(methylendithio)di-L-alanine, known as L,L-djenkolic acid (see **2-32**), which may cause poisoning if consumed by humans or livestock. It occurs, for example, in mildly toxic jengkol (djenkol) beans (*Archidendron pauciflorum*, syn. *Pithecellobium lobatum*, Fabaceae). Despite its strong smell, the beans are a popular food in Southeast Asia. Djenkolic acid also occurs in *Leucaena* forage legumes, such as *L. esculenta* (Mimosaceae) at about 2 g/kg and in seeds of trees and shrubs of the genus *Abarema* (syn. *Pithecolobium*), such as *A. undulatum* (Fabaceae) at a concentration of 20 g/kg dry weight.

A cause of livestock poisoning can also be selenium analogues of sulfur amino acids present in greater amounts in plants called Se-accumulators that grow on seleniferous soils (see Section 2.2.1.2.2).

Other toxic amino acid

Toxic effects, reflected particularly in farm animals, are exhibited by many other amino acids present in higher plants. Less frequently,

these amino acids may occur as toxic substances in human nutrition. Toxic amino acids also contain higher fungi (see Section 10.3.3.9).

Also toxic is the common amino acid L-3,4-dihydroxyfenylalanine (dopa), which occurs in relatively large quantities (about 50-60 g/kg fresh weight) in the immature seeds of faba beans (*Vicia faba*, Fabaceae), which are also involved in the formation of favism (see Section 10.3.1.3). The mature seeds contain about ten times lower levels of this amino acid. Similar concentrations of dopa also occur in the sub-tropical and tropical legume known as velvet bean (*Mucuna pruriens*). Toxic for ruminants in higher amounts are the proteinogenous amino acid L-tryptophan and its degradation product 3-methylindole (skatole, see **2-112**), respectively. Skatole is produced from tryptophan in the rumen as a product of decomposition by bacteria of the genus *Lactobacillus*.

An important amino acid toxic to livestock is L-mimosine, β-(3-hydroxy-4-pyridone-1-yl)-L-alanine (see **2-62**). It occurs in plants of genera *Leucaena* and *Mimosa* of the family Mimosaceae. Its quantity in the fodder plant *L. leucocephala* can reach up to 30–50 g/kg of dry matter.

An unusual toxic amino acid containing a cyclopropane ring in the molecule is hypoglycin A, L-3-(methylencyclopropyl)alanine. Hypoglycin occurs as a mixture of (2*S*,4*R*)- and (2*S*,4*S*)-diastereoisomers in immature fruits (pulp and seeds) of ackee (akee) fruit (*Blighia sapida*) from the family Sapindaceae, originating from the island of Jamaica. It has hypoglycaemic effects but also exhibits other toxic effects. In immature seeds, the content of hypoglycin A is 1000–1110 mg/kg, but at maturation decreases to less than 100 mg/kg. Hypoglycin B is a less toxic γ-glutamyl derivative of hypoglycin A, which is only present in the seeds of the fruit. For example, the US Food and Drug Administration and Health Canada have set the maximum permissible level for hypoglycin A to 100 mg/kg.

10.3.3.9.2 Reactions and changes

Toxic amino acids undergo similar reactions and changes as the other amino acids. Compounds with a lathyrogenic effect also occur in protein isolates obtained from seeds of vetchlings and vetches, but their content is reduced by 50–85% during protein isolation. Reduction of lathyrogens can also be achieved by various culinary practices. The amount of β-*N*-oxalylaminoalanine may be reduced by up to about 50% by cooking, and by up to 95% by seed soaking, cooking under pressure and subsequent fermentation. The detoxification partly consists in the conversion of the toxic β-form to the non-toxic α-form (Figure 10.14).

Some toxic amino acids can be partially removed from food or feed by leaching. For example, the content of canavanine in Jack bean seeds can be reduced from 50 to 8 g/kg by soaking, depending on the ratio of water to extracted material and temperature. The procedure for the preparation of immature seeds of ackee fruit is based on the removal of the pericarp and cooking, which reduces the hypoglycin concentration to an acceptable level of about 1 g/kg.

10.3.3.9.3 Biological effects

Lathyrisms, and correspondingly neurolathyrism, occurs in the poorer sections of the population, (particularly in certain parts of India, Bangladesh, Ethiopia and Nepal), after approximately 3–6 months' consumption of food that contains more than two thirds of the components originating from seeds of vetchlings. Cases of neurolathyrism have also been reported in other countries, including some in Europe. Symptoms of this disease are a neurodegenerative muscular rigidity and weakness of the lower limbs, which may extend to their paralysis. In extreme cases, the disease ends in death. This disease affects more young men than women.

The lower homologue of lysine and ornithine, 2,4-diaminobutanoic acid, interferes (like the arginine analogue) with reactions of the ornithine cycle, thereby increasing the ammonia content in the blood and brain. 2,3-Diaminopropanoic acid acts as an analogue of glutamate in the nervous system.

Canavanine and other arginine analogues (indospicin and homoarginin) are not very important in human nutrition, but the crops in which they are present are important in animal nutrition. Poisoning is primarily a manifestation of growth retardation. Most sensitive to this are poultry (and other birds), which do not have the ornithine cycle. Canavanine blocks the binding of arginine (as an agonist) at a receptor molecule. By acting as an antagonist of arginine, canavanine inhibits the growth and development of other organisms, and thus has an allelochemical effect. Toxicity is based upon its degradation to canaline (by arginase) and reaction of canaline with aldehydes, for instance with pyridoxal 5′-phosphate in molecules of decarboxylases and aminotransferases, which yields stable oximes. Canavanine in mammals is partially degraded. Indospicin additionally has hepatotoxic and teratogenic effects.

Kale poisoning, or a severe haemolytic anaemia in ruminants, was discovered in cattle in Europe in the 1930s, but its link to the degradation product of methiin – dimethylsulfide – was only discovered about 35 years later. The toxic agent is dimethyldisulfide, arising as a product of methiin degradation by intestinal microflora. Dimethyldisulfide oxidises glutathione in red blood cells, the function of which is to protect haem from oxidation to haematin. In humans and other monogastric animals, such symptoms were not demonstrated.

Djencolic acid affects kidney function due to precipitation of amino acids in body fluids. Symptoms of djenkol bean poisoning (djenkolism) are nausea, vomiting, bilateral loin pain, urinary obstructions, such as haematuria (presence of blood in the urine) and oliguria (low urinary out-put, less than 500 ml in every 24 hours).

The side effects of higher amounts of dopa in humans have been associated with dizziness, staggering, increased heart rate, vomiting and psychiatric disturbances, which are consistent with its role of a precursor of the neurotransmitter dopamine. In pigs, dopa in feeds results in reduced intake and depressed weight gains. In ruminants, however, the seeds of *Vicia* and *Mucuna* have been used without apparent ill effects.

Higher amounts of tryptophan (its degradation product skatole) in feeds of ruminants may cause acute pulmonary oedema (a build-up of fluid in the spaces outside the blood vessels of the lungs) and emphysema (a chronic respiratory disease causing a decrease in lung function and often breathlessness).

Feeding crops with a higher content of mimosine, which is a thyreotoxic amino acid, is manifested by reduction of weight gain, the animals lose hair (mimosine acts as an epilator) and ophthalmic

catarrh and goitre appear. The strumigene is 3,4-dihydroxypyridine formed from mimosine degradation in the rumen. Mimosine poisoning can lead to the death of affected animals. Mimosine also has teratogenic effects. It is excreted from the body in the urine, either freely or after decarboxylation as mimosinamine.

Hypoglycin causes hypoglycaemia (low blood sugar level that is below a level necessary to properly support the body's need for energy and stability throughout its cells) and also has other toxic effects known as Jamaican vomiting sickness. Acute toxic effects are manifested mainly in malnourished subjects and by strong vomiting in children. The toxic substances are hypoglycin metabolites, which are (3*R*)- and (3*S*)-2-methylenecyclopropylacetic acids (see Section 2.2.1.2.1). Symptoms of poisoning, known as toxic hypoglycaemic syndrome, occur 6–48 hours after ingestion of seminal immature follicles. The poisoning is manifested by vomiting, drowsiness, fatigue and hypoglycaemia. The toxin (the active metabolite is methylencyclopropylacetyl-CoA) interferes with the metabolism of branched-chain amino acids, irreversibly binds to FAD and inhibits acyldehydrogenases acting in β-oxidation of fatty acids.

10.3.3.10 Biogenic amines and polyamines

Biogenic amines are a group of aliphatic, aromatic or heterocyclic bases derived from amino acids, which exhibit a variety of biological effects, as they perform different functions in animal and plant tissues. Some biogenic amines are building materials for the biosynthesis of phytohormones of the auxin group, plant protoalkaloids (such as hordenine and gramine), true alkaloids and other secondary plant metabolites. In animal tissues they have the function of tissue hormones (e.g. histamine) and are precursors of adrenal hormones (catecholamines).

Biogenic amines are formed from amino acids by the action of carboxy-lyases (decarboxylases containing as a cofactor pyridoxal 5′-phosphate), or arise from amino acids and carbonyl compounds by the action of transaminases (see Section 8.2.10.1.2). The so-called endogenous biogenic amines are the products of metabolism and at low concentrations are natural components of almost all foods. Exogenous biogenic amines are formed in foods as a result of microbial contamination and fermentation processes.

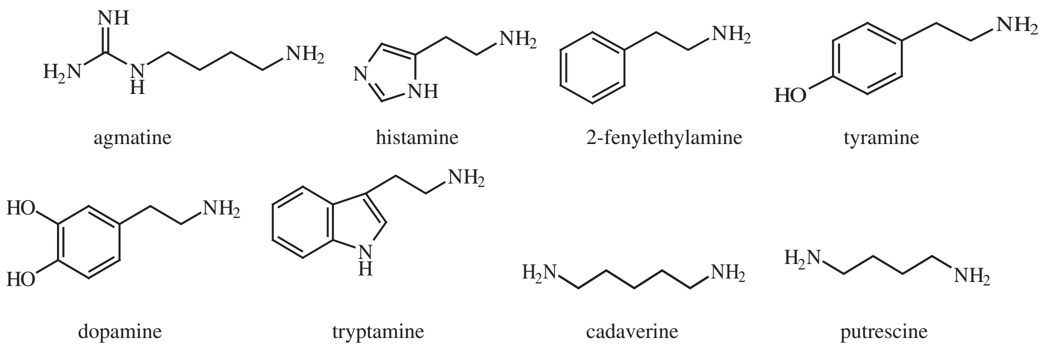
10.3.3.10.1 Structure, nomenclature and occurrence

Decarboxylation of arginine (by arginine decarboxylase) yields (4--aminobutyl)guanidine known as agmatine, histidine gives rise to 2-(1*H*-imidazol-4-yl)ethanamine known as histamine (histidine decarboxylase), phenylalanine gives phenylethan-2-amine also known as 2-phenylethylamine or phenethylamine (phenylalanine decarboxylase), tyrosine gives 4-(2-aminoethyl)phenol known as tyramine (tyrosine decarboxylase) and from 3,4-dihydroxyphenylalanine (dopa) and tryptophan (aromatic amino acid decarboxylase, also known as dopa decarboxylase or tryptophan decarboxylase) are formed 4-(2-aminoethyl)benzene-1,2-diol (dopamine) and 2-(1*H*-indol-3-yl)ethanamine (tryptamine), respectively. Decarboxylation of lysine (lysine decarboxylase) provides 1,5-diaminopentane (cadaverine), and ornithine (formed from arginine by the action of arginase) produces 1,4-diaminobutane (putrescine) by ornithine decarboxylase (**10-193**).

Putrescine, which is produced by decarboxylation of ornithine, and also arises from agmatine with catalysis by agmatinase, becomes the starting compound for the biosynthesis of spermidine and spermine. These reactions are catalysed by spermidine synthase and spermine synthase, respectively, involving *S*-adenosyl-L-methionine (for short AdoMet or SAM), and take place from bacteria to mammals (Figure 10.16). *S*-Adenosyl-L-methionine amide (dSAM) formed by decarboxylation of SAM provides trimethylene amine residue for this biosynthesis, which yields *S*-methyl-5′-thioadenosine (MTA).

Biologically active polyamines putrescine, spermidine and spermine, differ from the traditional group of biogenic amines. Spermidine and spermine arise under specific conditions and they also have different biological effects in comparison with the 'classical' biogenic amines, which are mainly histamine, tyramine, 2-phenylethylamine, putrescine, cadaverine, tryptamine and agmatine.

In the transformation of biogenic amines to other biologically active products, a number of different oxygenases, methyltransferases and other enzymes take part (Figure 10.17). Oxidation of tyramine yields 4-(2-amino-1-hydroxyethyl)phenol, known as octopamine, first demonstrated in *Octopus* species, which acts as a neurohormone and neuromodulator in invertebrates. Methylation



10-193, structures of biogenic amines

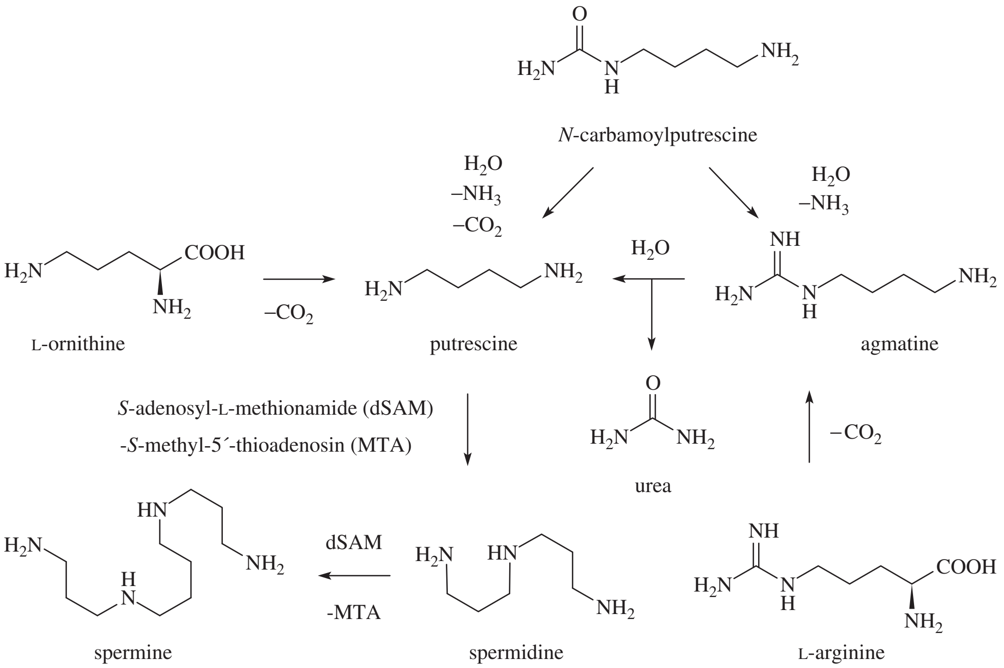


Figure 10.16 Biosynthesis of spermidine and spermine.

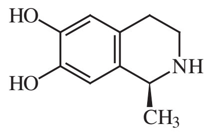
of tyramine gives rise to *N*-methyltyramine, which is a precursor of predominant bitter orange (*Citrus aurantium*) protoalkaloids (tyramine, *N*-methyltyramine, octopamine, hordenine and synephrine). The total amount of bitter orange biogenic amines ranges from about 10 to 80 g/kg. The main component is synephrine (8.8–71.5 g/kg). Synephrine also occurs in sweet oranges at low concentrations (about 13–35 mg/l in juice), which are, however, one of the main synephrine sources in a normal human diet. Hordenine occurs naturally in a variety of plants, taking its name from barley (*Hordeum*). In barley, hordenine levels reach a maximum within 5–11 days of germination, being about 20–30 mg/kg in malt and 12–24 mg/l in beer.

Oxidation of dopamine provides catecholamines of animals, such as adrenal hormone (*R*)-norepinephrine (also known as L-norepinephrine or noradrenaline), methylation of which yields another adrenal hormone (*R*)-epinephrine (L-epinephrine or adrenaline). Oxidation of dopamine via dopachrom leads to melanine pigments (see Section 9.3.1.1), and reaction with acetaldehyde yields salsolinol (6,7-dihydroxy-1,2,3,4-isoquinoline), which is, together with dopamine and epinephrine, the major metabolite in bananas. It is biosynthesised by non-enzymatic Pictet–Spengler condensation from dopamine and acetaldehyde, which is enzymatically generated from ethanol during the post-climacteric phase in banana (Figure 10.17). In dried banana chips, both (+)-(*R*)-salsolinol (**10-194**) and (–)-(*S*)-salsolinol occur at the 40 mg/kg level as a racemic mixture. In plants, catecholamines have a role in protection against predators and act in plant growth regulation. For example, they inhibit oxidation of phytohormone 3-indolylacetic acid called auxin (**10-85**), affect the activity of phytohormones known as gibberellins and interfere with ethylene biosynthesis (Figure 2.1).



10-194, (*R*)-salsolinol

The oxidation of tryptophan yields serotine, decarboxylation gives tryptamine, the oxidation of which leads to the hormone serotonine, from serotonine arises *N*-acetylserotonine (by the action of *N*-acetyltransferase), which is the precursor of hormone melatonin, which arises by the action of hydroxyindol-*O*-methyltransferase (Figure 10.18). An overview of biogenic amines occurring in foods, their precursors, biological activities and the main products of their transformation is shown in Table 10.22.

Biogenic amines are present in almost all foods as normal products of metabolism. At higher levels they are found in fermented products (such as cheeses, durable sausages, beer, wine and sauerkraut), where they are formed by microbial activities. Contaminating microflora primarily causes their presence in fish and meat during storage. High concentrations of biogenic amines occur in foods, such as vegetables, fruits and mushrooms, in advanced stages of spoilage under improper storage conditions.

Biogenic amines with more significant adverse effects on human health are histamine, tyramine and 2-phenylethylamine. The increased content of diamines putrescine and cadaverine serves primarily as an indicator of deficiencies in processing technology

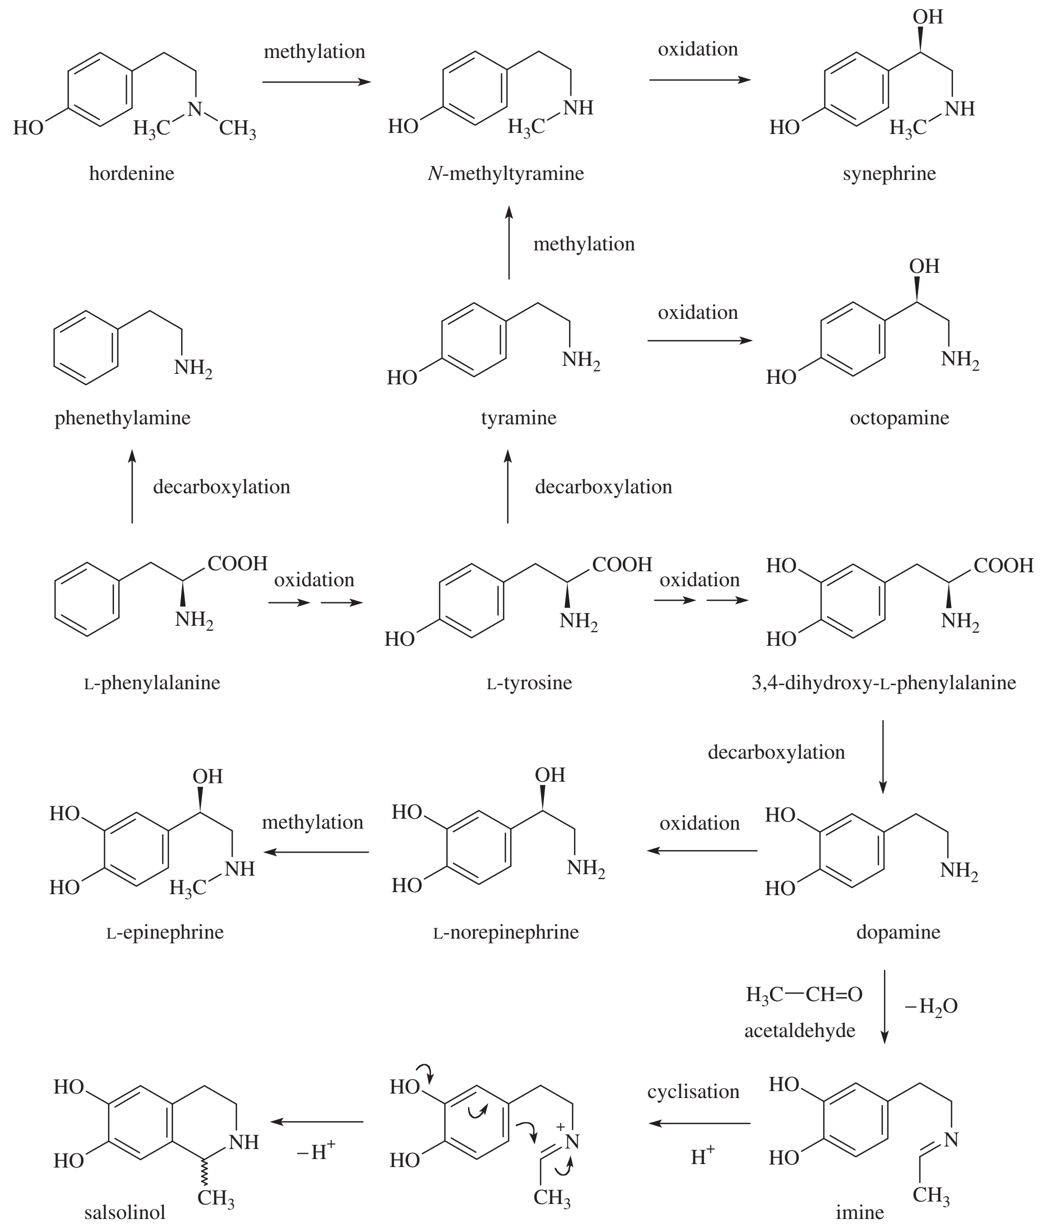


Figure 10.17 Formation of catecholamines and other metabolites of biogenic amines.

and storage of foods and food raw materials. The occurrence of tryptamine and agmatine is generally low and is not associated with adverse effects on human health. An overview of microorganisms involved in the production of biogenic amines in various foods is shown in Table 10.23. The contents of the main biogenic amines in some common foods are given in Table 10.24 (considerable variation in their contents is characteristic, as they depend on a number of factors).

Foods of animal origin

The main biogenic amines of meat, fish and cheese are histamine, cadaverine, putrescine and tyramine. During meat storage, the content of biogenic amines increases due to enzyme activity of microflora, therefore the content of some biogenic amines can be used as an indicator of meat freshness. Fresh pork meat contains, for example, up to 7 mg/kg of cadaverine and putrescine, while the rotten meat content of these two biogenic amines is 60 mg/kg and more. Cooking has relatively little influence on the content of biogenic amines, and their content only decreases by partial degradation and leaching, which is higher in pork meat. The level of the polyamines spermidine and spermine during thermal processing of meat and offal decreases by several tens of per cent, while higher decreases occur during baking and frying than during cooking or stewing.

The content of biogenic amines increases during the production of fermented sausages and ripening of cheeses. This increase is especially noticeable in the early stages of fermentation and is dependent

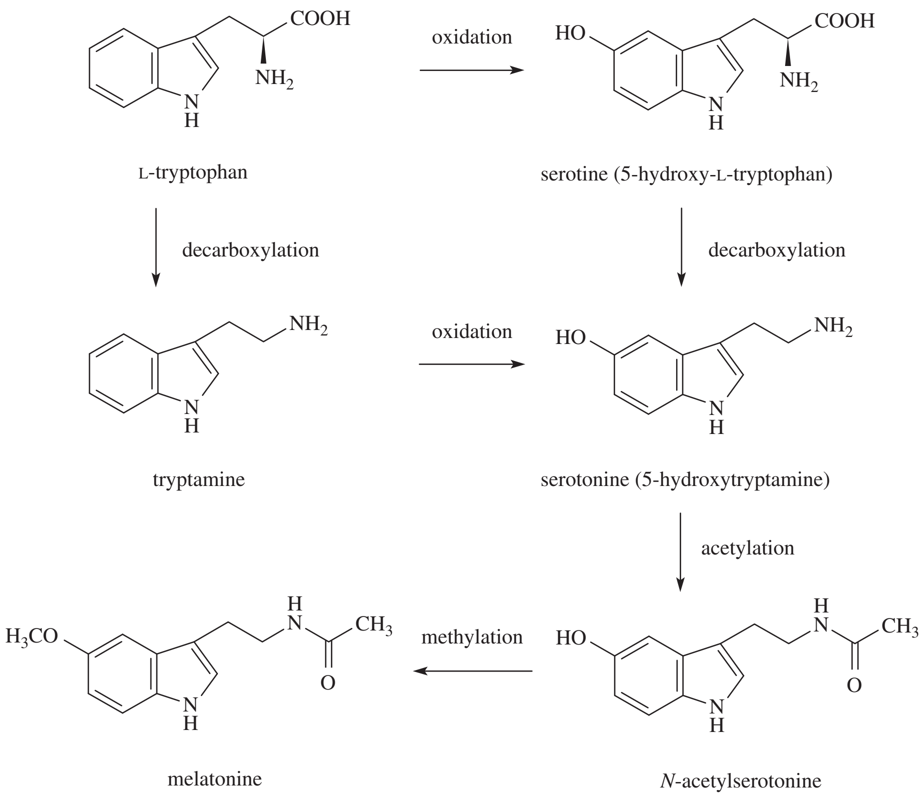

Figure 10.18 Decarboxylation and other reactions of tryptophan.

Table 10.22 Biogenic amines, their precursors, transformation products and biological activities.

Biogenic amine	Original amino acid	Other products	Biological ativity
Histamine	Histidine		Local tissue hormone, reduces blood pressure, effect on gastric juice secretion, participation in anaphylactic shock and allergic reactions
Cadaverine	Lysine		Stabilisation of macromolecules (nucleic acids), subcellular structures (ribosomes), stimulation of cell differentiation, vegetable hormone
Putrescine	Arginine *via* ornithine or citrulline	*N*-Methylputrescine, spermidine, spermine	Stabilisation of macromolecules (nucleic acids), subcellular structures (ribosomes), stimulation of cell differentiation, vegetable hormone
Agmatine	Arginine	Putrescine, *N*-methylputrescine, spermidine, spermine	Stabilisation of macromolecules (nucleic acids), subcellular structures (ribosomes), stimulation of cell differentiation, vegetable hormone
Phenethylamine	Phenylalanine	Tyramine, dopamine, epinephrine, norepinephrine	Neuromodulator, neurotransmitter in mammalian central nervous system
Tyramine	Tyrosine	Dopamine, epinephrine, norepinephrine, synephrine, hordenine	Precursor of dopamine, local tissue hormone, increases blood pressure, effect on smooth muscle contraction
Dopamine	Dopa	Norepinefrine, epinefrine	Mediators of sympathetic nerves
Tryptamine	Tryptophan	Serotonine, melatonine	Locan tissue animal and plant hormones (catecholamines), effect on blood pressure, intestinal peristalsis, mental functions

Table 10.23 Important microorganism producing biogenic amines.

Food	Microorganismd	Amines produced
Fish	*Morganella morganii*, *Klebsiella pneumoniae*, *Hafnia alvei*, *Proteus mirabilis*, *Proteus vulgaris*, *Clostridium perfringens*, *Enterobacter aerogenes*, *Bacillus* spp., *Staphylococcus xylosus*	Histamine, tyramine, cadaverine, putrescine, agmatine
Cheeses	*Lactobacillus buchneri*, *L. bulgaricus*, *L. plantarum*, *L. casei*, *L. acidophilus*, *L. arabinosae*, *Streptococcus faecium*, *S. mitis*, *Bacillus macerans*, *Propionibacterium* spp.	Histamine, cadaverine, putrescine, tyramine, tryptamine
Meat and meat products	*Pediococcus* spp., *Lactobacillus* spp., *Pseudomonas* spp., *Streptococcus* spp., *Micrococcus* spp., *Enterobacteriaceae*	Histamine, cadaverine, putrescine, tyramine, phenethylamine, tryptamine
Fermented vegetables	*Lactobacillus plantarum*, *Leuconostoc mesenteroides*, *Pediococcus* spp.	Histamine, cadaverine, putrescine, tyramine, phenethylamine, tryptamine
Fermented soya products	*Rhizopus oligosporus*, *Trichosporon beigllii*, *Lactobacillus plantarum*	Histamine, cadaverine, putrescine, tyramine, tryptamine

on the type of microorganisms. The formation of biogenic amines in durable salami and cheeses is caused by microorganisms of the processed raw material (Table 10.25). In rare cases, products may contain 100–1000 mg/kg of histamine, up to 580 mg/kg of putrescine, up to 90 mg/kg spermidine and up to 100 mg/kg spermine. The currently used starter cultures should have very low or negligible activity of amino acid decarboxylases.

Biogenic amines occur in fresh fish meat in small amounts. For example, tuna meat contains 0–10 mg/kg of histamine and 0–2 mg/kg of tyramine, but the content of biogenic amines increases with improper storage. During storage of fish at temperatures around 0 °C and lower, biogenic amines are formed in almost negligible quantities. At higher temperatures, the microflora in fish produces mainly histamine and tissues of Scrombroidae fish, which include tuna and mackerel, can contain up to 3000 mg/kg (mackerel) or even 8000 mg/kg (tuna) of histamine. The optimum temperature for histamine formation is 5–38 °C, but it depends mainly on the type of contaminating microflora. This is due to high levels of free, easily accessible histidine in the muscles of these fish species. In relatively high amounts other biogenic amines also arise, such as tyramine, cadaverine and putrescine. The minor biogenic amine agmatine is usually found in meat and fish in amounts of 1–3 mg/kg. High concentrations of agmatine, however, are found in some species of shellfish and dried fish. For example, the fresh Japanese abalones (*Haliotis sieboldii*) contain 40–200 mg/kg of agmatine. Its level in dried fish is up to 650 mg/kg.

Ripening of cheeses leads to a significant formation of biogenic amines only in plants with poor hygiene levels, where it is caused by contaminating microflora. With good technology and following good hygienic principles, even long-term ripened cheeses contain only small amounts of biogenic amines and polyamines, of which spermidine is present in the highest amount. The situation is different in cheeses made from unpasteurised milk (mainly milk of sheep and goats) that are often produced in small factories with hygiene deficiencies, even in developed countries.

The removal of already formed biogenic amines in foods is very difficult. A decrease in their concentration can be achieved by using diaminooxidase, but in practice it is impossible to use this enzymatic method of decontamination. Partial reduction of amines also occurs in heat-treated products, where biogenic amines can react with reducing sugars and their decomposition products in the Maillard reaction. The best way of producing foods containing small amounts of biogenic amines is the observance of such processes and hygienic conditions, which prevent their formation.

Foods of plant origin

Biogenic amines likewise occur as natural constituents in foods of plant origin. In some plants different derivatives of biogenic amines, which are commonly classified as protoalkaloids, are found in significant amounts. The main biogenic amine in fruits and vegetables is tyramine; many other biogenic amines are present in smaller quantities, often as conjugates with cinnamic or fatty acids. The main biogenic amine of bananas is tyramine, followed by phenylethylamine, histamine, dopamine, serotonine and norepinephrine. Higher amounts of putrescine occur in citrus fruits. In the United States, for example, oranges and grapefruits (including juices) represent the largest diet item in the intake of polyamines, which is due to the presence of putrescine. A less common biogenic amine is synephrine, which is derived from tyramine (Figure 10.17). It occurs almost exclusively in bitter oranges (*Citrus aurantium*, Rutaceae), and is also used in slimming diets. In spinach leaves, for example, free histamine occurs at a concentration of approximately 60 mg/kg, and also *N*-methylhistamine, *N*-acetylhistamine and histamine amides with various carboxylic acids.

Examples of conjugates of biogenic amines (**10-193**) with phenolic acids, which exhibit fungicidal activity, are hordatines (**10-195**), dimers of *p*-coumaroylagmatine, occurring in germinating barley. Wheat, for example, contains amides of 2-hydroxyputrescine along with ferulic and *p*-coumaric acids, which arise as phytoalexins.

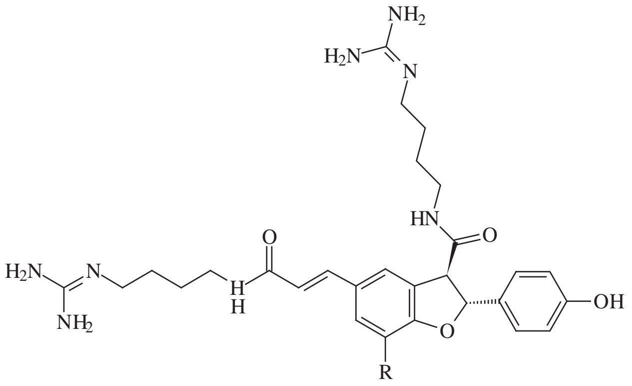
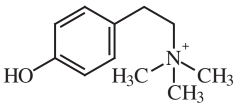
	2	3	1	1	2	5
	9	4	1	2	2	20
	21	3	1	3	2	21

Potent antioxidants comprise the polyamine conjugates, *N*,*N*′-dicoumaroylputrescine, *N*-*p*-coumaroyl-*N*′-feruloylputrescine and *N*,*N*′-diferuloylputrescine that were isolated from maize bran. In viral infections, tobacco produces caffeoylputrescine and other phytoalexins. In germinating barley (especially in the root) a derivative of tyramine known as hordenine (Figure 10.17) and the corresponding quaternary base candicine (**10-196**) are found.



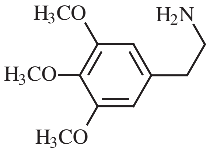
10-195, hordatine A, R = H
hordatine B, R = OCH_3



10-196, candicine

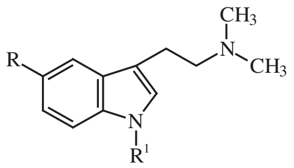
Biogenic amines, including polyamines, also occur in beer, where they are produced by contaminating lactic acid bacteria. Their concentrations are as follows: histamine <0.2–22 mg/kg, cadaverine <0.2–49 mg/kg, putrescine <0.3–31 mg/kg, spermidine <0.2–7 mg/kg, spermine <0.2–15 mg/kg, agmatine 0.5–47 mg/kg, phenethylamine <0.2–8 mg/kg, tyramine <0.3–68 mg/kg and tryptamine 0–10 mg/kg.

Several species of cacti, especially the species *Lophophora williamsii* (Cactaceae) contain protoalkaloid mescaline (**10-197**) derived from tyramine, which has hallucinogenic effects. Aztecs used these cacti in religious ceremonies.



10-197, mescaline

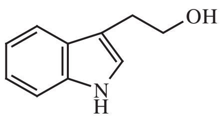
Germinating barley gives rise to protoalkaloids gramine and *N*-methylgramine (**10-198**), from tryptophan derivatives of tryptamine, which accumulate mainly in the leaves. The maximum content of gramine in leaves during the first two weeks of growth is about 900 mg/kg of fresh matter. Gramine occurs in many other monocotyledonous plants, such as grasses (Poaceae) and has the function of protection against sucking insects and plant pathogens and acts as an inhibitor of growth of certain other plants. Dimethylamine arises by partial decomposition of gramine in malt (see Section 8.2.10.1.2).



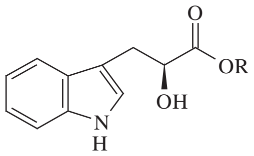
10-198, gramine, R = H, R^1 = H
N-methylgramine, R = H, R^1 = CH_3
bufotenine, R = OH, R^1 = H

Tryptamine is a precursor of a series of protoalkaloids, such as psilocin and psilocybin, which occur in hallucinogenic mushrooms (see Section 10.3.3.11.4). A protoalkaloid of certain plants,

especially mushrooms and secretions of some amphibians (frogs), is bufotenine (**10-198**), which is derived from 5-hydroxytryptamine. Tryptamine is also a precursor of plant hormones (phytohormones), a representative of which is 3-indolylacetic acid (**10-85**). A small amount of this acid is found in many foods of plant origin. In wines, for example, 3-indolylacetic acid occurs together with biosynthetic intermediates and other related compounds, such as 3-indolylethanol (**10-199**), 3-indolyl-L-lactic acid, ethyl 3-indolyl-L-lactic acid (**10-200**) and its β-D-glucoside.



10-199, 3-indolylethanol



10-200, 3-indolyl-L-lactic acid, R = H
ethyl 3-indolyl-L-lactate, R = CH_2CH_3

Phytohormones include **auxins** (such as 3-indolylacetic acid), which control cell division, germination, phototropism (the tendency of growing plant organs to move or curve under the influence of light) and other processes. The mechanism of their action is to increase the rate of RNA transcription. Another group are **gibberellins** (e.g. some terpenoids), which stimulate cell division, determine the stability of the plant shape and regulate geotropism (the downward growth of plant roots). Their mechanism of action is to stimulate the synthesis of RNA. **Cytokinins** (some isopentenyladenosines) regulate cell differentiation. Phytohormones also include **ethylene** (stimulating maturation of fruits) and **abscisic acid** (regulating aging, loss of leaves and opening of stomates).

10.3.3.10.2 Reactions and changes

Biogenic amines are reactive substances (Figure 10.19). In addition to enzymatic reactions that lead to biogenic amine derivatives and other compounds, these compounds can give rise to aldehydes by oxidative deamination. Under long-term storage or at elevated temperatures they react with triacylglycerols to form fatty acid amides. Analogously with other amino compounds, biogenic amines react with reducing sugars in the Maillard reaction yielding corresponding imines and other products. Imines also arise by oxidation of biogenic amines with hydrogen peroxide or lipid hydroperoxides. Secondary amines can react with nitrogen oxides to form carcinogenic nitrosamines. Proteins react with biogenic amines such as phenylethylamine, putrescine, histamine, tyramine and spermidine, to form β-*N*-substituted derivatives of diaminopropanoic acid. The likely mechanism of formation of these amino acid derivatives is β-elimination of cysteine residues and subsequent addition of an amine to the double bond of dehydroalanine,

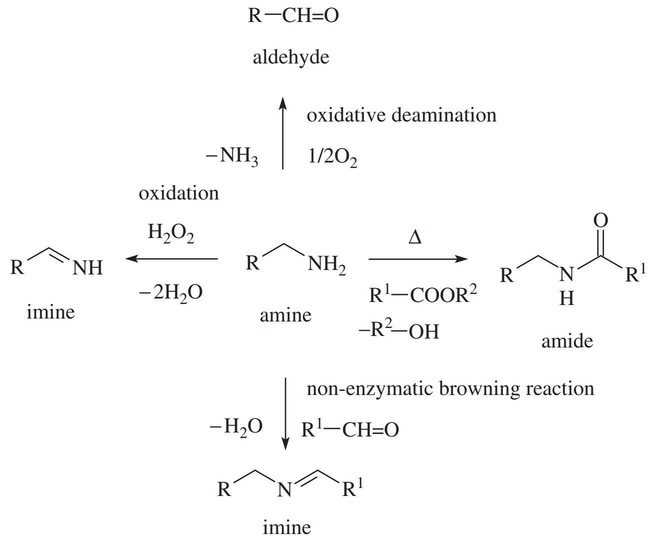


Figure 10.19 Main reactions of biogenic amines.

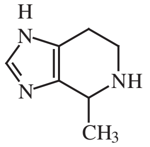
which arises analogously as in the case of lysinoalanine formation (see **2-121**). A Pictet–Spengler condensation reaction product of tryptamine (and tryptophan) with aldehydes in many foods yields 1,2,3,4-tetrahydro-β-carboline and β-carboline alkaloids (see Section 2.5.2.3.1). Reaction of histamine with acetaldehyde yields 4-methyl-4,5,6,7-tetrahydro-1*H*-imidazo[4,5-*c*]pyridine), known as 4-methylspinaceamine, which is present in fermented foods, such as oriental sauces and some cheeses (**10-201**).



10-201, 4-methylspinaceamine

10.3.3.10.3 Biological effects

Biogenic amines (in the narrower sense, biogenic amines does not include polyamines spermidine and spermine) are indispensable for the body, but at high concentrations may act as:

- psychoactive amines
- vasoactive amines.

Psychoactive amines act as transmitters in the central nervous system, vasoactive amines act directly or indirectly on the vascular system. According to the action, vasoactive amines can be divided into:

- vasocontractibile amines (e.g. tyramine)
- vasodilating amines (such as histamine).

Symptoms of consuming high doses of biogenic amines are vomiting, difficulty breathing, sweating, palpitations, hypotension

(histamine) or hypertension (tyramine) and migraine (phenylethylamine and tyramine). Monoamine oxidase and diamine oxidase are the main enzymes that decompose biogenic amines in the gut. Spermine and spermidine are decomposed by polyamine oxidase, but polyamine oxidase-mediated catabolism of spermine and spermidine produces putrescine and toxic acrolein (Figure 10.20). The toxic effect of biogenic amines is strongly influenced by the activity of these enzymes, which may be different for different individuals and depends on many factors, such as the presence of inhibitors (certain medicines, particularly from the group of psychotropic drugs, and to a lesser extent alcohol) or potentiators. High concentrations of biogenic amines cannot be eliminated by this enzyme system. Part of its capacity is needed particularly for the detoxification of histamine and tyramine depletes putrescine and cadaverine, which do not themselves possess a health risk, but their content may be quite high in a variety of foods (Table 10.24).

When evaluating the toxic effect of biogenic amines, it is necessary to consider not only the presence of a particular amine, but also other factors, such as the amount of food consumed, the presence of other toxic substances and other issues. For this reason it is very difficult to set the levels that have adverse effects in food. No adverse health effects were observed after exposure to the following biogenic amine levels in food (per person per meal): 50 mg histamine for healthy individuals, but below detectable limits for those with histamine intolerance; 600 mg tyramine for healthy individuals not taking monoamino oxidase inhibitor (MAOI) drugs, but 50 mg for those taking third generation MAOI drugs or 6 mg for those taking classical MAOI drugs and for putrescine and cadaverine. Concentrations of histamine higher than 500-1 000 mg/kg are considered to be dangerous to humans. Increased amounts of histamine can cause anaphylactic shock (very serious allergic reaction manifested by dizziness, loss of consciousness, laboured breathing, swelling of the tongue and breathing tubes, blueness of the skin, low blood pressure, heart failure and death). Histamine poisoning (histaminosis) from marine fish and fish products in coastal countries is the most common cause of foodborne poisonings. In many countries the maximum amount of histamine and tyramine is set, but information on the toxicity of other biogenic amines is inadequate. Commission regulation (EC) No. 2073/2005 on microbiological criteria for foodstuffs sets the limits for fishery products from fish species associated with a high amount of histidine (particularly fish species of the families Scombridae, Clupeidae, Engaulidae, Coryfenidae, Pomatomidae and Scombresosidae) to 100–200 mg/kg and to 200-400 mg/kg for fishery products, which have undergone enzyme maturation treatment in brine. For example, the Decree No. 305/2004 Coll. (in the Czech Republic) set limits for histamine to 200 mg/kg in fish and fish products and to 20 mg/l for beer and wine.

As multifunctional cations polyamines spermidine and spermine perform many important biological roles. The most important of these is the participation in protein biosynthesis and biosynthesis of nucleic acids. The biological processes in animals involve polyamines from three sources: endogenous produced in cells, produced by the gastrointestinal tract microflora and foodborne polyamines. Increased intake of dietary polyamines is desirable for accelerated healing of wounds, burns, development and recovery of the intestinal mucosa and for other processes, but the dietary intake should be low in people with cancer. There is an increased level of polyamines in young, fast-growing and metabolically active tissues (such as the liver and kidney). Plant products contain more spermidine than spermine, while animal products contain more spermine than spermidine. The physiological need for polyamines is not known.

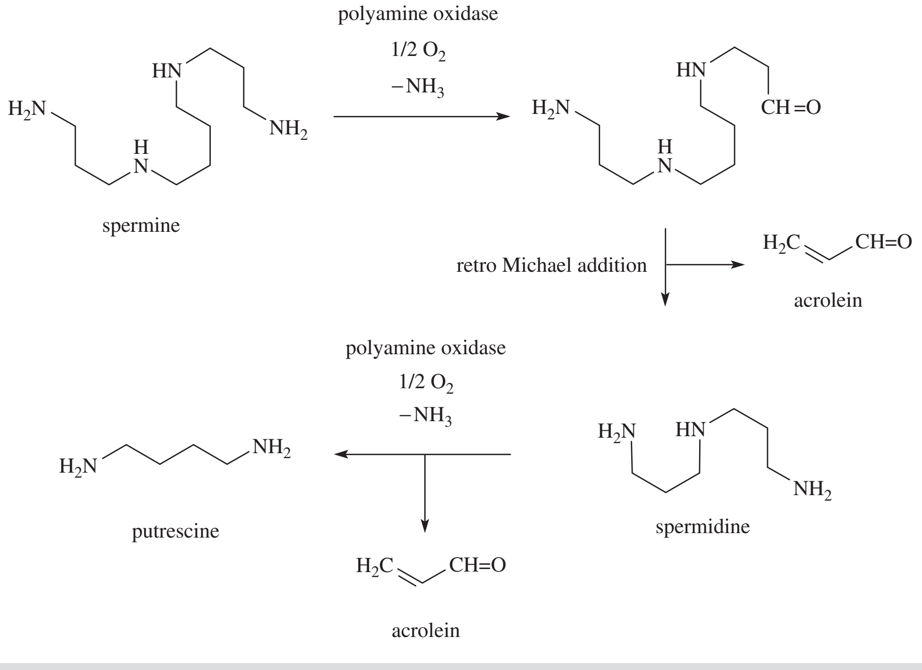


Figure 10.20 Catabolism of spermine and spermidine.

The protoalkaloid gramine, found mainly in grasses of the genus *Phalaris* (Poaceae), may cause sudden collapse and death of the grazing cattle. In sheep, the chronic poisoning is manifested by degenerative changes in the central nervous system.

10.3.3.11 Mushroom toxins

Mushrooms have inspired the cuisines of many cultures (notably Chinese, Japanese and European) for centuries and many species have been used in folk medicine for thousands of years, but approximately 70% of poisonings caused by natural substances can be attributed to mushrooms. About 5000 mushrooms species occur in nature, of which approximately 50–100 are known to be poisonous, only about ten are fatally poisonous and only 200–300 species have been clearly established to be eaten safely. However, many people are still hospitalised after eating mushrooms and several deaths are also reported annually after mushroom poisoning. Mushroom poisoning is more common in Europe than in America. The only way to be able to tell if a particular fungus is edible is to correctly identify its species.[4] There are no short cuts. Toxic substances occurring in mushrooms can be chemically divided into:

- toxic proteins
- toxic cyclopeptides
- toxic amino acid
- toxic amines, alkaloids and other nitrogenous compounds
- toxic terpenoids.

According to the severity, the most dangerous form of mushroom poisoning, which accounts for most mushroom related deaths, is that caused by cyclopeptides of toxic species of toadstools (*Amanita* spp.), called **phalloidin poisoning**, which is followed by poisoning due to cortinars (webcaps, *Cortinarius* spp.), which is called **orellanine poisoning**.

10.3.3.11.1 Proteins

Structure, nomenclature and occurrence

The toxic protein of false parasol, also known as the green-spored parasol (*Chlorophyllum molybdites*, Agaricaceae) has a relative molecular weight of 400 kDa and is composed of several subunits of molecular weights of 40–60 kDa. Bolaffinin is a toxic protein isolated from spotted bolete (*Xanthoconium affine*, syn. *Boletus affinis*, Boletaceae) containing 234 amino acid residues (molecular weight of 22 kDa) with one disulfide bridge. Bolesatin is a toxic glycoprotein with a molecular weight of 63 kDa isolated from devil's bolete (Satan's mushroom, *Boletus satanas*, Boletacae). Wood pink gill (*Entoloma rhodopolium*, syn. *Rhodophyllus rhodopolius*, Entoolomataceae) contains a toxic protein with a molecular weight of 40 kDa.

Reactions and changes

The toxic protein of false parasol is labile and is cleaved by proteolytic enzymes. Bolaffinin loses toxicity after being boiled for 15 min. Bolesatin is relatively thermostable and is resistant to hydrolysis by proteolytic enzymes.

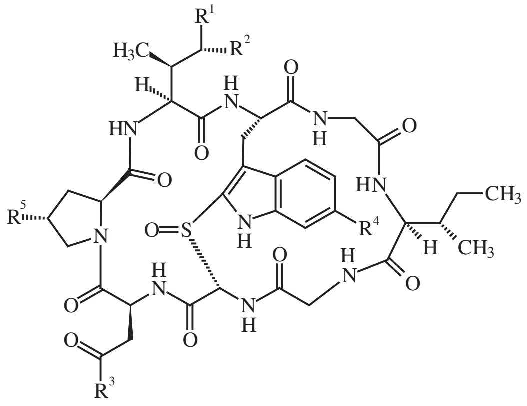
Biological effects

Toxic protein of false parasol exhibits haemolytic activity and causes poisoning, which is manifested by diarrhea and hypersensitivity to light and noise, but the poisoning results in death only in rare cases. Bolaffinin inhibits protein synthesis and damages the liver. By similar effects as lectins (cytotoxicity, inhibition of protein synthesis, see Section 10.3.3.8) manifests bolesatin.

10.3.3.11.2 Peptides

Structure, nomenclature and occurrence

The most important compounds of this group of fungi toxins are the cyclic peptides amatoxins or amanita toxins (**10-202**) and phallotoxins (**10-203**) of the death cap (*Amanita phalloides*, Amanitaceae) that cause the phalloidin poisoning. The main toxin is phalloidin



10-202, α-amanitin, $R^1 = CH_2OH$, $R^2 = OH$, $R^3 = NH_2$, $R^4 = OH$, $R^5 = OH$

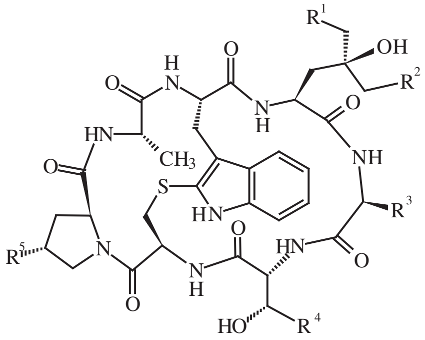
proamanulline, $R^1 = CH_3$, $R^2 = H$, $R^3 = NH_2$, $R^4 = OH$, $R^5 = H$

[4]The taxonomy of the Fungi kingdom (the sub-kingdom Dikarya) is in a constant flux; therefore, the most recent 2007 classification adopted by a coalition of mycologists has been used. Out of seven phyla (divisions) proposed, the toxic fungi of this section belong to the phylum Basidiomycota (known as club fungi), subphylum Agaricomycotina, class Agaromycetes, subclass Agaromycetidae, which covers most of the so called higher fungi. The phylum Ascomycota (sac fungi) covers only higher fungi belonging to the subdivision Pezizomycotina, class Pezizomycetes, subclass Penzizomycodidae, order Pezizales.



10-203, phalloidin, $R^1 = OH$, $R^2 = H$, $R^3 = CH_3$, $R^4 = CH_3$, $R^5 = OH$
phalloin, $R^1 = H$, $R^2 = H$, $R^3 = CH_3$, $R^4 = CH_3$, $R^5 = OH$

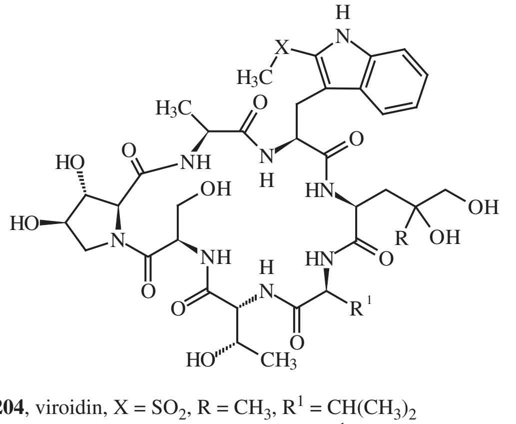
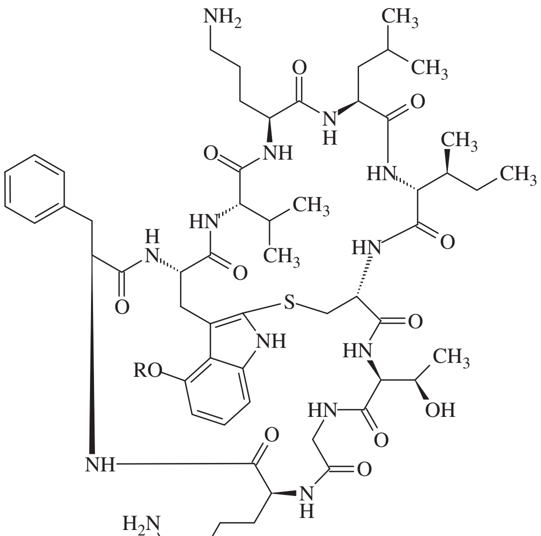
(about 100 mg/kg of fresh mushroom), in comparable amounts occur α-amanitin (about 80 mg/kg) and β-amanitin (50 mg/kg), other toxins are present in smaller amounts. Amanita toxins are similarly found in several other Amanita species (*A. bisporigera*, *A. hygroscopia*, *A. ocreata*, *A. suballiacea*, *A. tenuifolia* and *A. virosa*) and some members of the genera *Galerina* (*G. autumnalis*, *G. marginata* and *G. venenata*) and *Lepiota* (*L. brunneoincarnata*, *L. chlorophyllum*, *L. helveola* and *L. josserandii*). A number of other related peptides known as cycloamanides have no biological activity. Similar structures and toxicities to those of phallotoxins are seen in virotoxins (**10-204**) present in the European destroying angel (*A. virosa*).

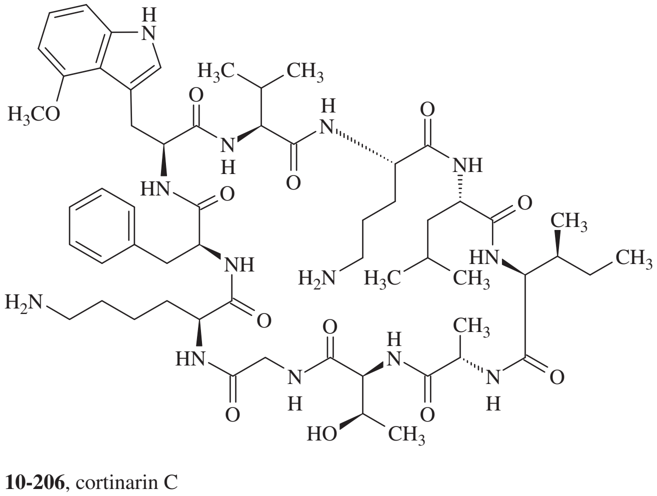


10-204, viroidin, $X = SO_2$, $R = CH_3$, $R^1 = CH(CH_3)_2$
deoxyviroidin, $X = SO$, $R = CH_3$, $R^1 = CH(CH_3)_2$
[Ala[1]]viroidin, $X = SO_2$, $R = CH_3$, $R^1 = CH_3$
[Ala[1]]deoxyviroidin, $X = SO$, $R = CH_3$, $R^1 = CH_3$
viroisin, $X = SO_2$, $R^1 = CH_2OH$, $R = CH(CH_3)_2$
deoxyviroisin, $X = SO$, $R = CH_2OH$, $R^1 = CH(CH_3)_2$

Less toxic cyclic peptides are also found in other fungi. Examples are toxins known as cortinarins (**10-205** and **10-206**) of fool's web cap (*Cortinarius orellanus*, Cortinariaceae) and other web caps that cause orellanine poisoning.



10-205, cortinarin A, $R = CH_3$
cortinarin B, $R = H$



10-206, cortinarin C

Reactions and changes

Amatoxins, phallotoxins and virotoxins are stable under all normal conditions of storage and processing, and technological processes, including heat treatment, do not reduce their high toxicity.

Biological effects

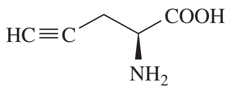
The toxicity of amatoxins is caused by the inhibition of RNA polymerase II in eukaryotic cells, toxicity of phallotoxins by selective binding of toxins to the membrane of actin (F-actin) and stabilisation of this complex. Amatoxins, of which α-amanitin is present in the highest concentration in the death cap and is responsible for its toxicity, are about 10–20 times more toxic than related phallotoxins, which exhibit toxicity only after intravenous administration. Toxicity of amatoxins and phallotoxins manifests by effects similar to cholera: gagging, vomiting and diarrhea about 20 h after eating the toadstools. These toxins are among the most toxic natural substances as they are inhibitors of important enzymes responsible for the metabolism of the major nutrients and damage the liver and kidneys. In most cases, poisoning ends with death.

Cyclic peptides cortinarins A, B and C are nephrotoxic, the poisoning manifests by acute or chronic damage to the kidneys 3–14 days after ingestion of mushrooms.

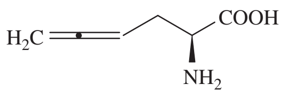
10.3.3.11.3 Amino acids

Structure, nomenclature and occurrence

As well as toxic proteins and peptides, mushrooms contain a number of free amino acids, which cause poisoning manifested by symptoms similar to those caused by the death cap toadstool. For example, (*S*)-2-amino-pent-4-ynoic acid, also known as L-2-aminopent-4-ynoic acid or L-propargylglycine (**10-207**), (*S*)-2-aminohexa-4,5-dienoic acid, also called L-2-aminohexa-4,5-dienoic acid (**10-208**), (*S*)-allylglycine or L-allylgycine (**10-209**) and related amino acids occur in some other toadstool species, such as the abrupt-bulbed lepidella (*Amanita abrupta*) and European solitary lepidella (*A. echinocephala*, syn. *A. solitaria*), where they are found together with (2*S*,4*Z*)-2-amino-5-chloro-6-hydroxyhex-4-enoic acid. In addition to 2-amino-5-chloro-6-hydroxyhex-4-enoic acid, four other chlorinated allylic amino acids have been isolated from various Amanita species. A number of other C_6 and C_7 unbranched and branched amino acids have been isolated in recent years, reflecting great variability in the metabolism of branched-chain amino acids (valine, leucine and isoleucine) in different mushroom species.



10-207, L-propargylglycine

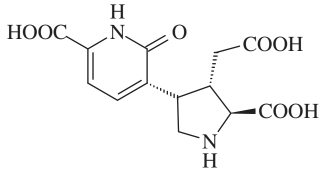


10-208, L-2-aminohexa-4,5-dienoic acid

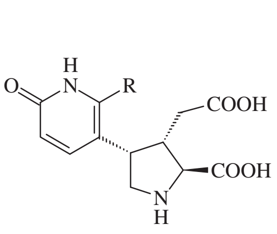
10-209, L-allylglycine

A number of other amino acids structurally related to L-glutamic acid exhibit neurotoxic (psychotropic) and other toxic effects. Glutamic acid acts as an excitatory neurotransmitter in the central nervous system of mammals. Glutamate receptors are involved in higher neural functions (such as memory and learning) and disorders (such as epilepsy). For example, the main toxic agent of the fly agaric (*A. muscaria*), which derives its name from the ability of its juice to stun and sometimes kill house flies (*Musca domestica*), and also of panther cap (*A. pantherina*) and European pine cone lepidella (*A. strobiliformis*), is (*S*)-2-amino-(3-hydroxy-5-isoxazolyl)acetic acid, known as ibotenic acid, formerly also as pantherin, agarin, α-toxin or premuscimol (**2-52**); enol and keto tautomers of ibotenic acid occur in the ratio of 96 : 4. Also present is a product of ibotenic acid decarboxylation 5-aminomethyl-3-hydroxyisoxazol, which is known as muscimol (or pyroibotenic acid or β-toxin). The ibotenic acid content in hats of toadstools is approximately 0.02%. Muscazone (2-amino-2,3-dihydro-2-oxo-5-isooxazoleacetic acid), showing antibacterial and antifungal activities, is probably formed by rearrangement of ibotenic acid. *A. strobiliformis* and Japanese mushroom *Tricholoma muscarium* (Tricholomataceae) contain another important neurotoxic amino acid (**2-53**), a dihydro analogue of ibotenic acid, 2-amino-2-(3-oxoisoxazolidin-5-yl)acetic acid, known as tricholomic acid (Figure 10.20).

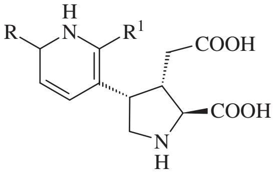
Other neurotoxins are acromelic acids (**10-210** to **10-212**). Acromelic acids A and B occur in *Clitocybe acromelalga* (Tricholomataceae) found in Japan, together with minority congeners acromelic acids C, D and E and many other related biologically active compounds.



10-210, acromelic acid A

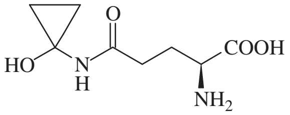


10-211, acromelic acid B, R = COOH
acromelic acid C, R = H



10-212, acromelic acid D, R= COOH, R[1] = H
acromelic acid E, R = H, R[1] = COOH

Present in the common ink cap (*Coprinopsis atramentarius*, syn. *Coprinus atramentarius*, Psathyrellaceae) and some other mushrooms, such as the fat-footed *Clitocybe* (*Clitocybe claviceps*, Tricholomataceae), sharp-scaly pholiota (*Pholiota squarrosa*, Strophariaceae) and lurid bolete (*Boletus luridus*, Boletaceae) is the toxic glutamine derivative, N^5-(1-hydroxycyclopropyl)-L-glutamine, which is known as coprine (**10-213**).



10-213, coprine

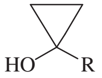
Reactions and changes

Most toxic amino acids of fungi are stable substances that do not undergo reactions leading to reduction of their toxicity. Decomposition of the original amino acid, in some cases, yields degradation products that are also toxic, such as the decarboxylation product of ibotenic acid referred to as muscimol (Figure 10.21).

Coprine is a protoxin without intrinsic toxicity, but which hydrolyses to the active toxic principle 1-aminocyclopropanol and cyclopropanone hydrate (cyclopropane-1,1-diol, **10-214**).

Biological effects

Poisoning by propargylglycine and 2-aminohexa-4,5-dienoic acid have similar symptoms as phalloidin poisoning. Although not as



10-214, 1-aminocyclopropanol, R = NH_2
cyclopropane-1,1-diol, R = OH

toxic as the death cap and the destroying angel, ingestion of the abrupt-bulbed lepidella may cause changes in liver function similar to these species. The poisoning begins with violent vomiting, diarrhea and dehydration after a delay of 10–20 h. The toxic effects of allylglycine are not yet precisely known.

Ibotenic acid is a likely carcinogen. In humans, poisoning is manifested by hallucinations. Ibotenic and tricholomic acids exhibit taste properties similar to those of monosodium glutamate (umami taste, see Section 8.3), but much more intense. Muscimol has similar effects as γ-aminobutyric acid (GABA or 4-aminobutanoic acid), which acts as an inhibitory neurotransmitter of the central nervous system.

Acromelic acids A and B also behave as neurotoxins, which act as agonists (activators) of the neurotransmitter L-glutamic acid. Their activity is manifested by special symptoms as they evoke powerful burning and reddish swellings on the legs, which last a month or longer. Deaths caused by poisoning are rare.

Many mushrooms fall into the category of those that cause only gastrointestinal-specific irritation, distress, abdominal cramping, diarrhea, nausea and vomiting. Most of these symptoms are poorly understood. To this category of mushrooms also belongs the common ink cap containing coprine, a substance that is toxic only when ingested in combination with alcohol. The degradation products of coprine, 1-aminocyclopropanol (**10-214**) and cyclopropane-1,1-diol, inhibit the enzyme aldehyde dehydrogenase, which catalyses conversion of acetaldehyde into acetic acid, which results in accumulation of acetaldehyde in the blood. Inhibition of aldehyde dehydrogenase produces a clinical syndrome similar to disulfiram (Antabuse, **10-215**) alcohol reaction, manifested by flushing,

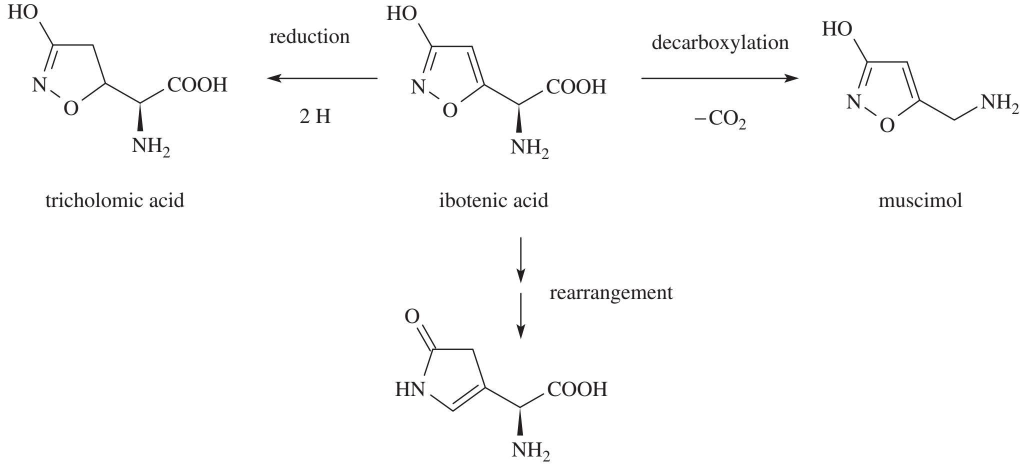


Figure 10.21 Reactions of ibotenic acid.

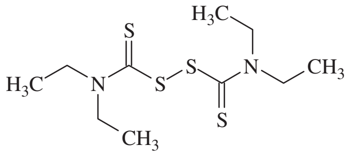


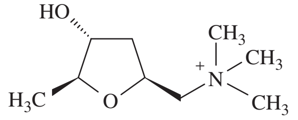
10-215, disulfiram

throbbing in the temples and usually headache starting 5–30 min after ingestion of alcohol.

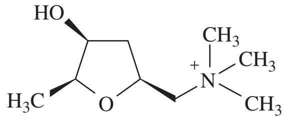
10.3.3.11.4 Amines, alkaloids and other nitrogen compounds

Structure, nomenclature and occurrence

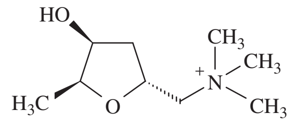
In addition to the main neurotoxin ibotenic acid, the fly agaric (*A. muscaria*) contains the toxic amine muscarine (**10-216**) in small quantities. Much higher amounts of this amine (about 500 times) occur in mycorrhizal fungi of the genus *Inocybe* that cause the **muscarinic poisoning**. The muscarine molecule has three asymmetric centres, thus can exist in eight stereoisomers, but only three muscarine isomers, epimuscarine (**10-217**), allomuscarine (**10-218**) and epiallomuscarine (**10-219**), have been found in nature.



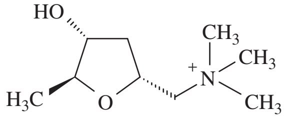
10-216, muscarine



10-217, epimuscarine

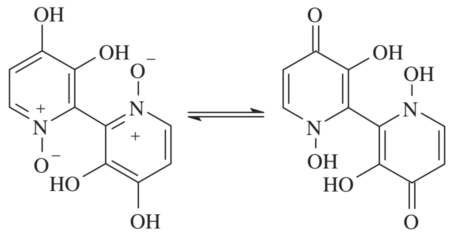


10-218, allomuscarine



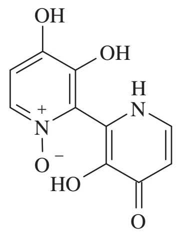
10-219, epiallomuscarine

The fungi fool's web cap (*Cortinarius orellanus*, Cortinariaceae) and deadly web cap (*C. rubellus*), and other species, that cause the so-called **orellanine poisoning**, contain a toxic pyridine alkaloid orellanine (**10-220**), its degradation products orellinine (**10-221**) and yellow orelline (**10-222**), which are produced by heating or by exposure to UV radiation. Orellanine is a highly polar compound due to tautomerism between the neutral and internal ionic form.

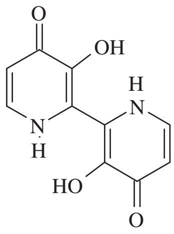


10-220, orellanine

In addition to these toxic alkaloids, these fungi contain toxic cyclic peptides cortinarins (see Section 10.3.3.11.2).

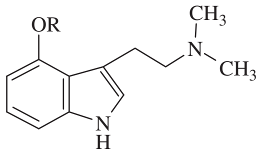


10-221, orellinine

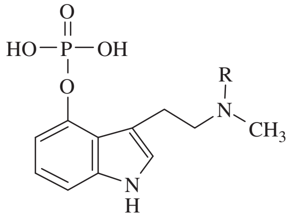


10-222, orelline

The psychedelic mushrooms of the genus *Psilocybe*, such as *P. mexicana* (Strophariaceae) and various other fungi belonging to genera *Paneolus*, *Pluteus*, *Conocybe* and some others, contain as the active component psilocin and its phosphoric acid ester psilocybin (**10-223**), which are carriers of hallucinogenic effects. Mushrooms *P. mexicana*, called *teonáncatl*, were used by Mayans for religious ceremonies over 2000 years ago. Other related hallucinogenic substances, such as baeocystin and norbaeocystin (**10-224**), occur in *P. baeocystis* of the same genus. Another hallucinogenic amine of similar structure is 3-(2-dimethylaminoethyl)-1*H*-indol-5-ol called 5-hydroxytryptamine or bufotenine (**10-198**), which is found in the false death cap, also known as citron amanita (*Amanita citrina*). The same amine also occurs in skin secretions of some toads (such as the cane toad *Bufo marinus*, Bufonidae), but also in some other animals (amphibians) and higher plants. For example, bufotenine is present at a concentration of 25 mg/l in the red latex (called *takini*) of the tree *Brosimum acutifolium* (Moraceae), which is native to the Amazon rainforest and is used in shamanic practices.



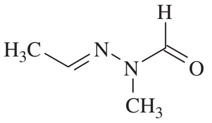
10-223, psilocin, R = H
psilocybin, R = PO_3H_2



10-224, baeocystin, R = CH_3
norbaeocystin, R = H

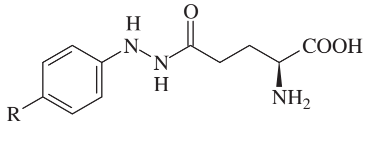
The toxic hydrazine derivative *N*-formyl-*N*-methylhydrazone of acetaldehyde, known as *N*′-ethylidene-*N*-methylformohydrazide or gyromitrin (**10-225**), occurs in the fruiting body of false

morrels (*Gyromitra esculenta*, Discinaceae) and in some other species of the phylum Ascomycota. Gyromitrin is accompanied by other *N*-formyl-*N*-methylhydrazones derived from butanal, 3-methylbutanal, pentanal, hexanal, octanal and (*E*)- and (Z)-oct-2-enal. Gyromitrin is the main toxic substance of false morels. Its concentration can generally reach up to 3600 mg/kg and the amount of gyromitrin and other hydrazones is in a ratio of about 88 : 12. The hydrazones of false morels are accompanied by *N*-formyl-*N*-methylhydrazine and *N*-methylhydrazine, the concentrations of which are 500 and 40–350 mg/kg, respectively. Parts of the gyromitrin and *N*-formyl-*N*-methylhydrazine are probably bound as glycosides linked to high molecular weight substances.



10-225, gyromitrin

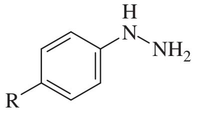
Another hydrazine of mushrooms is agaritine (**10-226**), β-*N*-[γ-L-glutamyl]-4-(hydroxymethyl)phenylhydrazine found only in fungi of the genera *Agaricus* and *Macrolepiota* (Agaricaceae), to which belong the dominant cultivated mushrooms, the common mushroom (*A. bisporus*) and the field mushroom (*A. campestris*). The best-known member of the genus *Macrolepiota* is the parasol mushroom (*M. procera*). The concentration of agaritine in fresh common mushrooms varies over a wide range (100–1700 mg/kg). For example, the average content of agaritine in the common mushroom cultivated in the Czech Republic was 272 mg/kg (165–457 mg/kg) and somewhat higher levels were found in young fruiting bodies. The agaritine content is also dependent on the growth cycle of mushrooms. Harvesting periods are repeated at 3–5 day cycles with breaks when the mushroom harvest is very small. The agaritine content is higher in fruiting bodies harvested in the latter days of the harvest cycle and lower in mushrooms grown on natural substrates than on synthetic or mixed ones. The horse mushroom (*A. arvensis*) growing in nature has a hgher agaritine content, sometimes up to 2000 mg/kg and more. Only consumption of raw mushrooms is potentially harmful, because agaritine partly decomposes under technological and culinary treatments.



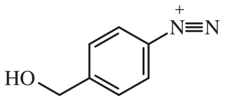
10-226, agaritine, R = CH_2OH

β-*N*-γ -L-[glutamyl]-4-(formyl)phenylhydrazine, R = CH=O
β-*N*-γ -L-[glutamyl]-4-(carboxy)phenylhydrazine, R = COOH

Agaritine may be enzymatically oxidised at the C-4 hydroxymethyl group to the corresponding formyl and carboxyl derivatives, β-*N*-[γ-L-glutamyl]-4-(formyl)phenylhydrazine and β-*N*-[γ-L-glutamyl]-4-(carboxy)phenylhydrazine (**10-226**), repectively. The presence of β-*N*-[γ-L-glutamyl]-4-(carboxy)phenylhydrazine, at a level of 40 mg/kg, has been demonstrated only in the field mushroom (*A. campestris*). Agaritine and β-*N*-[γ-L-glutamyl]-4-(carboxy)phenylhydrazine are hydrolysed to 4-(hydroxymethyl)phenylhydrazine and 4-(carboxy)phenylhydrazine (**10-227**), respectively. 4-(Carboxy)phenylhydrazine concentrations in mushrooms are about 10 mg/kg. 4-(Hydroxymethyl)phenylhydrazine is subsequently oxidised to the corresponding 4-(hydroxymethyl)benzenediazonium ion (**10-228**), the amount of which, in the basal-stalk sections of the commonly cultivated mushroom *Agaricus bisporus*, is about 1 mg/kg. In addition to these compounds, the common mushrooms contain some other precursors, metabolites and degradation products of agaritine, such as 4-carboxymethylbenzoic acid and agaritine analogues derived from 4-aminophenol, γ-glutamyl-4-hydroxybenzene, the characteristic yellow pigment agaricone (see **9-131**) of the yellow-staining mushroom *A. xanthodermus*, and other products.



10-227, 4-(hydroxymethyl)phenylhydrazine, R = CH_2OH
4-(carboxy)phenylhydrazine, R = COOH



10-228, 4-(hydroxymethyl)benzenediazonium ion

Reactions and changes

Most substances belonging to this group of toxins are stable during technological and culinary operations. Dried false morrel contains usually 1000–3000 mg/kg of gyromitrin, including its derivatives and degradation products, but drying does not have a significant influence on the gyromitrin content. For example, a prolonged drying in the air decreases the *N*-methylhydrazine content by about 30–70%. A significant decrease of hydrazine content (to 10–15% of the original value), however, occurs by leaching and volatilisation of products during cooking, and cooked mushrooms are therefore edible. The content of toxins in canned mushrooms is also much lower (6-65 mg/kg). On cooking, gyromitrin decomposes to form acetaldehyde and *N*-formyl-*N*-methylhydrazine, which is more stable than gyromitrin, but in acidic media it decomposes to *N*-methylhydrazine. Similar reactions proceed *in vivo* and 25–30% of gyromitrin may be transformed into *N*-methylhydrazine. By the action of hepatic mixed function monooxidases, however, highly toxic diazomethane and *N*-nitroso-*N*-methylformamide are produced (Figure 10.22).

The enzymatic hydrolysis of agaritine in common mushrooms by γ-glutamyl transferase gives 4-(hydroxymethyl)phenylhydrazine (**10-227**) and L-glutamic acid. The enzymatic hydrolysis occurs during storage of fresh, chilled or frozen mushrooms. During storage at temperatures of 2–12 °C, the agaritine concentration

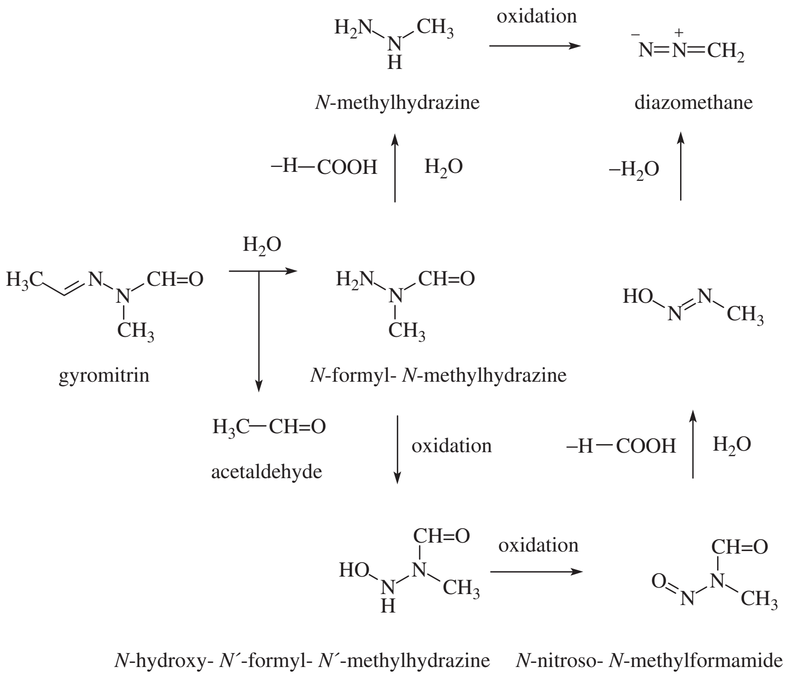


Figure 10.22 Metabolism and non-enzymatic decomposition of gyromitrin.

decreases by about 32%. Frozen mushrooms stored for 1 month and then defrosted contained about 25% of the agaritine present in fresh mushrooms. Drying does not have substantial influence on agaritine decomposition; therefore the content of agaritine in dried mushrooms is relatively high (up to 4600 mg/kg). A decrease of agaritine content of up to about 75% occurs during cooking (about 50% of the loss is due to leaching into water). Approximately 20–50% of agaritine remained after 120 min of heating mushroom extracts at 120 °C. Canned mushrooms contain 15–18 mg/kg of agaritine, which corresponds to about 5–8% of the original amount. Agaritine was successfully removed from mushroom water extracts by ethanol fractionation.

Biological effects

Muscarine is an agonist of cholinergic neurons, where acetylcholine acts as a neurotransmitter. Muscarine poisoning, which is not usually regarded as deadly, is manifested about 15–30 min after ingestion of mushrooms by typical symptoms such as sweating and salivation, accompanied by gagging, heavy breathing, decrease in heart rate and blood pressure.

Orellanine and orellinine are nephrotoxins, but the related orelline is a non-toxic compound. Manifestations of poisoning consist of renal impairment after a latency of 2–17 days. The most important symptoms are fatigue, loss of appetite, nausea or even vomiting, headache, severe thirst, urge to urinate, diarrhea, fever, chills without fever and pain in the limbs and the muscles generally. Progressive kidney damage later leads, conversely, to limited production of urine and constipation. Poisoning often results in death or permanent kidney damage, requiring regular dialysis or kidney transplantation.

Most of the approximately 200 species of mushrooms containing psilocybin fall in the genus *Psilocybe*. Psilocybin and psilocin act as hallucinogens, their activity is similar to the activity of the known hallucinogen lysergic acid diethylamide (LSD) as they also affect receptors of serotonine (5-hydroxytryptamine) in the central nervous system. For this reason, many countries have some level of regulation or prohibition of the so-called magic mushrooms.

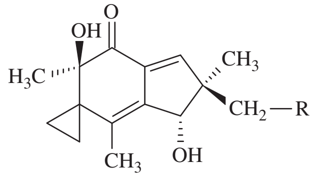
The consumption of false morel is widespread in Europe, but poisoning from consumption of this fungus appears only sporadically, because it can only be caused when raw mushrooms are eaten. Symptoms of gyromitrin poisoning are similar to the symptoms of toadstool poisoning (vomiting, diarrhea, cramps and other symptoms) and ends in 20–30% of cases in coma. Frequent consumption of false morel can generally cause jaundice and neurological disorders. The gyromitrin degradation products (*N*-formyl-*N*-methylhydrazine and *N*-methylhydrazine) are hepatotoxic and carcinogenic substances.

The metabolic fate of agaritine has been linked with the carcinogenity of the mushroom. Hydrazines arising from agaritine, such as 4-(carboxy)phenylhydrazine, β-*N*-[γ-L-glutamyl]-4-(carboxy)phenylhydrazine, 4-(hydroxymethyl)phenylhydrazine and β-*N*-[γ-L-glutamyl]-4-(formyl)phenylhydrazine, and 4-(hydroxymethyl)benzenediazonium salts, could pose some risk as carcinogens. The risk arising from the consumption of mushrooms, with regard to the amount consumed and content of agaritine and its derivatives, requires more detailed evaluation.

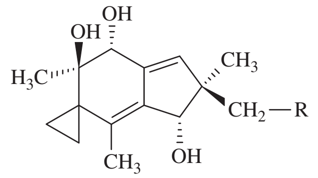
10.3.3.11.5 Terpenoids and other compounds

Structure, nomenclature and occurrence

In addition to toxic nitrogen compounds, fungi also contain many toxic terpenoids. The Jack o'-lantern mushroom (*Omphalotus olearius*, syn. *Clitocybe illudens*, Marasmiaceae) and some other fungi, contains toxic sesquiterpenoids illudins M and S (**10-229**), which are accompanied by non-toxic dihydroilludins M and S (**10-230**). The similarly poisonous Japanese mushroom known as *Tsukiyotake* (*Omphalotus japonicus* syn. *Pleurotus japonicus*) contains 6-deoxyilludins M and S (**10-231**). A compound of similar structure is leaianafulvene (**10-232**), which is found in *Mycena laevigata* (Mycenaceae).

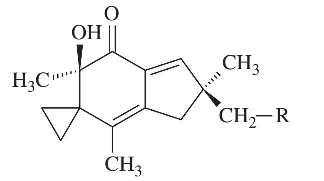


10-229, illudin M, R = H
illudin S (lampterol), R = OH

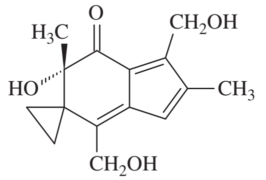


10-230, dihydroilludin M, R = H
dihydroilludin S, R = OH

Lanostane triterpenoid alcohols fasciculols A to F (**10-233**) are examples of biologically active components of the mushroom called sulfur tuft (*Naematoloma fasciculare*, Strophariaceae) and related species. Fasciculols B, C and F and three fasciculol esters, fasciculic acids A, B and C (**10-233**), have calmodulin inhibitory activity and fasciculols E and F are the toxic principles of this mushroom.

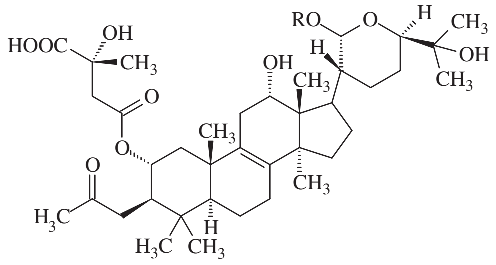


10-231, 6-deoxyilludin M, R = H
6-deoxyilludin S, R = OH



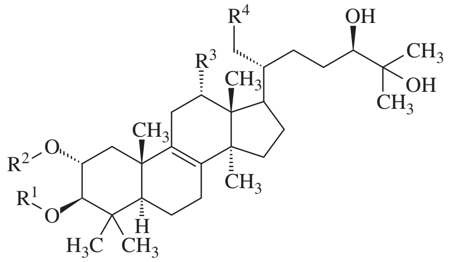
10-232, leaianafulvene

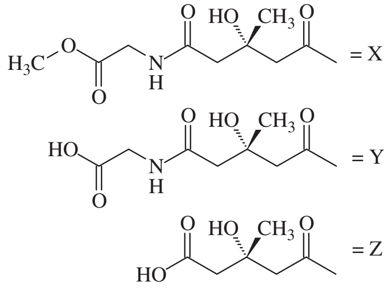
Calmodulin is a calcium-binding messenger protein of eukaryotic cells that mediates many crucial processes, such as inflammation, metabolism, smooth muscle contraction, intracellular movement, short-term and long-term memory and immune response. Toxic substances related to fasciculols and referred to as HS-A, HS-B (**10-234**) and HS-C (**10-235**) are toxins of *Hebeloma spoliatum*, a species of mushroom of the Hymenogastraceae family.



10-234, HS-A, R = H
HS-B, R = OCOCH$_3$

Hebevinosides are toxic triterpenoid diglycosides and monoglycosides. The aglycone structure is similar to the structure of related bitter cucurbitacins that occur in cucurbit plants (Cucurbitaceae, see Section 8.3.4.1.2). Hebevinosides are found in the mushroom *Hebeloma vinosophylum* (Cortinariaceae) growing on high nitrogen media. Approximately 14 different compounds have been identified with different substitutions: $R^1 = H$ or CH_3 and R_2 to $R_3 = H$ or $C(=O)CH_3$. Only glycosides containing D-glucose linked at C-16 are toxic. Examples of hebevinosides are toxic C-3/C-16 diglycosides (**10-236**) and C-16 glycosides (**10-237**).

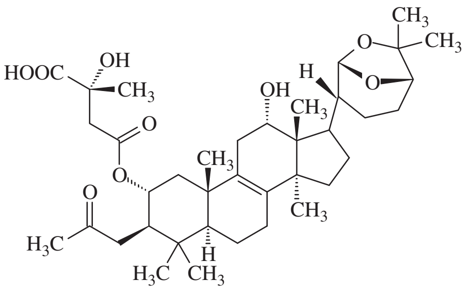




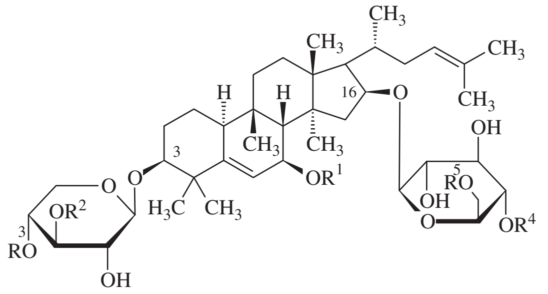
10-233, fasciculols and fasciculic acids

fasciculol A, $R^1 = H$, $R^2 = H$, $R^3 = H$, $R^4 = H$
fasciculol B, $R^1 = H$, $R^2 = H$, $R^3 = OH$, $R^4 = H$
fasciculol C, $R^1 = H$, $R^2 = H$, $R^3 = OH$, $R^4 = OH$
fasciculol D, $R^1 = H$, $R^2 = X$, $R^3 = OH$, $R^4 = H$
fasciculol E, $R^1 = X$, $R^2 = H$, $R^3 = OH$, $R^4 = OH$
fasciculol F, $R^1 = H$, $R^2 = X$, $R^3 = OH$, $R^4 = OH$

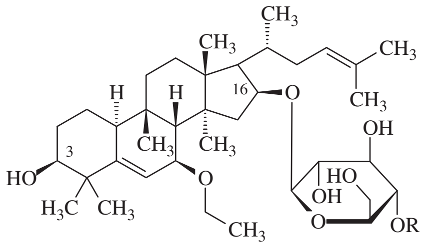
fasciculic acid A, $R^1 = H$, $R^2 = Z$, $R^3 = H$, $R^4 = H$
fasciculic acid B, $R^1 = H$, $R^2 = Z$, $R^3 = OH$, $R^4 = H$
fasciculic acid C, $R^1 = Y$, $R^2 = H$, $R^3 = OH$, $R^4 = OH$



10-235, HS-C

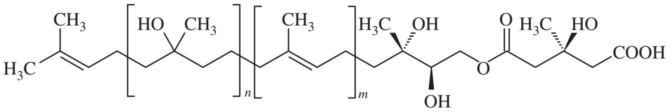


10-236, basic structure of hebevinosides (diglycosides)

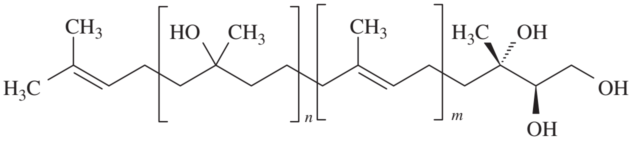


10-237, basic structure of hebevinosides (monoglycosides)

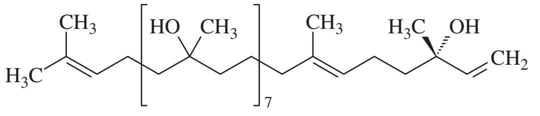
The linear terpenoid compound gymnopilin (**10-238**) is found in the hallucinogenic mushroom *Gymnopilus junonius* (syn. *G. spectabilis*, Cortinariaceae), called big laughing gym, as a mixture of congeners with different numbers of isoprene units ($m = 1$–3, $n = 5$–7). Compounds with more than one double bond ($m > 1$) are toxic. Toxicity depends also on the number of segments (n) with hydroxyl groups. Gymnopilin is furthermore responsible for the bitter taste of mushrooms. Its precursors are gymnoprenol (**10-239**) and gymnopilene (**10-240**).



10-238, gymnopilin

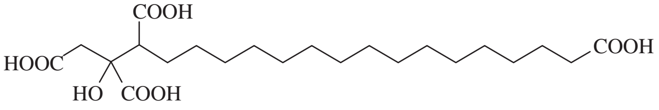


10-239, gymnoprenol



10-240, gymnopilene

The mushroom known as agaricone, quinine conk or white agaric mushroom (*Laricifomes officinalis*, Fomitopsidaceae) contains high amounts (14–16% of dry matter) of the bitter tasting citric acid derivative with a lipophilic substituent on C-2 (derived from palmitic acid), which is known as α-hexadecylcitric acid, α-cetylcitric, agaricinic, agaric or laricic acid, **10-241**). In the past, the mushroom was used for medical purposes and dry sponge impregnated with potassium nitrate was used as tinder.



10-241, agaricinic acid

Reactions and changes

Toxic terpenoids are stable, and fungal foods do not lose their toxicity even during cooking. Insignificant losses of these lipophilic toxins also occur by leaching.

Biological effects

Poisonings caused by illudin M and S, not regarded as deadly, are manifested by typical digestive problems, vomiting and diarrhea. Illudin S and 6-deoxyilludins M and S show some anticarcinogenic activity. Fasciculols E and F cause vomiting, diarrhea and in some cases, convulsions and paralysis. Poisoning may lead to death. Toxins HS-A, HS-B and HS-C can cause paralysis of limbs at higher concentrations (around 100 mg/kg) and diarrhea at lower concentrations (about 45 mg/kg). These substances not only affect the central nervous system, but also the autonomic nervous system. Hebevinosides act as paralytic toxins. Gymnopilin is a neurotoxic hallucinogenic substance. Owing to adverse biological effects (it acts as an antiperspirant, a substance preventing cutaneous respiration), the EU legislation allows agaric acid, as a bitter tasting flavouring, only for alcoholic beverages.

10.3.3.12 Marine toxins

The meat of some marine fish, shellfish and many other animals can be toxic. In most cases, the toxic substance is present throughout the organism, as it is usually caused by the consumption of phytoplankton, microscopic algae (Dinoflagellates), blue–green algae (Cyanobacteria) and diatoms (Diatomeae), which contain various hepatotoxins, neurotoxins, dermatotoxins or intestinal toxins. The primary sources of toxins are bacteria that live with these algae in symbiosis or as epiphytes. A number of toxins are also produced by

some fish and other marine animals. The most important seafood toxins include:

- saxitoxin and its derivatives
- okadaic acid and its analogues (dinophysistoxins)
- azaspiracids
- domoic acid and its analogues
- brevetoxins
- tetrodotoxin and its analogues
- ciguatoxins
- palytoxin.

10.3.3.12.1 Bivalve mollusc toxins

The class Bivalvia (bivalves) of the phyllum Mollusca (molluscs) includes molluscs known as Pacific oysters (*Crassostrea gigas*, Ostreidae), three closely related taxa of blue mussels (*Mytilus edulis*, Mytilidae), hard (round) clams (*Mercenaria mercenaria*, Veneridae) and common whelks (*Buccinum undatum*, Buccinidae), plus many others. The number of cases of serious poisoning by oysters, mussels, clams and other bivalves has been increasing in recent years. Shellfish (a culinary term for exoskeleton-bearing aquatic invertebrates used as food, including molluscs and crustaceans) take in toxic algae from the water as food, and these contain toxins. With the growing proliferation of toxic algae in the oceans, due to eutrophication and climate change, the degree and extent of contamination of shellfish has been increasing. Global aquaculture development, along with the growing popularity of seafood and other factors, is contributing to the increase in health problems after consuming these marine animals. Improved diagnosis of poisoning and closer international monitoring will certainly play a role.

Toxins of shellfish are characterised by strong, sometimes fatal, acute human toxicity. They are thermostable and show no sensory warning signals. Occurrence of toxins in various areas is sporadic, and probably dependent on meteorological and climatic conditions (such as wind direction and speed, water temperature, depth and currents and microlocation) that control the spread of toxic algae. This leads to the utter unpredictability of the degree of contamination and expansion of shellfish, with a consequent high demand for continuous monitoring and control of production sites.

The most important groups of biologically active compounds in shellfish are distinguished by the type of toxic effects (Table 10.26). Some marine toxins are found in the South Seas, while others predominate in colder waters. In Europe, the two most common syndromes of shellfish poisoning are paralytic shellfish poisoning (PSP) and diarrheic shellfish poisoning (DSP). Other types of shellfish poisoning are azaspiracid poisoning (AZP), amnaesic shellfish poisoning (ASP) and neurotoxic shellfish poisoning (NSP).

Paralytic neurotoxins

Structure, nomenclature and occurrence The cause of paralytic shellfish poisoning is the consumption of shellfish contaminated by hydrophilic heterocyclic guanidines, a group of more than 20 related carbamate alkaloid neurotoxins, which are either non-sulfated (saxitoxins; STX), singly sulfated (gonyautoxins; GTX) or doubly sulfated (*N*-sulfocarbamoyl-11-hydroxysulfate toxins; C-toxins). Saxitoxin (**10-242**), is accompanied by structurally related toxins neosaxitoxin and gonyautoxins I to IV, the corresponding *N*-sulfocarbamoyl derivatives ($R^4 = O{-}CO{-}NH{-}SO_3^-$) and decarbamoyl derivatives ($R^4 = OH$). These toxins accumulate in shellfish through ingestion of the dinoflagellates during blooms. The most important sources are dinoflagellates of genera *Gymnodium* (in Europe, Japan and North America), *Alexandrium* (such as *A. tamarense* and *A. catenella* in South America) and *Pyrodinium* (in the Indo-Pacific region). Saxitoxins and related analogues are known to inhibit nerve-muscle transmission by blocking the sodium channels in the excitable membrane and cause a lethal toxicity through breathing muscle paralysis.

Table 10.26 Overview of toxins in molluscs.

Syndrome	Toxin	Symptoms	Occurrece	Limit (EU)
PSP	Saxitoxins	Neurological (mortality)	Europe, Japan, America, Pacific ocean	800 μg/kg
DSP	Okadaic acid and dinophysis-toxins	Gastrointestinal	Europe (northwest), South America	160 μg/kg
AZP	Azaspiracids and analogues	Gastrointestinal	Ireland (Europe)	160 μg/kg
ASP	Domoic acid	Gastrointestinal/short-term memory loss (mortality)	Global (Canada)	20 mg/kg
NSP	Brevetoxins	Neurological (Gastrointestinal)	Florida, Caribean region, New Zealand

C4, $R^1 = OH$, $R^2 = OSO_3^-$, $R^3 = H$, $R^4 = OCONHSO_3^-$

Saxitoxin may be found in oysters, common whelks and other species of marine molluscs, but can occur also in some microscopic freshwater blue–green algae (*Aphanizomenon flos-aquae*) and red macroscopic algae of the genus *Jania*, which become the source of saxitoxin in crab meat.

Reactions and changes The toxins are extremely thermostable and cannot be removed by cooking or meat pickling.

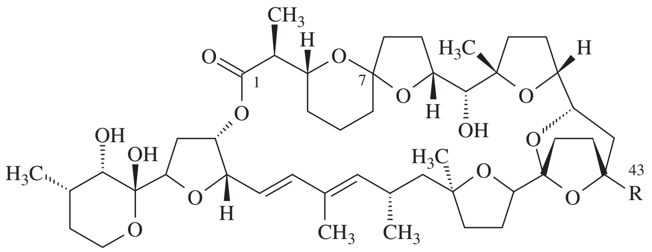
Biological effects Saxitoxin and its derivatives are neurotoxins. The mechanism of action is based on the blockade of conductance in sodium tubules of nerve membrane with subsequent blockade of transmission of nerve impulses. Clinical symptoms may appear within 1 hour and are characterised by numbness in the extremities, which spreads to the neck and face, along with symptoms of severe nausea. In severe cases paralysis of respiratory muscles may occur, at high doses within 2 h after exposure. PSP toxins are quickly eliminated from the body and survival for 24 h means a good chance of recovery. Treatment must be implemented as soon as possible and is only symptomatic. On a global scale, each year about 2000 cases of poisoning occur with approximately 15% mortality. Total toxicity of saxitonins is calculated using toxicity equivalents (TEQ, see Section 12.4.1.5.1) based on the relative toxicities of individual congeners (toxicity equivalency factors, TEF) in the edible portion of molluscs. The effective dose in humans is estimated at 2–30 μg of TEQ per kg body weight, severe poisonings were observed at a dose of 10–300 mg TEQ per kg body weight. Poisoning periodically appears in various localities.

Detection and control The hygienic limit in the EU is currently 80 μg of paralytic toxins in 100 g of edible shellfish portion. Both the EU and other countries have drawn up detailed legislative regulations for the control of saxitoxin complexes.

Diarrhoetic toxins

Structure, nomenclature and occurrence Diarrhoetic shellfish poisoning is associated with the consumption of marine shellfish (scallops, oysters and other shellfish) accumulating toxins from dinoflagellates, such as *Dinophysis* and *Prorocentrum* spp. Poisonings of this type are widespread throughout the world, mainly in Japan, Scandinavia, North-West Europe and South America. The cause of the DSP is the okadaic acid group of lipophilic toxins, which include okadaic acid (**10-243**) and its analogues (dinophysistoxins), such as dinophysistoxin-1, known as (*R*)-35-methylokadaic acid, dinophysistoxin-2 (distinct from okadaic acid by the position of the methyl group), which are the main toxic components, and a number of substituted congeners occurring as diol esters and sulfated diol esters in algae and as fatty acid esters in shellfish, such as dinophysistoxin-3, also known as 31-demethyl-35-methylokadaic acid.

A poisoning with similar symptoms as those caused by okadaic acid can be a result of other related toxins, such as pectenotoxins (PTX, **10-244**) from marine dinoflagellates of the genus *Dinophysis*



10-244, pectenotoxin-1, R = CH_2OH
pectenotoxin-2, R = CH_3

adriatoxin

10-245, yessotoxin and related toxins

and disulfates of cyclic polyethers yessotoxins (YTX, **10-245**), which are produced by planktonic algae *Protoceratium reticulatum* and possibly also by dinoflagellates *Lingulodinium polyedrum*. These toxins have a different mechanism of action and are not included in the hygienic limits for dinophysistoxins.

The most commonly found pectenotoxin in algae is pectenotoxin-2. Pectenotoxin-2 is enzymatically hydrolysed into a pectenotoxin-2 seco acid form by many shellfish species, a reaction that constitutes a detoxification mechanism. Spontaneous epimerisation at C-7 of pectenotoxin-2 seco acid produces

7-epi-pectenotoxin-2 seco acid. Both compounds occur in blue mussels (*Mytilus edulis*) from Ireland as fatty acid esters. Other enzyme-mediated conversions of pectenotoxin-2 include oxidation at C-43 in the scallop *P. yessoensis* to yield pectenotoxin-1, pectenotoxin-3 and pectenotoxin-6 (**10-244**).

The structures of the yessotoxins differ from those of toxins in the diarrhetic shellfish poisoning toxins group and the pectenotoxins but are similar to the brevetoxins and ciguatoxins in having a ladder-shaped polycyclic ether skeleton. Yessotoxin (**10-245**) was evidenced in a marine bivalve mollusc called yesso scallop (*Patinopecten yessoensis*, Pectinidae), but has since been found in a wide range of shellfish from around the world. More recently, 45-hydroxyyessotoxin and 45,46,47-trinoryessotoxin were also isolated from scallops. 45-Hydroxyyessotoxin was isolated from mussels, as were homoyessotoxin, 45-hydroxyhomoyessotoxin, 1-desulfoyessotoxin, adriatoxin, carboxyyessotoxin, carboxyhomoyessotoxin and numerous minor related compounds.

Reactions and changes Toxins are thermostable, as well as other toxins in shellfish and structurally similar ciguatera toxins of fish, and cannot be removed by heat treatments.

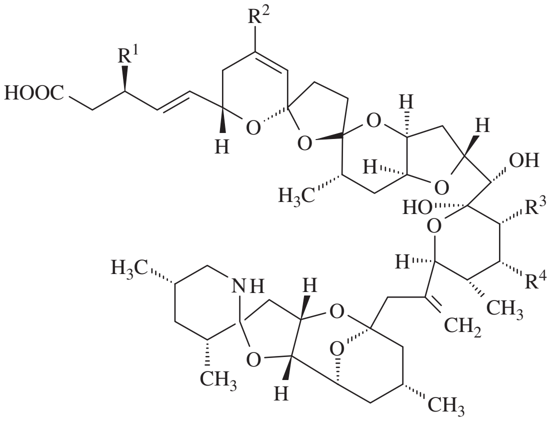
Biological effects Okadaic acid is an inhibitor of phosphatases, which leads to phosphorylation of proteins controlling excretion of fluids from the intestine. The main symptoms of poisoning are indigestion exhibited by stomach pain, nausea, vomiting and diarrhea. These symptoms occur quickly (30 min after ingestion of shellfish) and disappear spontaneously after 3–4 days without the need for hospitalisation. Data on long-term toxicity of dinophysistoxins in humans are lacking. In laboratory rodents, high doses of these toxins act as carcinogenicity promoters, but their genotoxicity was not confirmed.

The existing hygienic limits for diarrhoetic toxins in the EU are based on acute toxicity in the form of ARfD (Acute Reference Dose). Toxicity of the whole group of toxins is translated into okadaic acid using toxic equivalency factors: TEF for okadaic acid and dinophysistoxin-1 = 1, dinophysistoxin-3 = 2; TEF for dinophysistoxin-3 is equal to the corresponding non-esterified compounds (okadaic acid, dinophysistoxin-1 and dinophysistoxin-2). Cases of human poisoning have been observed in areas having 0.8 mg okadaic acid toxicity equivalents per kg body weight.

Detection and control In the EU the currently applied hygienic limit is 160 μg of okadaic acid toxicity equivalents per kg for edible molluscs, but this limit is being discussed in terms of adequate protection during the eating of large portions of this food.

Azaspiracids

Structure, nomenclature and occurrence The group of marine toxins known as azaspiracids (AZA) was only recently discovered to be the cause of shellfish poisoning in humans. Their source is the algae of the genus *Protoperidinium*. Azaspiracids are a group of polyethers (such as okadaic acid), but they contain a nitrogen heterocyclic amine piperidine (**10-246**). About 20 different derivatives have been identified, of which azaspiracid-1 (AZA1) and azaspiracid-3 (AZA3) are relevant to the toxicity.



10-246, azaspiracids

AZA1, $R^1 = R^2 = H$, $R^3 = CH_3$, $R^4 = H$

AZA2, $R^1 = H$, $R^2 = CH_3$, $R^3 = CH_3$, $R^4 = H$

AZA3, $R^1 = R^2 = R^3 = R^4 = H$

AZA4, $R^1 = OH$, $R^2 = R^3 = R^4 = H$

AZA5, $R^1 = R^2 = R^3 = H$, $R^4 = OH$

Reactions and changes Azaspiracids are thermostable and cannot be removed by heat treatment.

Biological effects AZP syndrome was first described in 1995 after a poisoning case involving the eating of blue mussels (*Mytilus edulis*) from Ireland. In subsequent years, poisoning cases have been reported from other European countries, but the mussels were always of Irish origin. Poisoning is characterised by digestive problems: nausea, vomiting, diarrhea and stomach pain. In all cases there is spontaneous recovery within a few days.

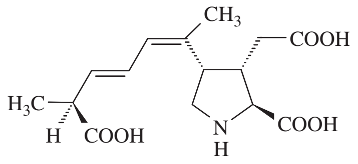
As in other toxins, the hygienic limits are based on the acute toxicity (ARfD) and the total exposure to individual azaspiracid analogues is converted into AZA1 using TEF equivalents. The lowest dose that causes toxic effects is estimated to be approximately 2 mg of AZA1 equivalents per adult person.

Detection and control The EU hygienic limit is (similar to the case of DSP) 160 μg of AZA1 toxicity equivalents per kg of edible shellfish portion. After the introduction of mandatory monitoring, low levels of toxins in shellfish were registered in different EU countries. In one case (France in 2008), there was a mass poisoning (of 208 people). In this case it was shown that the hygienic limit had been exceeded by several times.

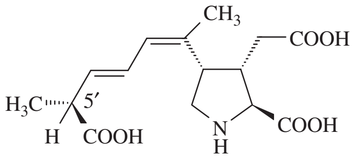
Amnestic toxins

Structure, nomenclature and occurrence ASP is a less common type of poisoning. It occurs after ingestion of shellfish contaminated by a specific toxic amino acid referred to as domoic acid (**10-247**), a naturally occurring neuroexcitatory toxin produced primarily by the marine diatom *Pseudonitzschia multiseries*, which is widespread

in warm and in colder seas. Other compounds of similar structure include domoic acid diastereomer 5′-domoic acid (**10-248**) and ten domoic acid isomers (isodomoic acids A to H, **10-249**). The first human poisoning case was reported in 1987 by ingestion of domoic acid-contaminated blue mussels (*Mytilus edulis*). Contamination was later found in various molluscs. Domoic acid was originally isolated in Japan from red algae *Chondria armata* called *doumoi*.



10-248, 5′-domoic acid



10-247, domic acid

Reactions and changes Domoic acid is thermostable and cannot be removed by heat treatment. It has been shown that domoic acid may degrade in acidic media, but the practical importance of such treatment (e.g. pickling in vinegar) is not known.

Biological effects Amnaesic shellfish poisoning is characterised by relatively mild gastrointestinal symptoms (vomiting, stomach pain and diarrhea). In serious cases, especially in the elderly (over 50 years) and also in impaired and sick individuals, the neurotoxic symptoms accompanied by persistent amnaesia may outweigh the gastrointestinal symptoms. A case of public poisoning was reported

in 1987 in Canada (over 100 people, resulting in four deaths) after ingestion of blue mussels (*Mytilus edulis*). The mechanism of toxic effect is the interaction of toxins with specific glutamate receptors in the brain. Continuous stimulation of receptors leads to the accumulation of Ca^{2+} in nerve cells with consequent damage of the nervous tissue. Mild gastrointestinal symptoms of poisoning in humans were found after the intake of domoic acid at a concentration of 0.9–1.9 mg per kg body weight. Severe neurological changes start at domoic acid levels ranging from 1.9 to 4.2 mg per kg of body weight.

Detection and control In the Canadian study, the lowest concentration of domoic acid in shellfish leading to mild gastrointestinal problems was estimated at 200 mg/kg of edible portion, and the hygienic limit was set at 20 mg/kg of edible portion. This limit is also applied in other countries, including the EU. Contamination of shellfish is occasionally detected in shellfish in different countries, but since the introduction of the limit no cases of poisoning have occurred.

Neurotoxic toxins

Structure, nomenclature and occurrence Neurotoxic brevetoxins are metabolites that are found in the microscopic algae *Gymnodinium breve* (syn. *Ptychodiscus brevis*), which occur in the Gulf of Mexico, the Caribbean region and New Zealand. The extreme algae blooms, for example, along the coast of Florida, creates a so-called red tide, which is a frequent cause of mass fish poisoning. Toxins present in the air as an aerosol may cause temporary inhalation problems when inhaled.

In humans, these neurotoxins cause irritation of the eyes and occasionally poisoning when consuming different bivalves that eat these algae. The most effective toxin produced by algae *Gymnodinium breve* is brevetoxin A (**10-250**), which occurs together with brevetoxin B (**10-251**).

Reactions and changes Brevetoxins, as well as structurally similar ciguatoxins, are thermostable and cannot be removed by heat treatments.

Biological effects Symptoms of poisoning by brevetoxins are similar to symptoms of ciguatera fish poisoning (CFP). These neurological symptoms accompanied by digestive difficulties disappear spontaneously within 48 h.

10.3.3.12.2 Fish toxins

Tetrodotoxin

Structure, nomenclature and occurrence The most effective fish toxin is tetrodotoxin (**10-252**), *O*-methyl-*O*′,*O*′′-isopropylidene-tetrodotoxin hydrochloride, which is accompanied by related 6-epitetrodotoxin, 11-deoxytetrodotoxin, 11-oxotetrodotoxin, (*R*)-11-nortetrodotoxin-6-ol, (*S*)-11-nortetrodotoxin-6-ol and

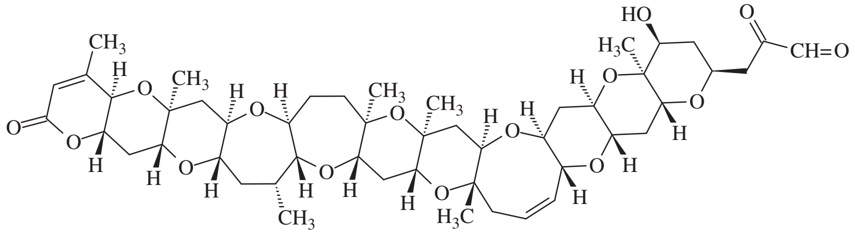
10-250, brevetoxin A



10-251, brevetoxin B

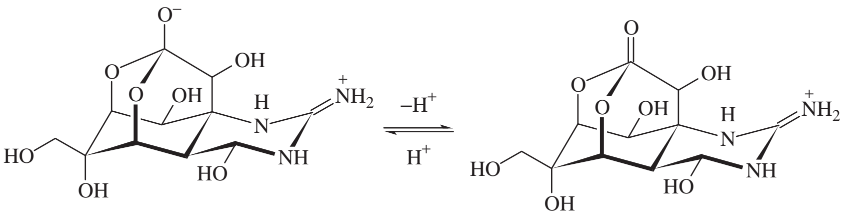


Figure 10.23 Tetrodotoxin salt tautomers.

chiriquitoxin. Both epimers of 11-nortetrodotoxin are probably decarboxylation products of hypothetical tetrodonic acid. Tautomerism is typical for tetrodotoxin and its derivatives; these substances exhibit some properties of ketones and some properties of alcohols (Figure 10.23).

Tetrodotoxin is found in fish known by various names, such as puffer fish, puffers, balloon fish, blowfish and puffu of the family Tetraodontidae, of the genera *Tetraodon* and *Fugu*, which are consumed in Japan as a delicacy. The toxin is not present in the meat, but is present in the female roe, liver, intestines and skin. The source of the toxin is algae consumed by fish, accordingly, bacteria originally classified in the genus *Pseudomonas* and later to the genus *Alteromonas*. The current name is *Shewanella alga*. Tetrodotoxin and chiriquitoxin are also found in some Central American salamanders and frogs (*Atelops chiriquiensis*).

Reactions and changes Toxicity of fish can be reduced by extraction with water or water acidified with acetic acid. Toxicity of roe can also be reduced by the action of alkaline reagents. During heating, the toxic compounds are partially degraded to form less toxic derivatives. Sometimes even the meat may be toxic due to the migration of the toxin from the skin to the internal tissues.

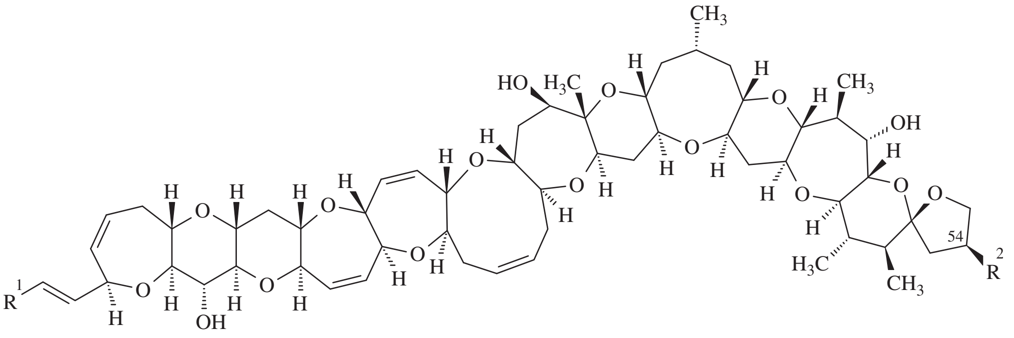
Biological effects Tetrodotoxin is a powerful neurotoxin (paralytic poison, which prevents the function of neuronal channels for Na^+ ions). More than 60% of poisonings are fatal. About as toxic as tetrodotoxin ($LD_{50} = 8–10\ \mu g/kg$ in mice) is chiriquitoxin, while other compounds are less toxic.

Ciguatoxins

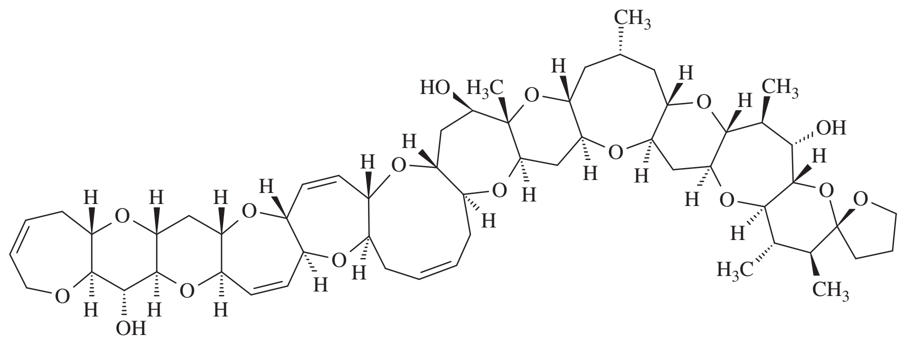
Structure, nomenclature and occurrence Poisoning caused by species of moray eels, such as giant moray (*Gymnothorax javanicus*, Muraenidae), found at coral reefs in tropical seas in the Indo-Pacific, is known as ciguatera fish poisoning (CFP). Mainly responsible for the poisoning are ciguatoxin and maitotoxin and its congeners, which are members of the polycyclic ether family of marine toxins found in the fish flesh contaminated with toxins. Ciguatoxin (**10-253**) and its polar congeners arise by the action of fish oxidases from polar congeners derived from dinoflagellates (organisms of the phylum Dinoflagellata). Dinoflagellates adhere to coral, algae and seaweed, where they are eaten by herbivorous fish that in turn are eaten by carnivorous fish, such as giant moray. For example, ciguatoxin-3C (formerly known as gambiertoxin 4b, **10-254**) is detected in the epiphytic dinoflagellate species *Gambierdiscus toxicus* (Goniodomataceae) along with other related compounds, such as gambierol (**10-255**). The congener 54-deoxyciguatoxin (ciguatera-4B, **10-254**), which is found only in fish, is the immediate precursor of ciguatoxin. A related polycyclic ether is maitotoxin (**10-256**).

Reactions and changes Ciguatoxins do not affect the organoleptic characteristics of meat, are thermostable and cannot be removed by thermal procedures. Long-term water extraction may partially reduce their content.

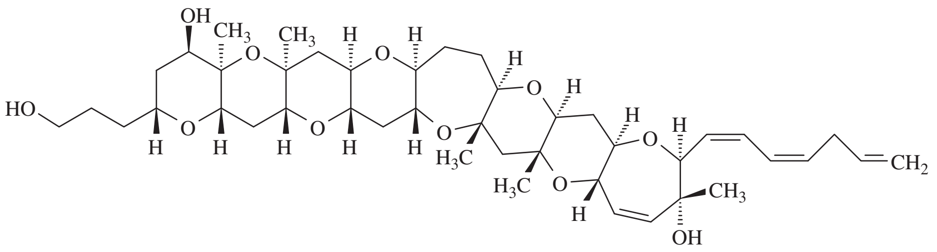
Biological effects Ciguatera fish poisoning is the most common poisoning after eating fish. Symptoms of poisoning appear a few



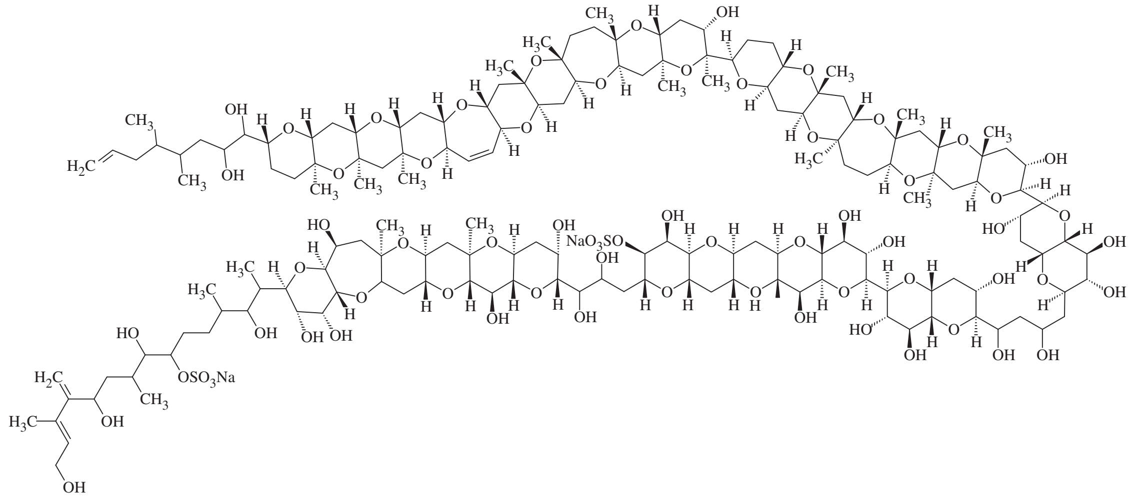
10-253, ciguatoxin, $R^1 = CH(OH)CH_2OH$, $R^2 = OH$
ciguatoxin-4B, $R^1 = CH{=}CH_2$, $R^2 = H$



10-254, ciguatoxin-3C



10-255, gambierol

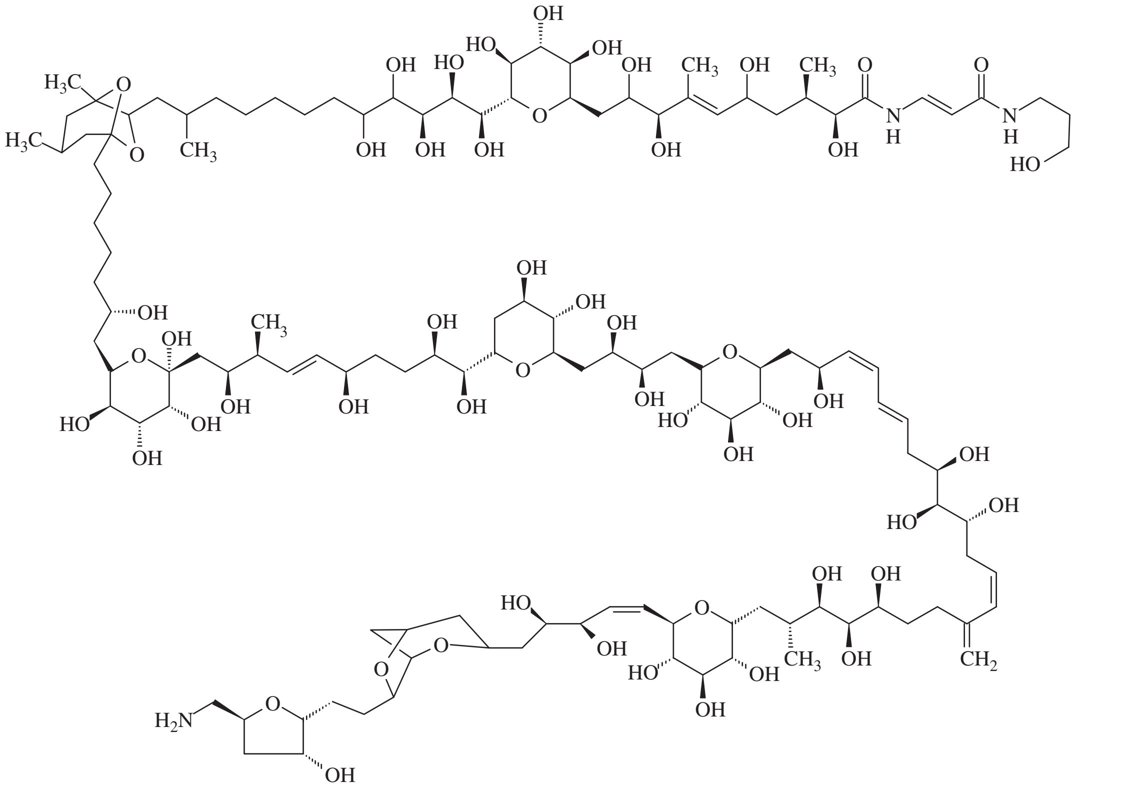


10-256, maitotoxin

hours after eating as digestive problems and subsequent neurological symptoms, muscle pain, weakness, low blood pressure, change in heart rate and more. The variety of symptoms is often associated with the presence of maitotoxin and other bioactive compounds. Mortality caused by this poisoning is low. Ciguatoxin is about ten times more toxic than less polar congeners (such as ciguatoxin-4B). Maitotoxin belongs to the most toxic non-protein compounds (LD_{50} = 50 ng/kg in mice).

Palytoxin

Structure, nomenclature and occurrence Palytoxin is a group of related lipophilic toxins, the structure of which may vary in different species of zoanthids (animals within the order Zoantharia) that are commonly found in coral reefs. Palytoxin (**10-257**) was first isolated from the Hawaiian seaweed-like coral zoanthid *Palythoa toxica*. Later it was found in the red algae *Chondria armata* (Rhodomelaceae), crabs of the genera *Demania* and *Lophozozymus* (Xanthidae), fish species pink tail triggerfish (*Melichthys vidua*, Balistidae) and scrawled filefish (*Aluterus scriptus*, Monacanthidae), and was also identified in the liver of parrot fish (*Ypsiscarus ovifrons*). Even though the appearance of palytoxin was initially restricted to tropical areas, the recent occurrence in micro alga, the dinoflagellate of the genus *Ostreopsis* in Mediterranean Sea, point to a worldwide dissemination probably related to climate change.



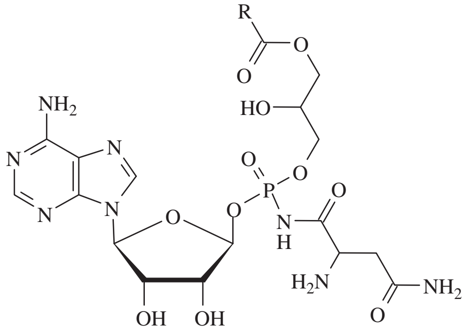
10-257, palytoxin

Reactions and changes Palytoxin group toxins are relatively stable. No data on their changes during cooking or industrial processing are known.

Biological effects Palytoxin targets the sodium–potassium pump protein by binding to the molecule analogously as tetrodotoxin. It probably also has carcinogenic effects. Palytoxin is considered to be one of the most toxic non-peptide substances known, second only to maitotoxin ($LD_{50} = 0.1–0.3\,\mu g$ in mice) of the same class as botulotoxin. Palytoxin is responsible for lethal poisonings caused by eating the meat of crabs *Demania reynaudii* in the Philippines. Poisoning causes similar symptoms as tetrodotoxin poisoning, the symptoms of which are angina-like chest pains, asthma-like breathing difficulties, tachycardia (racing pulse), unstable blood pressure with episodes of low blood pressure and haemolysis. The onset of symptoms is rapid, with death occurring within minutes.

Other toxins

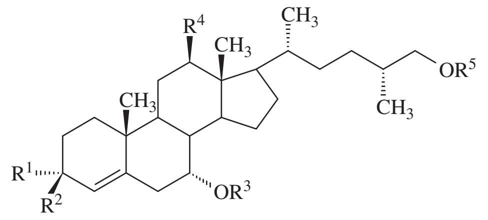
In saltwater fish a number of other biologically active metabolites of algae occur that cause different types of poisoning. In addition to these secondary metabolites, some fish also produce their own toxins. For example, the fish *Stichaeus grigorjewi* (Stichaeidae), common in the Northwest Pacific, contains toxic lipoproteins, which are known as α-, β- a γ-lipostichaerins, in the roes. In addition to neutral lipids, lipostichaerins contain unusual toxic phospholipid dinogunellin, which is composed of adenosine and



10-258, dinogunellin

2-aminosuccinamide (**10-258**, R = fatty acid residue). The same ichthyotoxin was found in the eggs of other fish that are toxic, especially at the time of spawning. Lipoproteins easily denature by heat, but the toxic component dinogunellin is stable. The toxin affects the central nervous system, but poisoning is not usually fatal.

The blood of some fish species of the garden eel family Congridae and the freshwater eel family Anguillidae, for example the blood of European eel (*Anguilla anguilla*), contains ichthyohaematoxin. This protein decomposes with acids, bases and by the action of proteolytic enzymes and is denatured by heating to a temperature of 70 °C or higher or by UV irradiation. Different individuals are sensitive to the eel's blood in different ways. Poisoning occurs rarely



10-259, pavoninin 1, R^1 = OH, R^2 = OH, R^3 = β-D-Glc*p*NAc-(1®, R^4 = H, R^5 = $COCH_3$
pavoninin 2, R^1 = OH, R^2 = OH, R^3 = β-D-Glc*p*NAc-(1®, R^4 = H, R^5 = H

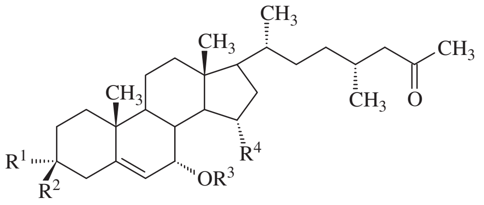
mosesin 5, R^1 = OH, R^2 = H, R^3 = β-D-Gal*p*-(1®, R^4 = OH, R^5 = $COCH_3$

because the blood is toxic only when consumed in large quantities. Toxicity depends on the season and is the highest at the time of spawning.

Ichthyocrinotoxins occur in toxic skin secretions of many fish species of the families Soleidae, Ariidae, Ostraciidae, Tetraodontidae, Gobiidae, Serranidae, Batrachoididae and Muraenidae. They show strong haemolytic effects and serve as protective agents against microorganisms and parasites. The structure of toxins is dependent on their origin. Toxic secretion components are peptides, steroids and various fatty acid derivatives that have a bitter taste and the food is unacceptable, but poisoning of humans is unknown.

For example, the skin secretion of the fish peacock sole *Pardachirus pavoninus* (Soleidae), occurring in the Indo-Pacific region, contains linear peptides produced by a series of toxic glands along the bases of dorsal- and anal-fin rays. These toxic peptides, composed of 33 amino (2800 Da), are called pardaxin 1, pardaxin 2 and pardaxin 3. For example, the primary structure of pardaxin 1 is formed by the following sequence of amino acids: Gly-Phe-Phe-Ala-Leu-Ile-Pro-Lys-Ile-Ile-Ser-Ser-Pro-Leu-Phe-Lys-Thr-Leu-Leu-Ser-Ala-Val-Gly-Ser-Ala-Leu-Ser-Ser-Ser-Gly-Glu-Gln-Glu. Other pardaxins have similar structures. As with other polypeptides, paradaxins are labile compounds that are relatively easily hydrolysed by proteolytic enzymes, and partly also by cooking.

Other compounds present in the toxic secretion of peacock sole are glycosides of steroid toxins called pavoninins (**10-259** to **10-262**). The skin secretion of a related fish species known as finless sole (*P. marmoratus*) are structurally related lipophilic toxins called mosesins (**10-259**, **10-260** and **10-262**).



10-260, pavoninin 3, R^1 = OH, R^2 = H, R^3 = H, R^4 = β-D-Glc*p*NAc-(1®
pavoninin 5, R^1 = H, R^2 = OH, R^3 = H, R^4 = β-D-Glc*p*NAc-(1®

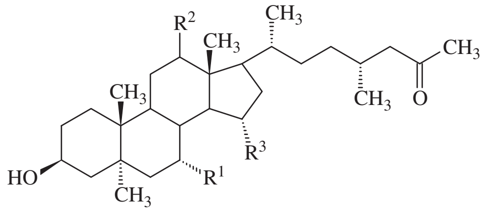
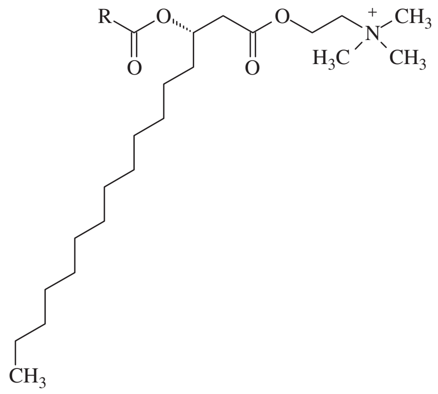
10-261, pavoninin 6, R = β-D-Glc*p*NAc-(1®



10-262, pavoninin 4, R^1 =, R^2 = H, R^3 = β-D-Glc*p*NAc-(1®O
mosesin 3, R^1 = β-D-Gal*p*6Ac-(1®O, R^2 = OH, R^3 = H
mosesin 4, R^1 = β-D-Gal*p*-(1®O, R^2 = OH, R^3 = H



10-263, pahutoxin, R = CH_3
homopahutoxin, CH_2CH_3

The skin secretion of *Ostracion lentiginosus* and of various other members of the Ostraciidae family contains the toxin pahutoxin, (*S*)-2-(3-acetyloxyhexadecanoyl)oxyethyltrimethylazanium chloride (choline chloride ester of 3-acetylhexadecanoic acid, **10-263**). Pahutoxin is a cationic surfactant, which can be released to the surrounding area, which negatively affects other fish, as the toxic effect is similar to the effect of saponins. The secretion of Hawaiian boxfish *O. immaculatus* contains pahutoxin and related homopahutoxin, (choline chloride ester of 3-propionylhexadecanoic acid), which has the systematic name (*S*)-(2-(3-propanoyloxyhexadecanoyl)oxyethylazanium chloride (**10-263**).

11

Food Additives

11.1 Introduction

In the broadest sense, food additives are substances or mixtures intentionally added to food to improve its quality. Basically, anything that is not naturally a part of a food is considered a food additive. Legally, the term food additive means 'any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food, whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in it or its byproducts becoming directly or indirectly a component of such foods' (European Council Directive 89/107/EEC). Food additives have always played a vital role in food supply. Before modern food manufacturing, salting fish and meat was one of the oldest techniques to extend their shelf life. Today's food additives allow the world's growing urban population to have a variety of toxicologically safer and nutritionally and organoleptically more valuable food all the year round, without the inconvenience of daily shopping and cooking.

The use of food additives has a number of advantages, such as:

- reduced product spoilage and extended shelf life of foods using preservatives, which prevent poisonings by bacterial and fungal origin, including life-threatening botulism;

- improved or maintained nutritional value by the addition of vitamins and minerals, which helps to reduce malnutrition;

- prevention of formation of potentially toxic oxidation products of lipids and other food constituents by antioxidants and prevention of formation of various off-flavours and off-tastes, while maintaining palatability and nutritional value, which is associated with the content of easily oxidisable essential fatty acids and lipophilic vitamins;

- giving food a desirable feel by the addition of emulsifiers, thickeners and gelling agents, which allow the product to maintain a consistent texture and wholesomeness, and enable production of low-energy foods and novel foods with reduced sugar and fat content;

- enhancing flavour by the addition of spices, natural and synthetic flavours, or imparting a desired colour by the addition of natural pigments or synthetic colorants, which enhance the appearance of foods to meet consumer expectations.

Of course, some additives could be eliminated if we were willing to grow our own food and spend many hours cooking and canning, or if we accepted increased risks of food spoilage. The beneficial use of additives, however, is offset by some risks. Short-term adverse effects of sulfur dioxide, for example, may manifest in some particularly sensitive individuals by gastric irritation, nausea, diarrhoea, asthma attacks and skin rashes. The negative effect of nitrites depends on their potential induction of methaemoglobinaemia, especially in children (see Section 6.6.1.2.2) and their reaction with secondary amines to form carcinogenic nitrosamines. In test animals, saccharine, which is banned in some countries, interferes with blood coagulation, blood sugar levels and digestive function and may cause cancer of the bladder, uterus, ovaries, skin and blood vessels. However, the risks of the long-term use of additives by humans are not well documented; nevertheless, the use of some additives (such as nitrite and saccharin) is potentially problematic and other substitutes are being sought. Especially important is the continuous evaluation of the potential risks in the light of new knowledge in the field of toxicology.

The EU legislation on food additives is based on the principle that only those additives that are explicitly authorised may be used. Most food additives may only be used in limited quantities in certain foods. If no quantitative limits are anticipated for the use of a food additive, it must be used according to good manufacturing practice, which means only as much as necessary to

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

achieve the desired technological effect. Food additives may only be authorised if:

- there is a technological need for their use
- they do not mislead the consumer
- they present no hazard to the health of the consumer.

To assess the possible harmful effects of a food additive, it must be subjected to appropriate toxicological testing and evaluation by the Scientific Committee on Food, an expert panel that advises the European Commission in questions relating to food. The evaluation should also take into account, for example, any cumulative, synergistic or potentiating effect of its use, and the phenomenon of human intolerance to substances foreign to the body. All food additives must be kept under continuous observation and must be re-evaluated in the light of changing conditions of use and new scientific information. The use of food additives must always be labelled on food product packaging by their category (e.g. antioxidant, preservative or colour) with either their name or E-number. E-Numbers are codes for food additives for use within the European Union (the 'E' prefix means for 'Europe') and Switzerland.

The source of international food standards, *Codex Alimentarius*, is published by the Food and Agricultural Organization and World Health Organization (FAO/WHO) of the United Nations. In Europe, the sources of food standards are EU directives. The Codex Committee on Food Additives and Contaminants (CCFAC) deals with the issue of additives, contaminants and natural toxins in food, and also proposes the Maximum Residue Level (MRL, in mg/kg food) for food additives, for example, in the case of arbitration of the World Trade Organisation. The advisory body of CCFAC is the Joint FAO/WHO Expert Committee on Food Additives (JECFA), composed of experts from Member States and Associated Countries of the FAO/WHO. Recommendations for the EU come from a committee of experts nominated by an authority called the Scientific Committee for Food (SCF). These recommendations are converted into legislative form in different countries. In the United States, for example, the source of food standards is the U.S. Food and Drug Administration (FDA).

In this chapter, food additives are classified according to their use as substances that prolong food shelf life, regulate flavour (odour and taste), colour and texture and increase the biological value and technological quality of food. Substances prolonging the shelf life of foods include antimicrobial substances (preservatives) and antioxidants. Substances enhancing odour and taste include food aromas and sweeteners, both natural and synthetic, acidulants and acidity regulators and bitter substances. The section devoted to colours includes natural pigments and synthetic dyes used as food additives, inorganic pigments and bleaching agents (including flour treatment agents). Substances used for regulation of texture are thickeners, gelling agents and emulsifiers. The focus is on vitamins and minerals with substances that increase the biological value of food. Other food additives include humectants, aroma carriers, dispersion stabilisers, anti-caking, bulking, raising, clarifying, haze forming, anti-foaming and glazing agents, lubricants and releasing substances, sequestrants, propellants and packaging gases, catalysts and solvents used in different food technologies. For each of these groups of food additives, the chapter will focus on the relevant legislation and health aspects.

11.2 Substances prolonging the shelf life of foods

There are two basic types of agents that can prolong the shelf life of foods:

- antimicrobial agents, known as preservatives, which are used to protect food against undesirable microorganisms;
- antioxidants, which protect lipids and some other sensitive food constituents (such as vitamins) from oxidation.

11.2.1 Preservatives

Antimicrobial substances (preservatives) prolong shelf life of foods by protecting them against deterioration caused by undesirable microorganisms. Preservation usually involves preventing the growth of bacteria and fungi (yeasts and moulds). A large number of natural components of food materials have antimicrobial effects, and a number of other substances can be intentionally added to foods. Used as preservatives (E-number range is E200–E299) are some organic acids and their salts or inorganic acids, their oxides, salts and esters (E200–E219, E242, E280–E285), including sulfur dioxide and some derived compounds (E220–E228), nitrites and nitrates (E249–E252). Some phenols (E230–E232) and thiabendazole (E233), which is a representative of synthetic fungicides, are active as fungicides. Certain antibiotics (E234 and E235) have special uses, and the enzyme lysozyme is listed with additional chemicals (E1105). Other organic and inorganic substances also show preservation effects, and are formally classified in different groups of food additives (such as acetic acid, ranked among the acidulants) or substances that are not classified as food additives (e.g. sucrose and sodium chloride).

In industrial and also in culinary practice, methods based on physical principles are widely used in addition to these chemical methods of food preservation. Of these, it is primarily food preservation by heat treatment (pasteurisation and sterilisation), cold (chilling and freezing), drying (dehydration), irradiation, and more recently by high pressure, which attract the most attention.

11.2.1.1 Acids and their derivatives

11.2.1.1.1 Benzoic acid

Benzoic acid (E210) and benzoates (E211–E213) are primarily used as antifungal agents. Most fungi (yeasts and moulds) are inhibited by undissociated acid, the concentration of which is 500–1000 mg/kg. Some bacteria are inhibited at a concentration of 100–200 mg/kg, but many bacteria are inhibited by much higher

Table 11.1 Antimicrobial spectrum of benzoic acid.

Microorganisms	pH	Minimum inhibitory amount (mg/l)	Microorganisms	pH	Minimum inhibitory amount (mg/l)
Bacteria			***Yeasts***		
Bacillus cereus	6.3	500	*Hansenula* spp.	4.0	180
Escherichia coli	5.2–5.6	50–120	*Rhodotorula* spp.	–	100–200
Lactobacillus spp.	4.3–6.0	300–1800	*Saccharomyces bayanus*	4.0	330
Lysteria monocytogenes	5.6	2000–3000	*Zygosaccharomyces* spp.	4.8	1000–4800
Micrococcus spp.	5.5–5.6	50–100	***Moulds***		
Pseudomonas spp.	6.0	200–480	*Aspergillus* spp.	3.0–5.5	200 > 4000
Streptococcus spp.	5.2–5.6	200–400	*Bysochlamys nivea*	3.3	500
Yeasts			*Cladosporium herbarum*	5.1	100
Candida crusei	–	300–700	*Mucor racemosus*	5.0	30–120
Debaromyces hansenii	4.8	500	*Penicillium* spp.	2.6–5.0	30–2000
Pichia membranefaciens	–	700	*Rhizopus nigricans*	5.0	30–120

concentrations (Table 11.1). According to the type of food, the concentration used ranges from 150 to 2000 mg/kg.

The active form is undissociated acid (pK = 4.19 at 25 °C), which is about 100 times more effective than its anion. The antimicrobial effect is probably due to inhibition of amino acid utility by microorganisms, inhibition of transport of substrates and inhibition of enzymes involved in the acetic acid metabolism, oxidative phosphorylation and the citric acid cycle.

In small amounts, benzoic acid (free or bound in esters) occurs as a natural component of foods. It is mainly present in fruits and some fermented dairy products (see Section 8.2.6.1.6).

11.2.1.1.2 Sorbic acid

(2E, 4E)-Hexa-2,4-dienoic acid, known as sorbic acid (E200), and its salts (sorbates, E201–E203) are potent inhibitors of a number of fungi, yeasts and some bacteria. Sorbic acid is used (according to the type of food) in quantities of 200–2 000 mg/kg. The active form is the undissociated acid (pK = 4.76 at 25 °C), which is roughly 10–600 times more effective than the anion. The effect is related partly to inhibition of dehydrogenases involved in the oxidation of fatty acids, sulfhydryl enzymes (it is added to the cysteine thiol group) and partly to the interference with the transport of substances through cytoplasmic membrane.

Sorbic acid has a conjugated system of double bonds, which makes it susceptible to autoxidation and nucleophilic attack, sometimes giving mutagenic products. Autoxidation of sorbic acid yields unstable hydroperoxides, which decompose and the main final products are acetaldehyde and fumaric acid monoaldehyde (β-carboxyacrolein). This aldehyde reacts with amino acids and proteins and is responsible for the browning of certain foods preserved with sorbic acid. Other products of oxidation are acrolein and crotonaldehyde. In the presence of sulfur dioxide, α-angelica lactone and 2-acetyl-5-methylfuran are produced. Nucleophiles attack the sorbic acid molecule in position C-5. With amines under conditions typical of food processing (50–80 °C) cyclic products are formed, N-alkyl-6-methyl-3,6-dihydropyrid-2-ones, resulting from a double addition reaction. The reaction with sulfur dioxide (bisulfites) and thiols yields mainly 5-substituted hex-2-enoic acids. Because sorbic acid inhibits the growth of *Clostridium botulinum* bacteria as well as the formation of nitrosamines, it has been proposed as a partial replacement for nitrite in meat curing. However, this practice may lead to other toxicological problems since sorbic acid reacts with nitrite to yield mutagenic products. At pH 3.5–4.2, the main mutagens are unstable 1,4-dinitro-2-methylpyrrole, ethylnitrolic acid and a derivative of furoxan (1,2,5-oxadiazole 2-oxide) 3-(5-methyl-4-furoxanyl)prop-2-enoic acid, which undergo decomposition to other products. Ascorbic acid completely eliminates the mutagenicity of 1,4-dinitro-2-methylpyrrole by reduction of the C-4 nitro group to a C-amino group. The 1-nitro-2-methyl-4-amino pyrrole formed is non-mutagenic (Figure 11.1).

Some microorganisms (such as *Penicillium roqueforti*) decarboxylate sorbic acid to penta-1,3-diene, which causes an off-flavour (resembling kerosene) in cheeses (Figure 11.1). The threshold concentration of penta-1,3-diene is 1 mg/kg. Also reported are cases of contaminated margarines, fruit drinks, jams and marzipan, and similar products that used pure cultures of microbial strains (such as blue cheese and fermented dairy products).

11.2.1.1.3 Parabens

Alkyl esters (methyl, ethyl, propyl and heptyl esters, previously also benzyl ester) of p-hydroxybenzoic (4-hydroxybenzoic) acid are

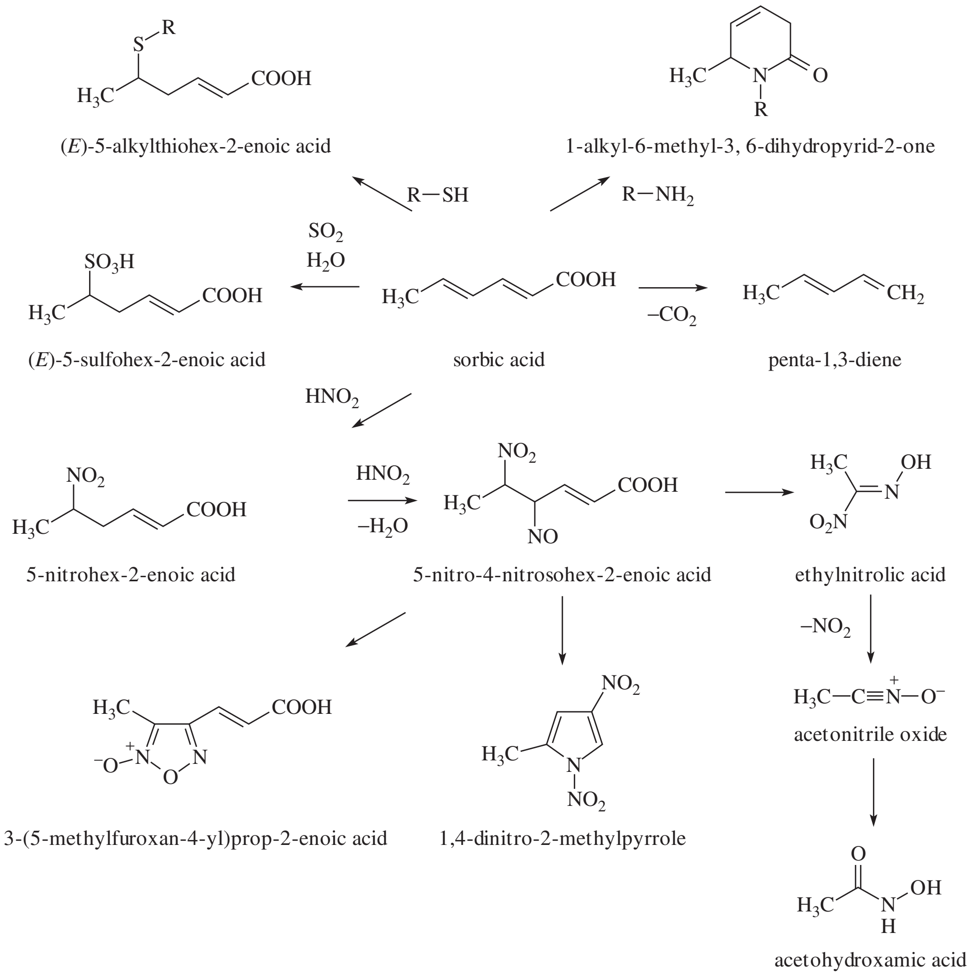


Figure 11.1 Reactions of sorbic acid in foods.

collectively called parabens. Formerly, these esters were also known as abegins or under various trade names. Unlike free acids (benzoic and sorbic acid), parabens and their salts (E209, E214–E219) are effective in less acidic and slightly alkaline environments. Their antimicrobial effectiveness increases with the length of the alkyl residue, which, on the other hand, decreases their solubility in water and thus the possibility of practical use. Salts of parabens are particularly soluble. Their effect on the taste and smell of protected foods is very small. Parabens are mainly active against fungi and yeasts and less active against gram-positive bacteria (Table 11.2). Their preservative effect is based on influencing the permeability of cell membranes. Parabens are used in amounts ranging from 500 to 1000 mg/kg.

11.2.1.1.4 Other acids and their derivatives

Formic acid ($pK = 3.75$ at 25 °C, see Section 8.2.6.1.1) is a carboxylic acid which shows the highest antimicrobial activity of all lower carboxylic acids (E236). Formic acid and formates are especially effective against bacteria and yeasts. Lactic acid bacteria and yeasts are relatively resistant. Formic acid is used for preserving acidic fruit juices or purées, whose colour is derived from anthocyanins (such as strawberries), which therefore cannot be preserved by sulfur dioxide. During thickening, formic acid is volatilised with water vapour and removed from the product. Because of its smell, its use is very limited. The other disadvantage is that formic acid partially hydrolyses pectin. In the EU, formic acid is not approved.

Acetic acid ($pK_a = 4.53$ at 25 °C, see Section 8.2.6.1.1) is used as a preservative and also as an acidifying agent (acidulant, E260). It is effective against yeasts and bacteria, but less so against moulds. Tolerant bacteria are acetic acid and lactic acid bacteria and gram-positive bacteria producing butyric acid under anaerobic conditions. Acetic acid is mainly used for the preparation of pickles for preserved vegetables, in production of ketchups, dressings, mayonnaises, fish and other products. The mechanism of action is the inhibition of the transport of substances through cytoplasmic membranes and inhibition of electron transport. Sodium acetate and sodium diacetate (E262, a 1 : 1 mixture of sodium acetate and acetic acid, also known as sodium hydrogen acetate) are effective preservatives against bacteria and fungi.

Dehydroacetic acid (E265, **11-1**) and its sodium salt is mainly active against fungi at higher pH values, when other acids are ineffective. In the EU, it is not approved, but in the United

Table 11.2 Antimicrobial spectrum of parabens.

Microorganism	Concentration (mg/l) causing inhibition			Microorganism	Concentration (mg/l) causing inhibition		
	Methyl	Propyl	Heptyl		Methyl	Propyl	Heptyl
Bacteria				*Fungi (yeasts and moulds)*			
Bacillus cereus	2000	125–400	12	*Candida albicans*	1000	125–250	–
Escherichia coli	2000	400–1000	–	*Saccharomyces bayanus*	930	220	–
Lysteria monocytogenes	> 512	512	–	*Saccharomyces cerevisiae*	1000	125–200	100
Pseudomonas aeruginosa	4000	8000	–	*Aspergillus flavus*	–	200	–

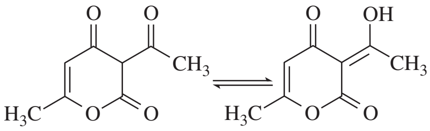
Staphylococcus aureus	4000	350–500	12	*Rhizopus nigricans*	500	125	–

States this acid is allowed for the preservation of cut or peeled squash. It was similarly used as a fungistatic agent for surface treatment of cheeses or for suppressing the microbial defects of bread and related products called ropiness or ropy bread, which is caused by the thermophilic spore-forming bacterium *Bacillus mesentericus* (a variant of *Bacillus subtilis*), whose spores survive cooking temperatures that do not exceed 100 °C inside the bread, and can germinate under favourable conditions. Bread ropiness is a result of slime casings production by these bacteria and enzymatic hydrolysis of starch and gluten. On the second or third day, the bread crumb becomes damp and sticky as a result of the formation of gummy products that stretch into strands when the bread is pulled apart. In addition to ropiness, the spoiled bread has an off-flavour, sometimes characterised as fruity or pineapple-like, and turns yellow. Formerly, when ropiness occurred, bakers acidified doughs with vinegar as a protective measure. Dehydroacetic acid has also been shown to be an effective antifungal agent against black bread moulds, particularly *Aspergillus niger* and *Rhizopus nigrificans*.



11-1, dehydroacetic acid

Propionic acid arises in Emmental cheeses by propionic acid fermentation (see Section 8.2.6.1.1). Propionic acid (E280) and its salts (E281–E283) are active as preservatives in weakly acidic medium (to pH 5 , pK = 4.87 at 25 °C), especially against moulds but less against gram-negative bacteria, while the activity against yeasts is almost completely absent. Propionic acid is mainly used as a preservative in stored animal feed and grain. It is also used for extending the shelf life of bread, tortillas and other cereal products, as it prevents the growth of moulds (as calcium propionate and sodium propionate). The inhibition of bacteria that cause bread ropiness occurs at concentrations of 2000–3000 mg/kg. The mechanism of action is mainly based on accumulation of propionic acid in the cells of microorganisms and inhibition of important enzymes.

Lactic acid (pK = 3.83 at 25 °C, see Section 8.2.6.1.3) occurs as a natural compound in many fermented products (e.g. yoghurt, fermented sauerkraut and olives). As a preservative, lactic acid (E270) is mainly used as an acidulant. The undissociated form diffuses through cell membrane of many bacteria and lowers the pH within the cell. It has a bacteriostatic effect on pathogenic bacteria *Mycobacterium bovis*, a member of the *M. tuberculosis* bacteria, the causative agent of bovine tuberculosis in cattle. Lactic acid is also effective against other bacteria, so it is used, for example, for surface decontamination of meat and in production of delicacies. Usually it is applied in combination with sodium lactate.

Fumaric acid ($pK_1 = 3.09, pK_2 = 4.60$ at 25 °C, see Section 8.2.6.1.2) is used as an acidulant and preservative (E297) for inhibition of lactic acid fermentation in wines. Fumaric acid and its esters (especially monomethyl and monoethyl esters) may slow down the formation of botulinum toxin formation in canned meat and prevent the growth of moulds in bread.

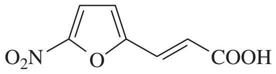
Other organic acids are important mainly as acidulants. Approved substances in the EU are citric, malic, tartaric (see Section 8.2.6.1.3) and ascorbic acids (see Section 5.14.1) and their sodium, potassium and calcium salts.

11.2.1.2 Other organic substances

In addition to carboxylic acids, their salts and esters, some other organic compounds that have antimicrobial effects can similarly be used as food preservatives. These substances include some antibiotics, enzyme lysozyme, biphenyl, *o*-phenylphenol, thiabendazole, dialkyl dicarbonates and alkylene oxides. Other substances with antimicrobial effects belong to other categories of food additives. For example, sucrose esters with palmitic and stearic acid, used as emulsifiers, are active against fungi of the genera *Aspergillus*, *Penicillium* and *Cladosporium*. Some other organic compounds, which are used for food preservation, are not considered food additives, such as sucrose, as well as different natural substances with antimicrobial effects occurring in some vegetables (such as allicin from garlic or allyl isothiocyanate from horseradish) or spices (e.g. piperine in

black pepper and capsaicin from hot peppers). Many other natural substances show antimicrobial effects, some of which are listed in Section 10.3.3.6.

During the last few decades, some previously used preservatives have been dropped due to hygienic–toxicological reasons (in some cases it was found that they were potential carcinogens) and are prohibited in the EU and other countries. Such substances include, for example, dehydroacetic acid (**11-1**) and its sodium salt (previously used to preserve jams and margarines), 8-hydroxyquinoline (for tobacco), thiourea (for fresh fruits), salicylic acid (for fruits and vegetables), 3-(5-nitrofuran-1-yl)acrylic acid (for wines, **11-2**).



11-2, 3-(5-nitrofuran-1-yl)acrylic acid

11.2.1.2.1 Antibiotics

The use of antibiotics in food is problematic, because the use of the same substances in human and veterinary medicine are not allowed. With regard to this requirement, only polypeptide antibiotics produced by lactic acid bacteria are approved in the EU and other countries (including certain strains of the genera *Lactococcus*, *Lactobacillus*, *Leuconostoc* and *Pediococcus*), known under the general common name **bacteriocins**.

Nisin

The thermoresistant polypeptide nisin (E234), produced by some strains of *Streptococcus lactis*, which is effective against gram-positive bacteria, is important as a preservative, and may occur naturally in certain cheeses as a result of fermentation processes. Gram-negative bacteria are resistant to nisin, because their cell walls are far less permeable than those of gram-positive bacteria. Its use is legally limited to certain milk products, such as aged and processed cheeses, puddings and creams. The molecule of nisin (**11-3**) is composed of 33 amino acid residues arranged in five cycles. Nisin contains some unusual amino acid residues: Abu = 2-aminobutanoic acid, Dha = dehydroalanine (2-aminoacrylic acid) and Dhb = dehydrobutyrine (2-aminocrotonic acid), which occurs as the L- or D-enantiomer, and thioether cross-linkages (*meso*-lanthionine and 3-methyllanthionine residues **2-123**) that are indicated as Ala-S-Ala and Abu-S-Ala, respectively (in which the amino-terminal moieties have the D-configuration). The peptide diplococcin produced by *Streptococcus cremoris* (*Lactococcus lactis*, ssp. *cremoris*) has a comparable antibacterial spectrum.

Natamycin

Natamycin (E235), also known as pimaricin or tennecetin (**11-4**) is a polyene macrolide substituted by sugar residues derived from 3-amino-3,6-dideoxy-β-D-mannose. It is produced by certain strains of the bacteria *Streptomyces natalensis* or *Streptococcus lactis* and is allowed for surface treatment of cheeses and durable meat products. Natamycin is active against most fungi and yeasts at concentrations of 5–10 mg/kg, but is ineffective against bacteria. Like other polyene antibiotics, natamycin inhibits fungal growth by binding to ergosterol in the plasma membrane, preventing ergosterol-dependent fusion of vacuoles, as well as membrane fusion and fission.

11.2.1.2.2 Lysozyme

The active substances against gram-positive bacteria is the enzyme lysozyme (neuramidinase) from the group of hydrolases. Lysozyme is allowed in many countries for the treatment of some dairy products and wine.

11.2.1.2.3 Biphenyl and its derivatives

Biphenyl (E230) and *o*-phenylphenol (E231), also known as 2-biphenylol (**11-5**) or its sodium salt sodium *o*-phenylphenol (E232) have been used for the surface treatment of citrus fruits. They are active against fungi.

11.2.1.2.4 Thiabendazole

The fungicide 2-(4-thiazolyl)benzimidazole, known as thiabendazole (E233) has been used for the same purpose as biphenyl and *o*-phenylphenol and for the surface treatment of bananas.

11.2.1.2.5 Hexamethylenetetramine

Hexamethylenetetramine (E239), also known as urotropine, hexamine, methenamine or 1,3,5,7-tetraazaadamantane (**8-57**), arises as a reaction product of formaldehyde with ammonia. Its preservation effect appears to be due to the gradual liberation of formaldehyde (E240, which is not approved in the EU) and its oxidation product formic acid under acid conditions or in the presence of proteins. The most abundant end-product of formaldehyde in cheeses preserved with hexamethylenetetramine is spinacine, 4,5,5,7-tetrahydro-3*H*-imidazo[4,5-*d*]pyridine-6-carboxylic acid (**11-6**), derived from the *N*-terminal histidine residue in γ-casein.

11.2.1.2.6 Dialkyl dicarbonates

Diethyl dicarbonate (diethyl pyrocarbonate) was used in the past as a preservative for soft drinks and some alcoholic beverages (including wine). In aqueous solution, however, diethyl dicarbonate is rapidly hydrolysed to ethanol and carbon dioxide, and in alcoholic beverages it is transformed into diethyl carbonate by reaction with ethanol. In the presence of ammonium salts toxic ethyl carbamate then results, which is also known as urethane (Figure 11.2). For these reasons, diethyl dicarbonate is not approved in the EU, but the approved compound is dimethyl dicarbonate (E242), which can be used for the preservation of soft drinks, teas, herbal teas and in some countries to stabilise wine. The methyl carbamate produced from dimethtyl dicarbonate is a non-toxic substance. In treated wines it occurs in amounts up to 10 μg/l.

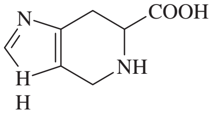
o-phenylphenol, R = OH



11-6, spinacine

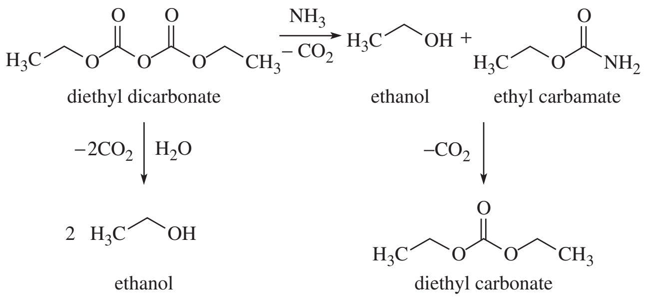


Figure 11.2 Degradation of diethyl dicarbonate in foods.

11.2.1.2.7 Alkylene oxides

Effective substances against all microorganisms (vegetative forms and spores) and also with insecticidal properties are ethylene oxide (oxirane) and propylene oxide (methyloxirane). In some countries, these compounds are approved for fumigation of foods with low water contents, where other methods of preservation are not applicable (such as sterilisation of spices, nuts, starch and flour). The modern alternative is irradiation.

Oxiranes are highly toxic alkylating agents and the hydrolysis product of ethylene oxide ethylene glycol and reaction products of oxiranes with chloride ions is likewise toxic. The latter reaction yields 2-chloroethanol, which arises from oxirane, and isomeric vicinal chloropropanols (chlorohydrins) resulting from methyloxirane (Figure 11.3). Oxiranes react with a number of other food components, such as vitamins (riboflavin, pyridoxine, niacin and folic acid) or amino acids (methionine and histidine) to form biologically inactive products.

11.2.1.3 Inorganic compounds

11.2.1.3.1 Sulfur dioxide and sulfites

Sulfur dioxide (SO_2, E220) and some of its derivatives, such as sulfites (SO_3^{2-}; E221, E225, E226), sodium bisulfite (E222) and disulfites, commonly known as pyrosulfates or metabisulfites ($S_2O_5^{2-}$; E223, E224), can be used as preservatives, but also as inhibitors of enzymatic and non-enzymatic browning reactions, bleaching agents and antioxidants. Calcium bisulfite (E227) is used as a firming agent.

Aqueous solutions of sulfur dioxide (SO_2 dissolves up to 9.5% solution at 20 °C) give rise to sulfurous acid (H_2SO_3), the anhydride of which is sulfur dioxide. Sulfurous acid dissociates into two stages ($pK_1 = 1.76, pK_2 = 7.20$). Depending on the pH of the medium, solutions of sulfurous acid contain, in addition to SO_2 and undissociated acid, bisulfite (HSO_3^-) and sulfite (SO_3^{2-}) ions. In acidic foods of pH 3–4, bisulfites dominate:

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 \xrightleftharpoons{pK=1.81} H^+ \; HSO_3^- \xrightleftharpoons{pK=6.91} 2\; H^+ + SO_3^{2-}$$

In acidic aqueous solution, disulfite salts decompose to bisulfites and sulfur dioxide:

$$S_2O_5^{2-} + H^+ \rightarrow HSO_3^- + SO_2$$

The active form is undissociated acid, which is the only form effective against yeasts, therefore sulfur dioxide and sulfites are only effective in acidic foods (pH < 4). In some countries, sulfur dioxide solutions can be used to inhibit the growth of bacteria (although they are less sensitive against yeasts and moulds) on the surface of meat and meat products. The main applications of sulfur dioxide and sulfites concern the growth inhibition of acetic acid and lactic acid bacteria and wild yeasts in wine. The levels of $Na_2S_2O_5$or $K_2S_2O_5$ (sodium or potassium metabisulfite) and/or $KHSO_3$ (potassium bisulfite) compounds allowed by the European Union for some types of wine vary from 160 to 260 mg/l. Other applications are related to protecting the fruit from the growth of moulds. Sulfur dioxide acts against certain bacteria in concentrations of around 1–2 mg/l, which is a bacteriostatic effect, but at higher concentrations its effect is bactericidal. Concentrations of 1–10 mg/l (at pH 3.5), for example, inhibit the lactic acid fermentation of fruit products. Concentrations inhibiting yeasts (*Saccharomyces cerevisiae*) and moulds vary from 0.1 to 20 mg/l. The amounts of sulfur dioxide (sulfite) used may range, according to the type of food, from 10 to 2000 mg/kg.

Sulfur dioxide in foods yields a number of addition products with simple aldehydes, ketones and also with sugars (e.g. in wine), allyl isothiocyanate (e.g. in mustard) and a number of other food constituents in which it is reversibly bound. Aliphatic aldehydes form adducts with sulfur dioxide (bisulfites), whereas ketones are found predominantly in their free form. Reactions with sugars and their degradation products are described in Section 4.7.5.11. Sulfur dioxide also forms irreversibly bound forms, which are very stable. These products are formed with some sugar degradation products in the non-enzymatic browning reactions (see Section 4.7.1), oxidised phenols (such as chlorogenic acids, see Section 9.12.4) and also with proteins and peptides containing disulfide bonds, which are cleaved with the formation of thiosulfates (*S*-sulfonates, R–S–SO_3^-). In this reaction the cleavage of disulfide

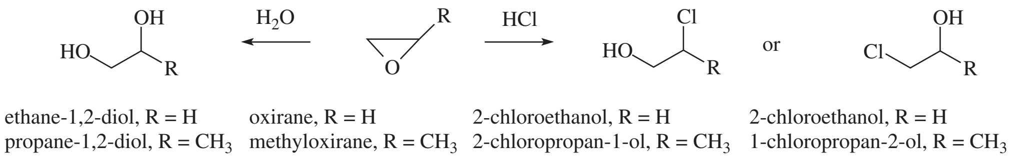

Figure 11.3 Reactions of oxiranes with water and hydrogen chloride.

bonds is produced by a nucleophilic displacement mechanism to form thiols and *S*-sulfonates:

$$R–S–S–R + SO_3^{2-} \rightarrow R–S–SO_3^- + RS^-$$

Sulfur dioxide (bisulfites) also reacts with thiamine yielding inactive compounds (see Section 5.6.6), forms adducts with riboflavin, nicotinamide, vitamin K, inhibits ascorbic acid oxidation (see Section 5.14.6.1.6) and reacts with ascorbic acid degradation products, reduces *o*-quinones produced in enzymatic browning reactions back to 1,2-diphenols (see Section 9.12.4), causes decolourisation of fruit anthocyanins (see Section 9.4.1.5.7) and reacts with synthetic azo dyes to form coloured or colourless products (see Section 11.4.1.3.2). Sulfur dioxide also reacts with pyrimidine bases *in vitro*, specifically with cytosine and 5-methylcytosine. Important reactions of sulfur dioxide are shown in Figure 11.4.

Sulfur dioxide or bisulfites are rarely used in combination with nitrites, because their reactions in acidic media yield sulfonates of either hydroxylamine or ammonia, which destroys the preservative activity of the individual additives. The reaction of alkali metal nitrites with bisulfite at lower temperatures leads to the formation of hydroxylamine *N*, *N*-disulfonate, $HON(SO_3)_2^{2-}$, which is hydrolysed to hydroxylamine *N*-sulfonate, $HONHSO_3^-$ and further to hydroxylamine (H_2NOH). At elevated temperatures complete substitution proceeds with the formation of ammonia *N*, *N*, *N*-trisulfonate, $N(SO_3)_3^{3-}$, which is hydrolysed to sulfamate, $H_2NSO_3^-$. Subsequent reaction of sulfamate with nitrous acid leads to production of bisulfate ion and nitrogen gas:

$$NO_2^- + 2HSO_3^- \rightarrow HON(SO_3)_2^{2-} + HO^-$$
$$HON(SO_3)_2^{2-} + H_2O \rightarrow HONHSO_3^- + HSO_4^-$$
$$HONHSO_3^- + H_2O \rightarrow H_2NOH + HSO_4^-$$
$$HON(SO_3)_2^{2-} + HSO_3^- \rightarrow N(SO_3)_3^{3-} + H_2O$$
$$N(SO_3)_3^{3-} + 2H_3O^+ \rightarrow H_2NSO_3^- + 2H_2SO_4$$
$$H_2NSO_3^- + HNO_2 \rightarrow N_2 + HSO_4^- + H_2O$$

11.2.1.3.2 Nitrites

In addition to use for meat colour stabilisation (see Section 9.3.1.5.2), nitrites (NO_2^-, E249 and E250), together with salt (sodium chloride), can also be used as antimicrobial agents. Their use is especially important in non-sterile meat products, as they inhibit the growth of *Clostridium botulinum* bacteria. The efficiency of the inhibition depends on pH, because it is proportional to the concentration of nitrous acid (HNO_2) formed from nitrites. Nitrates (NO_3^-) may also be used as preservatives, namely sodium nitrate (E251), known as Chile saltpetre, and potassium nitrate (E252), or saltpetre, that are reduced to nitrites by microorganisms.

11.2.1.3.3 Boric acid and its salts

Boric acid (H_3BO_3, E284) and disodium tetraborate ($Na_2B_4O_7$), known as borax (E285) are permitted for use as preservatives in some countries and in the EU are only approved to preserve caviar. Their preservative effect is based on inhibition of decarboxylases of amino acids and inhibition of phosphate metabolism.

11.2.1.3.4 Sodium chloride

Sodium chloride (NaCl) is commonly used in combination with other preservatives and preservation methods, but is not classified as a food additive. The antimicrobial activity of sodium chloride is related to its ability to reduce water activity, thus creating unfavourable conditions for microbial growth (sucrose is similarly active). The sensitivity of microorganisms varies considerably. Intolerant bacteria can be inhibited by a level of 10 g/kg, mesophilic bacteria and psychrotropic gram-negative rods tolerate

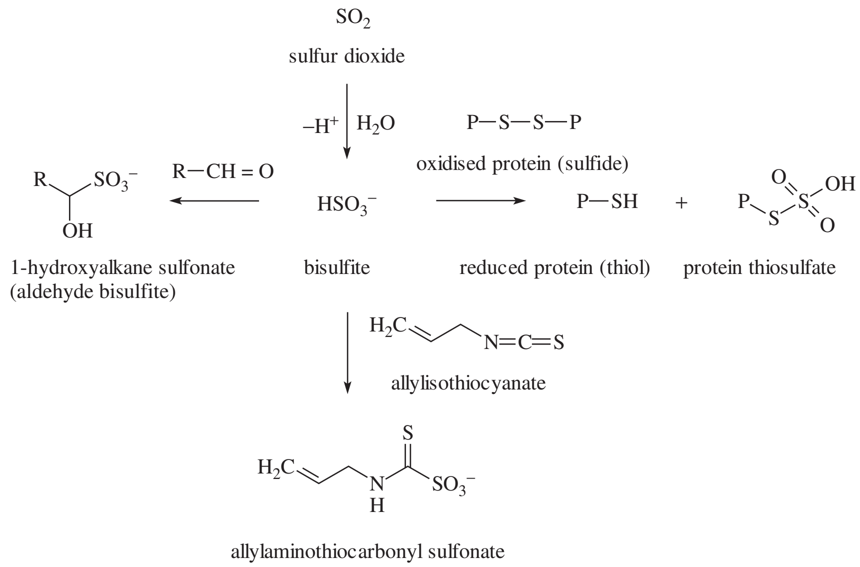

Figure 11.4 Important reactions of sulfur dioxide in foods.

concentrations 6–10 times higher, lactic bacteria survive in an environment where the concentration of sodium chloride ranges from 60 to 150 g/kg and spore-forming bacteria can even tolerate sodium chloride concentrations of 160 g/kg.

11.2.1.3.5 Other inorganic substances

Inorganic compounds exhibiting antimicrobial activity also include hydrogen peroxide, phosphates or carbon dioxide, which is effective against fungi and gram-negative psychrotropic bacteria, but lactic acid bacteria and anaerobes are less inhibited.

11.2.1.4 Legislation

Compounds that are conditionally permitted for food preservation in the EU are listed in Table 11.3. All preservatives may only be used for the preservation of listed foods and to the maximum amount allowed.

Benzoic acid and its salts can be used for jams, jellies and marmalades, either alone or in mixtures with sorbic acid. Benzoic acid in quantities of up to 30 mg/kg in fermented dairy products is not considered a food additive, as it arises from the hippuric acid (see **2-17**). For example, the maximum permissible level of benzoic acid for cooked red beet is 2000 mg/kg, and for cooked crustaceans and molluscs 1000 mg/kg. Sorbic acid alone is allowed, for example, for potato dough, pre-fried potato slices and processed cheeses (2000 mg/kg), dried fruit and gnocchi (1000 mg/kg) and wines (200 mg/l). Spirits with less than 15% alcohol by volume can contain a mixture of benzoic acid (200 mg/l) and sorbic acid (200 mg/l), olives and olive-based preparations may contain benzoic acid (500 mg/kg) and sorbic acid (1000 mg/kg). Sorbic acid with *p*-hydroxybenzoates or their salts may be used, for instance, in preserved jelly coatings of meat products and cereal- or potato-based snacks and coated nuts (1000 mg/kg).

The use of propionic acid and its salts are allowed for pre-packed sliced bread and rye bread (3000 mg/kg), and for energy reduced bread, partially baked, pre-packed bread and pre-packed fine bakery wares (including flour confectionery) with a water activity of more than 0.65 (2000 mg/kg). Fermented milk products (Emmental type cheeses) contain natural propionic acid arising in the fermentation process, which is not regarded as a food additive.

Nisin can be used for semolina and tapioca puddings and similar products (3 mg/kg), ripened and processed cheeses 12.5 mg/kg) and Mascarpone cheese (10 mg/kg). Natamycin may be used for surface treatment of hard, semi-hard and semi-soft cheeses and dried, cured sausages (1 mg/dm^2 surface up to a depth of 5 mm). Lysozyme is used in *quantum satis* (a Latin term meaning the amount, which is needed), for example, to preserve ripened cheeses.

Table 11.3 List of current EU approved preservatives and their E-numbers.

E-number	Name[a]	E-number	Name[a]
E200	Sorbic acid	E228	Potassium hydrogen sulfite
E202	Potassium sorbate	E230	Biphenyl (diphenyl)
E203	Calcium sorbate	E234	Nisin
E210	Benzoic acid	E235	Natamycin
E211	Sodium benzoate	E239	Hexamethylenetetramine
E212	Potassium benzoate	E242	Dimethyl dicarbonate
E213	Calcium benzoate	E249	Potassium nitrite
E214	Ethyl *p*-hydroxybenzoate	E250	Sodium nitrite
E215	Sodium ethyl *p*-hydroxybenzoate	E251	Sodium nitrate
E218	Methyl *p*-hydroxybenzoate	E252	Potassium nitrate
E219	Sodium methyl *p*-hydroxybenzoate	E280	Propionic acid
E220	Sulfur dioxide	E281	Sodium propionate
E221	Sodium sulfite	E282	Calcium propionate
E222	Sodium hydrogen sulfite	E283	Potassium propionate
E223	Sodium metabisulfite	E284	Boric acid
E224	Potassium metabisulfite	E285	Sodium tetraborate (borax)
E226	Calcium sulfite	E1105	Lysozyme
E227	Calcium hydrogen sulfite		

[a]Directive No. 95/2/EC of 20 February 1995 on food additives other than colours and sweeteners.

Biphenyl is only used for the surface treatment of citrus fruits. Hexamethylenetetramine is only approved for preservation of Provolone cheese that originates in Casilli near Napoli. A variant of Provolone cheese is also produced in North America and Japan. In the past, hexamethylenetetramine was also used as a preservative for collagen casings and fish products. Dimethyl dicarbonate is allowed for non-alcoholic flavoured drinks, alcohol-free wine and liquid-tea concentrates at the amount of 250 mg/l.

The maximum level of sulfur dioxide and sulfites (expressed as SO_2) differ significantly in the individual foodstuffs. For example, SO_2 content in peeled potato can be 50 mg/kg, 100 mg/kg in processed potatoes (including frozen and deep-frozen potatoes), potato dough, dried mushrooms and jams, jellies and marmalades made with sulfited fruit, 200 mg/kg in dried tomato, 400 mg/kg in dried white vegetables and dehydrated potato, 450 mg/kg in burger meat with a minimum vegetable and/or cereal content of 4% and in breakfast sausages, 600 mg/kg in dried apples and pears, 1000 mg/kg in dried bananas and 2000 mg/kg in dried apricots, peaches, grapes, prunes and figs. Under EU law, any wine containing more than 10 mg/l of SO_2 must be labelled as 'containing sulfites'. The maximum permitted levels of SO_2 are 160 mg/l in red wines, 200 mg/l in rose and white wines and 400 mg/l in sweet wines. In beer, including low-alcohol and alcohol-free beer, where SO_2 arises through yeast activity, its content may be up to 20 mg/l, and even 50 mg/l in beer when there is a second fermentation in the cask.

The maximum amount of nitrites that may be added during the manufacture of meat products and sterilised meat products is 150 mg/kg and 100 mg/kg (expressed as $NaNO_2$), respectively. The maximum residual levels are also set. Potassium and sodium nitrates can be used for non-heat-treated meats at a level of 150 mg/kg, and at 300 mg/kg for traditional immersion cured meat speciality products (such as, British Wiltshire bacon and Wiltshire ham, German *Rohschinken* and Spanish *jamón curado*).

Boric acid and borax are only allowed for caviar at a level of 4 g/kg (expressed as boric acid).

11.2.1.5 Health assessment

Benzoic acid and benzoates have low toxicity, and an amount of 5–10 g administered over several days does not have adverse effects (ADI = 5 mg/kg bodyweight). This is because there is an effective detoxification mechanism, consisting of conjugation of benzoates with glycine to hippuric acid, which is excreted in the urine. Around 66–95% of benzoates can be removed in this way, with the rest taking the form of glucuronate. Some individuals, however, show increased sensitivity to benzoic acid. Sorbic acid (also sorbates) is regarded as one of the least toxic preservatives (ADI = 25 mg/kg bodyweight), but in cosmetic and pharmaceutical products may irritate the skin in susceptible individuals. Parabens and the corresponding free acid are even less toxic than sorbic acid (ADI = 70 mg/kg bodyweight), but they are rapidly hydrolysed and the free acid is excreted as a conjugate with glycine and glucuronic acid. Parabens exhibit local anaesthetic effects and may cause dermatitis in susceptible individuals. The intake of propionic acid is not limited. The use of formic acid (ADI = 3 mg/kg bodyweight) is prohibited in food preservation in some countries (including the EU) and formic acid (as well as methanol from which formic acid arises through the action of alcohol dehydrogenase via formaldehyde) is known to be toxic to the optic nerve (see Section 8.2.2.2).

Nisin is authorised for food preservation in the EU. For nisin, an ADI equal to 0.13 mg/kg of body weight, and for natamycin an ADI equal to 0.3 mg/kg of body weight have been set. In 2003, the European Parliament announced that nisin should not be used because of possible worsening effect of antibiotics on humans, but the Scientific Panel on Food Additives, Flavourings, Processing Aids and Materials in Contact with Foods (AFC Panel) approved the use of nisin as a food additive in 2006. This substance is also permitted in the United States.

For the antifungal phenols, ADI = 0.05 mg/kg body weight for biphenyl and 0.2 mg/kg body weight for *o*-phenylphenol and its sodium salt have been determined. Hexamethylenetetramine may liberate free formaldehyde in the stomach. Both hexamethylenetetramine (ADI = 0–0.15 mg/kg body weight) and formaldehyde (ADI = 0.15 mg/kg body weight) have been shown to act as mutagens in *Drosophila*. Acute and short-term toxicological studies on spinacine led to an ADI = 3 mg/kg body weight. It was concluded that there is no appreciable health risk from consumption of cheese made using formaldehyde (Grana Padano cheese) or hexamethylenetetramine (Provolone cheese). The ADI value for dimethyl dicarbonate was not determined, as this ester decomposes when dissolved in the product.

Bisulfites are oxidised in the body by sulfite oxidase (sulfite: ferricytochrom c oxidoreductase) to sulfates, which are excreted in the urine. The enzyme activity is individual, and toxic effects of sulfur dioxide and sulfites are therefore variable. Some individuals tolerate amounts of up to 50 mg/kg, while in sensitive individuals such concentrations will cause headaches, nausea and diarrhoea. In asthmatics receiving steroids, sulfites may cause allergic reactions (ADI = 0.7 mg/kg body weight).

Health and toxicological evaluation of nitrates and nitrites is given in detail in Section 6.7.1.2. ADI values of 3.7 mg/kg body weight for nitrates and 0.07 mg/kg body weight for nitrites have been set. Nitrites can induce tumours either directly through effects on immune functions or indirectly via carcinogenic *N*-nitrosamines produced from nitrites and secondary amines. Repeated consumption of higher amounts of nitrites may cause methaemoglobinaemia, especially in children.

Boric acid and borax (ADI = 0.1 mg/kg body weight) resorb rapidly in the body and are slowly excreted. In comparison with other acids, which act as preservatives, these compounds are more toxic, but no side effects are known from foods. Concentrations of boric acid (borates) in pharmaceutical preparations are much higher and may cause several side effects. Chronic administration causes bleeding, dermatitis and anaemia.

11.2.2 Antioxidants

Antioxidants are substances that prolong the shelf life of foods by protecting them against deterioration caused by oxidation, which is reflected in rancidity in fats and other easily oxidising food components. Lipid oxidation causes other chemical changes in foods that negatively affect their nutritional value (oxidation of vitamins), sensory value (oxidation of flavour-active components

Table 11.4 List of current EU approved antioxidants and their E-numbers.

E-number	Name[a]	E-number	Name[a]

[b]Ascorbic acid (E300) is classified as a food supplement.

and pigments) and hygienic–toxicological quality (some oxidation products may be toxic). On the other hand, the oxidation of essential fatty acids also generates desirable aromas in certain foods (fruits, vegetables and mushrooms (see Section 3.8.1.8.5).

11.2.2.1 Classification

Antioxidants interfere with the process of oxidation of lipids and other oxylabile compounds so that they:

- react with free radicals (**primary antioxidants**) or reduce the resulting hydroperoxides (**secondary antioxidants**)
- bind to catalytically active metal complexes
- eliminate the oxygen present.

The reaction mechanism is detailed in the section dealing with the oxidation of lipids (see Section 3.8.1.8). The primary antioxidants include all authorised substances: ascorbic acid and erythorbic (isoascorbic) acid and their derivatives, tocopherols and phenolic antioxidants (Table 11.4). The secondary antioxidants include, for example, cysteine, cysteine-containing peptides (such as glutathione), methionine, lipoic acid and other naturally occurring compounds, which are not however used as antioxidants. A synthetic secondary antioxidant used in the past was 3,3′-thiodipropionic acid dilaurate (**11-7**).

Equally important is the classification of antioxidants according to their origin, through which are identified:

- **natural antioxidants**
- **synthetic antioxidants**.

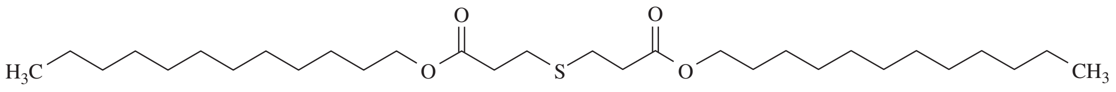
The authorised natural antioxidants include tocopherols, which today are usually synthesised. A variety of other natural antioxidants are present in a number of essential oils and other fats (especially in spices). However, they do not usually have a constant composition, tend to be less effective and are more expensive than synthetic antioxidants.

According to their structure the following may be recognised:

- **phenolic** antioxidants (of approved natural substances including tocopherols and phenolic antioxidants, but also a number of other compounds present in foods, spices and other natural materials);
- **enediols** (of approved compounds, enediols include ascorbic and erythorbic acids, their salts and other derivatives);
- **other substances**.

11.2.2.2 Mechanism of action

The mechanism of action of ascorbic acid and its derivatives is given in Section 5.14.6.1.4, and the mechanism of action of tocopherols is described in Section 5.4.6. Phenolic compounds (Ar–OH) as primary antioxidants may interfere with the oxidation of lipids (R–H) in a reaction in competition with the propagation phase reaction of autoxidation. They react with hydroperoxyl radicals



11-7, didodecyl-3,3′-thiodipropionate

($ROO^\bullet$) produced by lipid oxidation, or with alkoxyl radicals ($RO^\bullet$) arising by decomposition of lipid hydroperoxides. They provide these radicals with hydrogen, thereby interrupting the radical chain autoxidation reaction. The resulting products are phenoxyl (aryloxyl) radicals of antioxidants:

$$\text{Ar–OH} + \text{R–O–O}^\bullet \rightarrow \text{R–O–OH} + \text{Ar–O}^\bullet \text{ or}$$
$$\text{Ar–OH} + \text{R–O}^\bullet \rightarrow \text{R–OH} + \text{Ar–O}^\bullet$$

These free radicals react with hydroperoxyl and alkoxyl radicals of oxidised fatty acids in the termination phase of the reaction:

$$\text{R–O–O}^\bullet + \text{Ar–O}^\bullet \rightarrow \text{R–O–Ar} + \text{O}_2$$
$$\text{R–O}^\bullet + \text{Ar–O}^\bullet \rightarrow \text{R–O–O–Ar}$$

The reaction mechanism is shown in Figure 11.5. Phenoxyl radicals, however, cannot enter the chain radical reaction and cannot initiate the fission of other lipid molecules. These reactions, however, may occur at high concentrations of an antioxidant, which then acts as a pro-oxidant as follows:

$$\text{Ar–O}^\bullet + \text{R–O–OH} \rightarrow \text{Ar–OH} + \text{R–O–O}^\bullet$$
$$\text{Ar–O}^\bullet + \text{R–H} \rightarrow \text{Ar–OH} + \text{R}^\bullet$$

The relative stability and low reactivity of phenoxyl radicals is associated with the unpaired electron delocalisation in the aromatic system. The attack of atmospheric oxygen can be therefore very difficult. This situation is apparent, for example, in unsubstituted phenol, which is ineffective as an antioxidant. Recombination of phenoxyl radicals produces a number of dimeric and oligomeric products (Figure 11.6). Reported products from oxidation of phenol with molecular oxygen and ozone include a range of aromatic compounds, such as *o*-benzoquinone, *p*-benzochinone, catechol and hydroquinone and aliphatic compounds, such as maleic anhydride, maleic, fumaric, propionic, oxalic, glyoxylic, acetic and formic acid, carbon dioxide and carbon monoxide.

Substitution of phenol by alkyl groups in the *ortho* or *para* positions increases (by the conjugation effect) the density of electrons on the OH group, which increases the ability of phenol to react with free radicals. Stability of the resulting phenoxyl radical increases further in the presence of bulky substituents in the *ortho* position. Such antioxidants include the phenolic synthetic antioxidants BHA and BHT.

The antioxidant activity of phenol is also increased by the presence of additional hydroxyl group in the *ortho* or *para* positions. An example of such an antioxidant is TBHQ. The effectiveness of 1,2-dihydroxybenzene derivatives is attributed to a phenoxyl radical stabilised by an intramolecular hydrogen bond (**11-8**). The activity of 2-methoxyphenol is lower, because the generated radical cannot be stabilised by a hydrogen bond. The antioxidant activity of 1,2- and 1,4-dihydroxybenzene is partly caused by the fact that the semi-quinone radical can be further oxidised to the corresponding *o*-quinone or *p*-quinone, respectively, by reaction with another lipid radical (Figure 11.7) or may disproportionate to the corresponding quinone and hydroquinone.

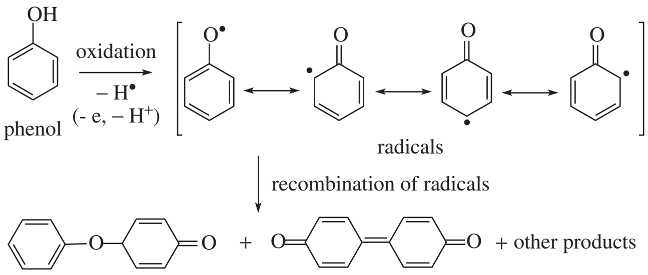


Figure 11.6 Mechanism of phenol oxidation.

11-8, stabilised radical of 1,2-dihydroxybenzene

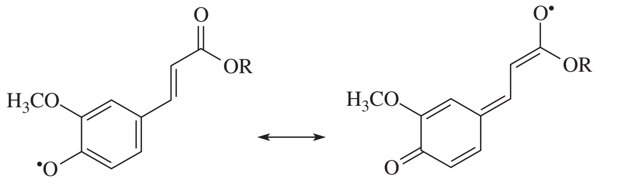

Figure 11.8 Stabilised radicals of 4-hydroxycinnamic acids.

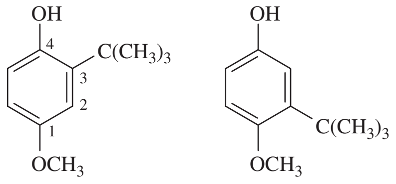
Primary antioxidants also include phenolic acids, in particular the substituted cinnamic acids and their esters (depsides), glycosides and amides. The phenoxyl radical of very effective 4-hydroxysubstituted cinnamic acids is stabilised by resonance (Figure 11.8). Many flavonoid substances are also primary antioxidants. Particularly effective compounds are chalcones, which provide resonance stabilised radicals (Figure 11.9).

11.2.2.3 Synthetic antioxidants

Modern antioxidant technology is merely about 70 years old. Only four synthetic antioxidants are widely used in foods, namely the phenolic antioxidants BHA, BHT and diphenol TBHQ (which are antioxidants of low polarity), while more polar antioxidants are esters of gallic acid (gallates) and esters of ascorbic acid. Polar antioxidants are ascorbic and erythorbic acids and their salts. Ascorbic acid, its derivatives and its analogue erythorbic (isoascorbic) acid are described in Section 5.13.1.

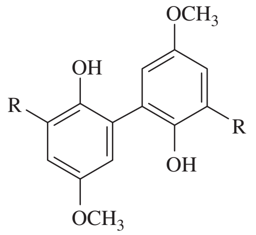
11.2.2.3.1 BHA

Commercial butylated hydroxyanisole (BHA, E320) is a mixture of two isomers. The mixture contains approximately 90% (at least 88%) 3-*tert*-butyl-4-hydroxyanisole (3-BHA) and about 10% 2-*tert*-butyl-4-hydroxyanisole (2-BHA, **11-9**). BHA is particularly effective for the protection of lipids containing fatty acids with shorter chains (in coconut and palm kernel oils) and in the aroma and colour of essential oils. Like BHT, BHA is often used in packaging materials, where it can migrate into food. Both compounds may (in contrast to the low volatile gallates) show slight odour reminiscent of phenols. BHA exhibits synergism with BHT and gallates, and in comparison with BHT it displays a somewhat higher so-called carry-through effect, which means that it is also effective as an antioxidant in the final heat treated product.

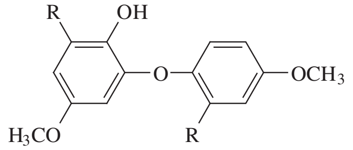


11-9, 3- *tert*-butyl-4-hydroxyanisol and 2-*tert*-butyl-4-hydroxyanisol (BHA)

As with all other antioxidants, BHA undergoes some transformation reactions during oxidation of lipids. The most common products are dimers, biphenyls (**11-10**) and their ethers (**11-11**). Most primary oxidation products still preserve the antioxidant activity.



11-10, 2,2′-dihydroxy-5,5′-dimethoxy-3, 3′-di-*tert*-butylbiphenyl, R = *tert*-butyl



11-11, 2′–,3-di-*tert*-butyl-2-hydroxy-4′, 5-dimethoxydiphenylether, R = *tert*-butyl

11.2.2.3.2 BHT

Butylated hydroxytoluene (BHT, also formerly known as Ionol, E321) is 3,5-di-*tert*-butyl-4-hydroxytoluene (**11-12**). In comparison with BHA, BHT is somewhat more effective as an antioxidant of animal fats. The formation of a BHT radical and its reactions are shown in Figure 11.10.

Important degradation products of BHT, which are also active as antioxidants, are 3,5-di-*tert*-butyl-4-hydroxybenzaldehyde (**11-13**) and 3,5,3′5′-tetra-*tert*-butyl 4,4′-dihydroxy-1,2-diphenylethane

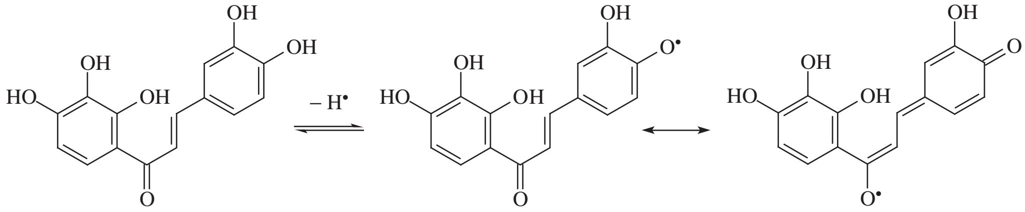


Figure 11.9 Stabilised radicals of chalcones.

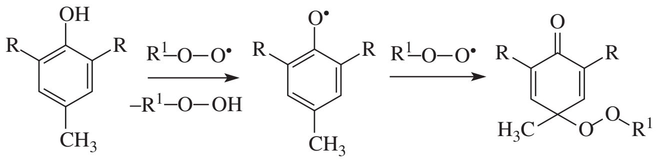

Figure 11.10 Reactions of BHT radical with hydroperoxyl radicals (R = *tert*-butyl).

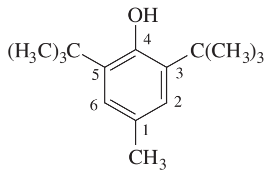
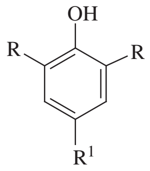
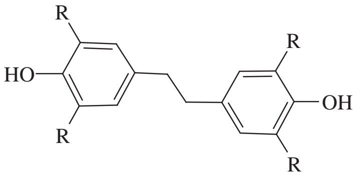
(**11-14**). In addition to these products, lower amounts of other phenols (**11-13**), quinones (**11-15**) and stilbenes (**11-16**) are formed. In addition to these products, mixed products (**11-17**) arise in mixtures of BHT and BHA.



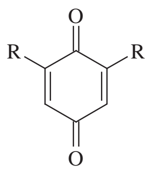
11-12, BHT



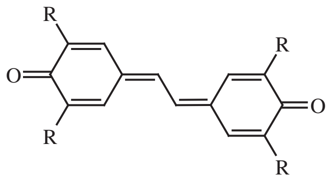
11-13, 3,5-di-*tert*-butyl-4-hydroxybenzaldehyde, R = *tert*-butyl, R^1 = CH = O
3,5-di-*tert*-butyl-4-hydroxybenzylalcohol, R = *tert*-butyl, R^1 = CH_2OH



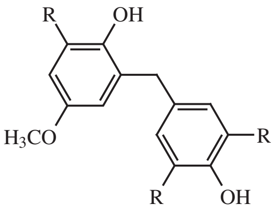
11-14, 1,2-di (3,5-di-*tert*-butyl-4-hydroxyphenyl)ethane, R = *tert*-butyl



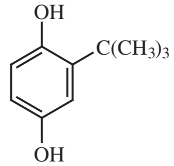
11-15, 2,6-di-*tert*-butylbenzoquinone, R = *tert*-butyl



11-16, 3,5,3´,5´-tetra-*tert*-butylstilbenequinone, R = *tert*-butyl



11-17, 3,3′ ,5′ -tri-*tert*-butyl-5-methoxy-2,
4′ -dihydroxydiphenylmethane, R = *tert*-butyl

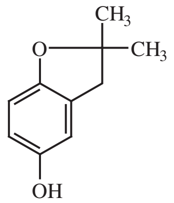


11-18, TBHQ

11.2.2.3.3 TBHQ

TBHQ (E319), 2-*tert*-butylhydroquinone (**11-18**), is the only diphenol used as an antioxidant. TBHQ is more effective in vegetable oils than BHA and BHT and is one of the best antioxidants designated for fats used for frying. Its carry-through effect is comparable with that of BHA. A further increase of TBHQ antioxidant activity, especially for the protection of vegetable oils, is possible in combination with chelating agents (such as citric acid). For example, a ternary mixture of TBHQ, monoacylglycerol citrate and ascorbyl palmitate exhibits high thermal stability and provides optimum protection in oils during high-temperature processing. In European countries and Japan, the addition of TBHQ to foods is not allowed.

As the diphenol antioxidant, TBHQ reacts with hydroperoxyl radicals to form semi-quinone radicals stabilised by resonance. These intermediates yield dimers and the original hydroquinone regenerates by dismutation. The intermediates can also react with other lipid radicals. The reaction is shown in Figure 11.11. All degradation products of TBHQ exhibit antioxidant activity, 2,3-dihydro-2,2-dimethylbenzofuran-5-ol (**11-19**) and 2-(2-hydroxy-2-methyl-1-propyl)hydroquinone (**11-20**) have even higher antioxidant activity than TBHQ.



11-19, 2,3-dihydro-2,2-dimethylbenzofuran-5-ol

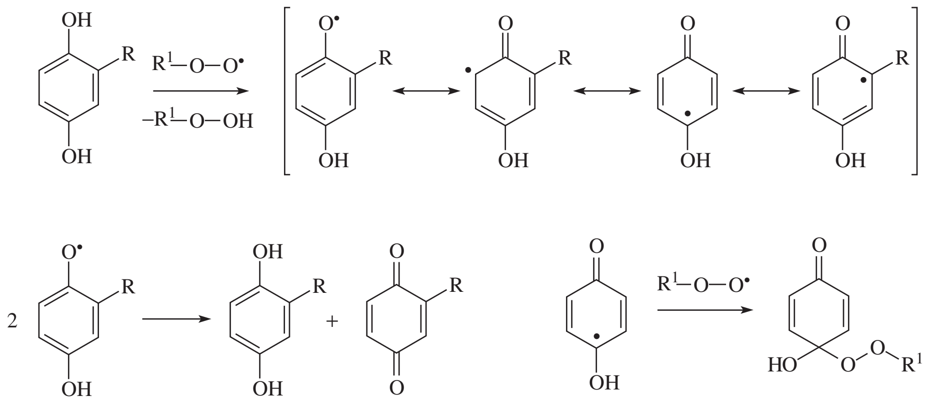


Figure 11.11 Reactions of TBHQ radicals with hydroperoxyl radicals (R = *tert*-butyl).

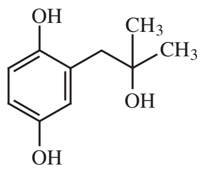
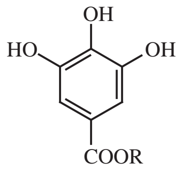


11-20, 2-(2-hydroxy-2-methyl-1-propyl)hydroquinone

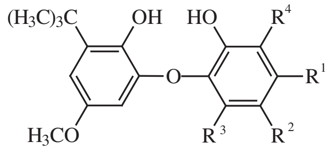
11.2.2.3.4 Gallates

Various esters of gallic acid, gallates (**11-21**), are found in small amounts in foods of plant origin. Only three esters can be used as antioxidants in the EU: propyl gallate (E310), octyl gallate (E311) and dodecyl gallate (E312). Propyl gallate is the only gallic acid ester permitted in foods in the United States and Canada. The antioxidant activity of gallates, which are more polar compounds than BHA, BHT and TBHQ, is higher in anhydrous fats or fats with minimum moisture, which is related to the solubility of gallates in the two phases, the oil and water. Propyl gallate is therefore suitable, for example, for the stabilisation of animal fats (e.g. lard and tallow). Gallates are more soluble in emulsions, but are less active than phenolic antioxidants BHA and BHT.



11-21, propyl gallate, R = $CH_2CH_2CH_3$
octyl gallate, R = $CH_2[CH_2]_6CH_3$
dodecyl gallate, R = $CH_2[CH_2]_{10}CH_3$

Propyl gallate is a relatively unstable compound, and is therefore not suitable for fats used for frying (where the temperature exceeds 190 °C). For the same reason, propyl gallate has a weak carry-through effect (unlike octyl gallate and dodecyl gallate). Propyl gallate forms blue–black complexes with iron and copper ions; therefore it is always used in combination with chelating agents (such as citric acid). Gallates exhibit synergism with BHA and BHT, but to use them together with TBHQ is illegal in the United States. One of the major degradation products arising from propyl gallate is ellagic acid (see Section 8.3.5.1), which also has antioxidant properties. In mixtures of propyl gallate with BHA, in addition to degradation products of propyl gallate and BHA, mixed dimers also arise with activity comparable to that of propyl gallate (**11-22**).

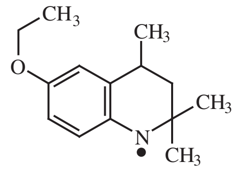


11-22, propyl-3,5-dihydroxy-4-(2-hydroxy-5-methoxy-3-*tert*-butylphenoxy)benzoate, R^1 = $COOCH_2CH_2CH_3$, R^2 = R^4 = H, R^3 = OH
propyl-3,4-dihydroxy-5-(2′-hydroxy-5′-methoxy-3′-*tert*-butylphenoxy)benzoate, R^1 = R^3 = H, R^2 = $COOCH_2CH_2CH_3$, R^4 = OH

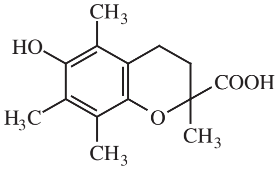
11.2.2.3.5 Other antioxidants

Antioxidants with a nitrogen heterocycle (such as dihydropyridine or dihydroquinoline derived compounds) are far less frequently used, because of their higher toxicity. An example of such an antioxidant is santokin (6-ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline), which is used by the feed industry. The active form in fats is a free radical (**11-23**). The water-soluble analogue of α-tocopherol, 6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid with the trade name trolox (**11-24**) has found use in biological, biochemical and food research. It is mainly used as a standard for measuring antioxidant capacities of other compounds. Many other antioxidants are used in cosmetics, the petrochemical industry and elsewhere.

Synthetic antioxidants (4-hexylresorcinol, see Section 10.2.3.4) and natural antioxidants approved in the EU as food additives, such as ascorbic acid, its salts, fatty acid esters and analogues (erythorbic acid) and tocopherols are included in Chapter 5. Natural compounds with antioxidative activity occurring in herbs and spices, including the extracts of rosemary (E392), are addressed in Section 10.3.3.7.



11-23, santokin



11-24, trolox

11.2.2.4 Legislation

Substances with antioxidant effects (Table 11.4) that may be used in food production in the necessary quantities include fatty acids esters of ascorbic acid (palmitate, stearate, see Section 5.14.4), natural products containing tocopherols and synthetic α-, β-, γ- and δ-tocopherol, which are identical to natural tocopherols, and rosemary extracts.

Erythorbic acid and sodium erythorbate may be used for preserved and semi-preserved fish products and frozen and deep-frozen fish at a concentration of 1500 mg/kg. The amount of these antioxidants allowed for preservation of cured and preserved meat products is only 500 mg/kg (expressed as erythorbic acid). The use of 4-hexylresorcinol (4-hexyl-1,3-benzenediol) is permitted up to 2 mg/kg as a colour retention agent for treatment of crustacean meat (fresh and frozen), namely to prevent black spots arising by enzymatic browning reactions, known as shrimp melanosis,

To a limited extent synthetic esters of gallic acid (propyl gallate, octyl gallate and dodecyl gallate) and phenolic antioxidants – butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) - may be used. When combinations of these antioxidants are used, the individual levels must be reduced proportionally, so that the sum of the individual antioxidants does not exceed the maximum amount of the individual antioxidants allowed for that food. For example, the maximum permissible amount of gallates and BHA is 200 mg/kg and 100 mg/kg for BHT in fats and oils for the professional manufacture of heat-treated foodstuffs, frying oil and frying fat, excluding olive pomace oil, fish oil, lard, beef, poultry and sheep fat. Dehydrated potatoes may only contain 25 mg/kg of gallates and BHA, individually or in combination, while chewing gums may contain 400 mg/kg of these antioxidants or BHT.

11.2.2.5 Health assessment

The ADI value for tocopherols is 0.15–2 mg/kg body weight. Vitamin E can cause several side effects in high concentrations that are not associated with the use of tocopherols as additives, but as vitamin supplements. A higher single dose of α-tocopheryl acetate (400–500 mg) could cause negative effects manifested by a higher intake of iodine by the thyroid gland. Dietary supplements containing amounts of about 1000 mg/day are therefore not recommended. No side effects are known to be caused by erythorbic acid and sodium erythorbate in the concentrations that are commonly used. The ADI value has not been established for 6-hexylresorcinol. There is negative evidence of carcinogenesis, and no significant untoward effects were observed in humans when it was used as an anthelmintic agent.

The toxicological evaluation of phenolic antioxidants is not yet entirely definitive. The only problem with the use of BHA (ADI = 0–0.5 mg/kg body weight, Group 2B agent possibly carcinogenic to humans, according to International Agency for Research on Cancer, IARC) seems to be the formation of lesions observed in experimental animals, although some pseudo-allergic reactions have also been reported. BHA in combination with high concentrations of vitamin C can produce free radicals, which can cause damage to the components of cells, including DNA. BHA is excreted in the urine after conjugation as D-glucuronide and sulfate; its oxidation is not significant. At high doses BHT (ADI = 0–0.125 mg/kg body weight, Group 3 agent, not classifiable as to its carcinogenicity to humans) can cause internal bleeding, which is related to its ability to reduce vitamin K. BHT can cause migraine in some people and liver damage in high concentrations; (pseudo)allergic symptoms have also been reported. BHT is metabolised primarily by oxidation of *tert*-butyl groups. TBHQ (ADI = 0–0.2 mg/kg body weight) is not allowed in some countries due to the lack of information on its toxicity (possible mutagenic activity). It is metabolised through oxidation and conjugation (sulfate and glucuronide). Gallates are metabolised after hydrolysis to the corresponding alcohols and gallic acid and methylation of gallic acid to 4-*O*-methylgallic acid. Gallic acid can cause eczema, stomach problems and hyperactivity. Gallates may cause contact dermatitis, which has been observed in bakers and in people handling gallates (ADI of propyl gallate = 0–2.5 mg/kg body weight).

11.3 Substances regulating odour and taste

Substances used for food flavouring are the most comprehensive group of additives. The following main groups are recognised:

- flavourings
- sweeteners
- acidulants and acidity regulators
- bitter substances and stimulants
- flavour enhancers.

11.3.1 Flavourings

Flavourings are substances that affect olfactory and gustatory receptors and induce human perception of smell or taste. They are used to give food taste and/or odour that would otherwise be absent or is not present in a characteristic intensity. Individual compounds responsible for the odour and taste of food raw materials and foods are described in detail in Sections 8.2 and 8.3, respectively.

11.3.1.1 Legislation

EU legislation defines different types of flavourings, such as:

- natural flavourings, that are derived from natural materials using physical, biotechnological (biochemical and microbiological) and other procedures;
- natural-identical, which are obtained by synthesis, but they are identical to substances present in natural materials;
- artificial flavouring substances, which are obtained by synthesis, but are not identical to natural flavouring substances.

In flavourings that are not chemically defined compounds, but mixtures of many substances, the following can be distinguished:

- flavouring preparations obtained by physical, enzymatic or microbiological processes from material of vegetable or animal origin or from other foodstuffs;
- process flavourings, which evolve flavour after heating and are obtained by heating a mixture of mostly amino acids and other nitrogen compounds with sugars or with other compounds for a maximum of 15 min;
- smoke flavourings, extracted from the waste products of the pyrolysis of materials used traditionally for smoked foods.

EU legislation also sets out general rules for the use of flavourings, requirements for labelling and maximum levels for substances, which raise concerns for human health. Flavourings are not substances, which exclusively have sweet, sour, bitter or salty tastes. Legislative regulations list more than 100 plant materials that are classified as foods or spices which, either in themselves or in the form of different products, can be used for food flavouring. Other flavouring substances are allowed in the production of tobacco products.

11.3.1.2 Health assessment

Substances which should not be added as such to food include (in alphabetical order) agaric acid, aloin, capsaicin, coumarin, hypericine, β-asarone, estragole, hydrogen cyanide, menthofuran, methyleugenol, pulegone, safrole, quassin, safrole, teucrin A, α-thujone and β-thujone. Table 11.5 lists the plant materials that contain these natural toxic substances. Examples of maximum levels of these substances naturally present in flavourings and food ingredients with flavouring properties, as well as their occurrence, health assessment and properties, are given in Chapters 9 and 10.

11.3.2 Sweeteners

Naturally occurring sweet substances are almost all monosaccharides (mainly glucose and fructose), disaccharides (sucrose and lactose) and sugar alcohols known as glycitols (such as D-glucitol, D-mannitol and xylitol) and other compounds. Nutritionists classify these sweet substances as dietary (nutritional) sweeteners because they are a source of energy and therefore have a certain nutritional value. With the exception of sugar alcohols, which are weakly cariogenic (D-glucitol and D-mannitol) or non-cariogenic (xylitol) and have little or no effect on blood glucose levels, mono- and disaccharides show cariogenic properties and their dietary intake is also associated with obesity and many other diseases.

Health, nutritional and economic aspects have led to the introduction of many natural, natural-identical and synthetic substances, which are generally characterised by having a higher sweetness than sucrose. Their physical, chemical and organoleptic properties are different from the properties of sugars, which may cause a number of food technology problems in formulation of novel products.

11.3.2.1 Classification

Sweeteners are classified according to their origin into the following groups:

- natural (e.g. thaumatin)
- natural-identical, which include synthetic substances identical to natural (such as sugar alcohols) or modified natural substances (such as neohesperidin dihydrochalcone)
- synthetic (such as saccharin).

From the nutritional point of view, two categories of sweeteners are recognised:

- nutritional (such as sugar alcohols)
- non-nutritional (virtually all other natural, modified natural and synthetic substances).

11.3.2.1.1 Nutritional sweeteners

Monosaccharides, disaccharides, sugar alcohols and other nutritional sweeteners derived from sugars are not considered food additives. These sweeteners are described in detail, including their relative sweetness, in Chapter 4, which deals with carbohydrates.

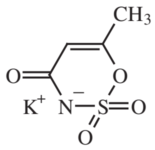
Sweet peptides (such as aspartame), proteins (e.g. thaumatin) and glycosides (stevioside), are a source of some energy, but in the quantities in which they are used, their contribution to the total energy intake is insignificant. These sweeteners are therefore ranked among non-nutritional sweeteners in Section 11.3.2.1.2.

Table 11.5 Main natural toxic compounds in plant materials used for aromatisation of foods and beverages.

Toxic compound	Plant English name	Plant Latin name
Agaric acid	White agaric mushroom	*Laricifomes officinalis*
Aloin	Aloe	*Aloe* spp.
β-Asarone	Calamus (sweet flag)	*Acorus calamus*
Coumarin	Woodruff	*Asperula odorata*
Coumarin	Yellow sweet clover (yellow melilot)	*Melilotus officinalis*
Coumarin	Cumaru	*Dipterix odorata*
Coumarin	Sweet grass	*Hierochloe odorata*
Estragole	Tarragon	*Artemisia dracunculus*
Hydrogen cyanide	Elder	*Sambucus nigra*
Hydrogen cyanide	Plum	*Prunus domestica*
Hypericin	St John's wort	*Hypericum perforatum*
Menthofuran	Peppermint	*Mentha piperita*
Methyleugenol	Clove	*Syzygium aromaticum*
Pulegone	Wrinkled-leaf mint	*Mentha crispa*
Pulegone	Peppermint	*Mentha piperita*
Pulegone	Pennyroyal	*Mentha pulegium*
Quassin	Quassia (bitterwood)	*Quassia amara*
Quinine	Cinchona trees (various species)	*Cinchona* spp.
Safrole and isosafrole	Nutmeg	*Myristica fragrans*
Teucrin A	Wall germander	*Teucrium chamaedrys*
α- and β-Thujone	Mugwort	*Artemisia vulgaris*
α- and β-Thujone	Wormwood	*Artemisia absinthium*
α- and β-Thujone	Santonica	*Artemisia cina*
α- and β-Thujone	Roman wormwood	*Artemisia pontica*
α- and β-Thujone	Tansy	*Tanacetum vulgare*
α- and β-Thujone	Common yarrow	*Achillea millefolium*
α- and β-Thujone	Musk Yarrow	*Achillea moschata*
α- and β-Thujone	Common sage	*Salvia officinalis*

11.3.2.1.2 Synthetic non-nutritional sweeteners

The relative sweetness of chemically modified natural and synthetic sweeteners is shown in Table 11.6.



11-25, acesulfame K

Acesulfame K

Acesulfame K (E950, K being the symbol for potassium) is a potassium salt of 6-methyl-1,2,3-oxa-3*H*-thiazin-4-one 2,2-dioxide (**11-25**). Some trade names are Sunett and Sweet One. This substance (approved in the EU in 1983 and in the USA in 2003 for general use, but not in meat or poultry) is often blended with other sweeteners (usually sucralose or aspartame) to mask its slightly bitter aftertaste. The stability of Acesulfame K makes it suitable for products

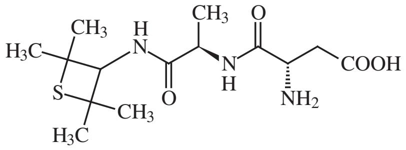
Table 11.6 Relative sweetness of chemically modified and synthetic sweet substances (sucrose = 1).

Compound	Sweetness
Modified substances	
Naringin dihydrochalcone	100–350
Neohesperidin dihydrochalcone	500–2000
(*E*)-Perillaldehyde oxime	350
Synthetic substances	
Acesulfame K	80–250
2-Amino-4-nitro-1-propoxybenzene	4000–5000
Alitame	2000
Aspartame	100–200
Cyclamates	30–60
Dulcin	70–350
Neotame	7000–13 000
Saccharin	200–700
Sucralose	600

that require a long shelf life (it decomposes at temperatures exceeding 235 °C). Acesulfame K is used in many applications and in particular in baked goods and in beverages. In carbonated drinks, it is almost always used in conjunction with another sweetener, such as aspartame or sucralose.

Alitame

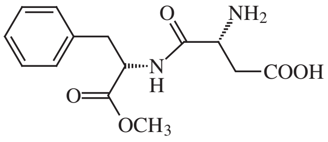
Like aspartame and neotame, alitame (in some countries known as aclame, **11-26**), L-α-aspartyl-*N*-(2,2,4,4-tetramethyl-3-thietanyl)-D-alanine amide, is an aspartic acid-based dipeptide, which is about ten times sweeter than aspartame and has no after-taste. As with aspartame, it is hydrolysed in acidic media, but does not contain bound phenylalanine and can therefore be used by people with phenylketonuria. Alitame is not approved for use in the EU or the USA, but is approved in Australia, China and some other countries.



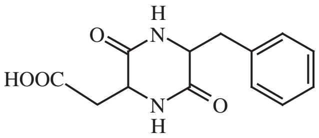
11-26, alitame

Aspartame

Aspartame (E951) is a methyl ester of linear dipeptide L-aspartyl-L-phenylalanine (**11-27**) that was used by several European Union countries in the 1980s, with EU-wide approval in 1994 (and in the United States in 1996 for general purpose). It does not show any after-taste. In non-aqueous media (such as powdered drinks, chewing gum and instant coffee), aspartame is stable. In acidic aqueous solution, depending on the pH and temperature, the ester bond of aspartame can be hydrolysed, creating the corresponding dipeptide (L-aspartyl-L-phenylalanine) and methanol. A product of the dehydration of this linear dipeptides is cyclic dipeptide cyclo-(L-aspartyl-L-phenylalanine, which is a derivative of 2,5-dioxopiperazine (**11-28**). On hydrolysis, dioxopiperazine provides a linear dipeptide, which is further hydrolysed to free aspartic acid and phenylalanine. Aspartame reactions are associated with a decrease in sweetness. Aspartame is therefore not suitable for all foods (especially acidic foods), or for all types of food processing. In non-alcoholic beverages, for example, about 20% or more of aspartame can be degraded at room temperature during four months of storage.



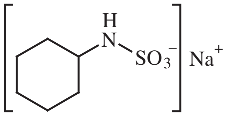
11-27, aspartame



11-28, 3-benzyl-6-carboxymethyl-2,5-dioxopiperazine

Cyclamates

Cyclamates is the generic name for cyclamic (cyclohexylsulfamic) acid and its sodium and calcium salts (E952), sodium cyclamate (**11-29**) and calcium cyclamate, which became popular in the 1950s. In 1958, cyclamate was classified as GRAS (Generally Recognized as Safe) in the United Staes, but it was subsequently banned in 1970 (see Section 11.3.2.3). Cyclamates are stable to heat, but exhibit minor after-taste; therefore they are used as sweeteners in baked goods, confectioneries, desserts, soft drinks, preserves and salad dressings, often in a mixture with saccharin (10 : 1) to produce a synergistic sweetening effect.

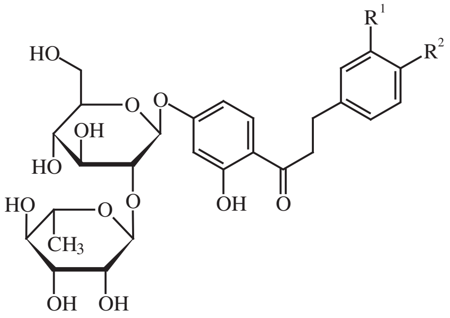


11-29, sodium cyclamate

Dihydrochalcones

A sweet taste is exhibited by some dihydrochalcones (see Section 9.4.2.6), which are obtained by the catalytic reduction of flavanone glycosides neohesperidin and naringin, which contain bound

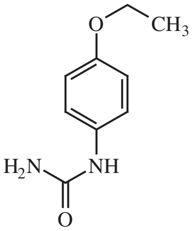
β-neohesperidose, α-L-Rha*p*-(1 → 2)-β-D-Glc*p* (**11-30**) in the C-7 position. Catalytic reduction of neohesperidin (hesperetin-7-neohesperidoside) obtained from bitter oranges yields neohesperidin dihydrochalcone (with β-neohesperidose bound to C-4), which has been approved in the EU as a sweetener since 1994 (E959). Naringin (naringenin-7-neohesperidoside) gives rise to naringin dihydrochalcone. Neohesperidin dihydrochalcone has some properties that limit its use as a sweetener. It has an intense cooling effect on the tongue, liquorice-like and bitter off-tastes that make it decidedly not sucrose-like and is slow in sweet taste onset. Because of these properties, neohesperidin dihydrochalcone is particularly suitable for use in the pharmaceutical industry and in animal nutrition. With respect to its properties as a sweetener and flavouring, neohesperidin dihydrochalcone has applications in sweets, canned vegetables, desserts, sauces and food supplements. Other important fields of neohesperidin dihydrochalcone application are the livestock industry, cosmetics (such as toothpastes) and pharmacy.



11-30, neohesperidin dihydrochalcone, R^1 = H, R^2 = OH
naringin dihydrochalcone, R^1 = OH, R^2 = CH_3

Dulcin

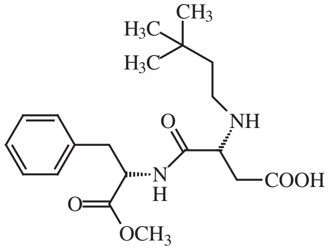
Dulcin (4-ethoxyphenylurea, **11-31**), also known as sucrol or valzin, was an important sweetener of the early 20th century and had an advantage over saccharin, with which in the past it had been used in blends. It has a more pleasant sweet taste and does not possess a bitter after-taste. However, in 1954, animal testing revealed unspecified carcinogenic properties of dulcin, which led to a ban on its use.



11-31, dulcin

Neotame

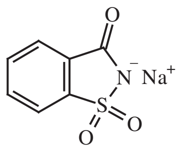
Neotame, *N*-(*N*-(3,3-dimethylbutyl)-L-α-aspartyl)-L-phenylalanine 1-methyl ester (**11-32**), is another sweetener from the family of dipeptides approved in the EU since 2011 as a flavour enhancer (E961) and since 2002 in the US. Neotame is a derivative of the dipeptide composed of aspartic acid and phenylalanine methylester, but unlike aspartame, aspartic acid occurs in the form of 3,3-dimethylbutylamide. Owing to the presence of the 3,3-dimethylbutyl group, peptidases are effectively blocked and the availability of phenylalanine is thus reduced, which is important for people suffering from phenylketonuria. Neotame functions effectively in a wide range of products, such as beverages, desserts, candy, ice creams, bakery goods and many others. It can be used alone or as part of a blend system with other non-nutritive or nutritive sweeteners.



11-32, neotame

Saccharin

Saccharin (E954) is a common name for the corresponding acid, 1,1-dioxo-1,2-benzothiazol-3-one, and its sodium (**11-33**), potassium and calcium salts. Substances in which the group $-SO_2-NH-$ is a part of rings are called sultames. It is the oldest sweetener, and became widespread during World War I (due to the shortage of sugar) and its popularity increased during the 1960s and 1970s among dieters. In the United States it was classified as GRAS. The onset of sweetness from saccharin is rapid. The disadvantage is that it shows faint metallic and bitter after-tastes, but they can be masked by lactose or saccharin may be used in combination with aspartame and other sweeteners. A 10 : 1 cyclamate : saccharin blend is common in countries where both these sweeteners are legal. Saccharin is very stable in foods even during heat treatments. The food industry uses saccharine salts in a variety of food and drinks, such as baked goods, breads and cookies, sweetened diet drinks, sweetened and fruit-flavoured yoghurt, jams, jellies and ice creams.

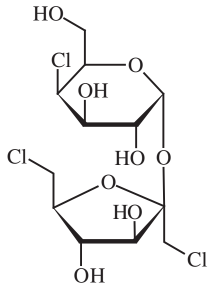


11-33, saccharin (sodium salt)

Sucralose

Sucralose (E955) or chlorogalactosaccharose is a trichloro derivative of a non-reducing disaccharide known as 4,1′,6′-trichloro-4,1′,6′-trideoxygalactosaccharose, or by the systematic

name 1,6-dichloro-1,6-dideoxy-β-D-fructofuranosyl-4-chloro-4-deoxy-α-D-galactopyranoside (**11-34**). In fact, it is a sucrose molecule in which three of the hydroxyl groups have been replaced by chlorine atoms. Sucralose is a relatively new sweetener, which has not yet been introduced in many countries. Sucralose was first approved for use in Canada in 1991, in 1999 as a general-purpose sweetener in the United States and in 2005 in all EU Member States. It appears to be only partially absorbed, which is followed by excretion in the kidneys. The sweet flavour profile is similar to that of sucrose, with a slightly bitter off-taste. Sucralose is resistant to acidic and enzymatic hydrolysis and is stable during thermal operations. At high temperature in aqueous solution, sucralose is hydrolysed to a small extent, producing 4-chloro-4-deoxy-D-galactose and 1,6-dichloro-1,6-dideoxy-D-fructose. Sucralose is widely used by the food, beverage and pharmaceutical industries and can be found in products, such as diet drinks, yoghurts and breakfast cereals.



11-34, sucralose

Other sweet compounds

In the past many other synthetic sweet substances were temporarily used as sweeteners, such as 2-amino-1-propoxy-4-nitrobenzene or 6-chlorotryptofan (about 100 times sweeter than sucrose), and so on. They have not found wider application, in particular due to toxicological reasons.

11.3.2.1.3 Natural non-nutritional sweeteners

Glycyrrhizin

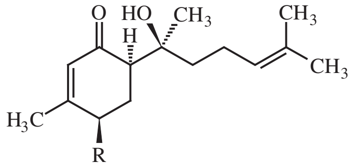
The rhizome of liquorice (*Glycyrrhiza glabra*, Fabaceae), native to Turkey, Iraq, Spain, Greece and northern China, contains triterpenoid saponins, the main sweet component of which, (with a characteristic liquorice taste, sometimes described as cooling is a glycoside known as glycyrrhizin (see Section 10.3.3.2.1). Glycyrrhizin extracted from liquorice rhizome is a mixture of potassium and calcium salts of glycyrrhizic acid. The aglycone is glycyrrhetic (glycyrrhetinic) acid. The sugar bound at C-3 is a disaccharide composed of two β-D-glucuronic acid units: β-D-Glc*p*A-(1 → 2)-β-D-Glc*p*A. The dried root of this plant has been used as a laxative and in confectionery. Glycyrrhizin is used to sweeten and flavour some candies, pharmaceutical preparations and tobacco products. It is reported to be relatively heat-stable. Glycyrrhizin is classified as a flavouring agent, although not as a sweetener. The relative sweetness of glycyrrhizin and some other natural sweet substances is shown in Table 11.7.

Table 11.7 Relative sweetness of natural sweet compounds (sucrose = 1).

Compound	Sweetness
Brazzein	2000
Dulcoside A	30
Glycyrrhizin	50
(+)-Hernandulcin	1250
Monellin	1500–3000
Osladin	3000
Perillaldehyde	12
Phyllodulcin	200–800
Rebaudioside A	130
Stevioside	100–300
Thaumatin	2000–3000

Hernandulcin

Sweet sesquiterpenoids (+)-hernandulcin, 6-(1,5-dimethyl-1-hydroxyhex-4-en-1-yl)-3-methylcyclohexen-2-one, and (+)-4β-hydroxyhernandulcin (**11-35**) occur at a level of about 0.04% in the sweet herb *Phyla dulcis* (syn. *Lippia dulcis*, Verbenaceae) native to tropical Central and South America. Leaves with the sweet taste (hernandulcin is about 1250 times sweeter than saccharose) are used in traditional medicine. Because of its slightly bitter taste and minty after-taste, hernandulcin has only limited use as a sweetener.



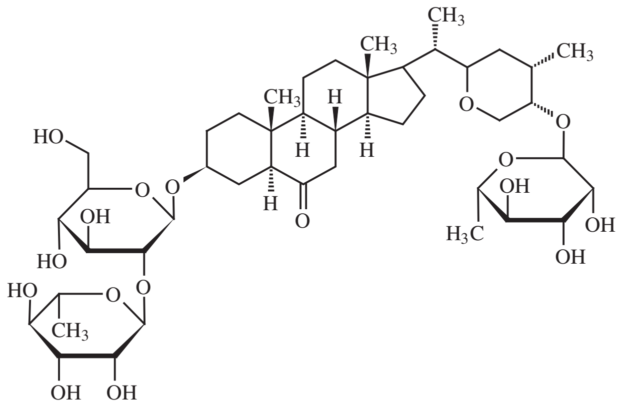
11-35, hernandulcin, R = H
4β-hydroxyhernandulcin, R = OH

Osladin

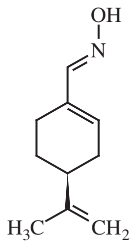
Osladin (**11-36**) is a steroidal saponin occurring in the rhizomes of the common polypody fern (*Polypodium vulgare*, Polypodiaceae). Sugar components are α-L-rhamnose and disaccharide α-L-Rha*p*-(1 → 2)-β-D-Glc*p* (β-neohesperidose). Osladin has not find applications due to toxicological reasons.

Perillaldehyde

The monoterpenic aldehyde (-)-perillaldehyde, also known as perillal (see Section 8.2.4.1.1), which occurs in small quantities as a



11-36, osladin



11-37, perillaloxime

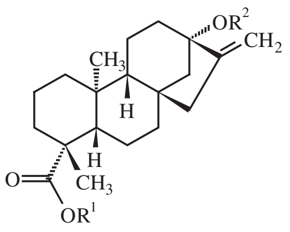
component of various essential oils (such as oils of citrus fruits), has a sweet taste. In the past, perillaldehyde was used as a starting compound for the synthesis of much sweeter (*E*)-perillaldehyde oxime (perillaloxime) called perillartin (**11-37**, Table 11.6).

Phyllodulcin

The isocoumarin phyllodulcin occurs in the leaves of big leaf hydrangea (*Hydrangea macrophylla*, Hydrangeaceae) native to Japan and in leaves of mountain hydrangea (*H. serrata*) native to Japan and Korea, along with related compounds (see Section 10.3.3.5.2). The sweetness of phyllodulcin is characterised by a slow onset and long-lasting sensation of sweet taste and an off-taste resembling liquorice. Phyllodulcin has found use in sweetening confectionery and chewing gums and to make regionally popular herbal teas, such as *amacha* tea in Japan, which is used in the celebration of Buddha's birth.

Stevioside

The sweet substance called stevioside is an *ent*-kaurene diterpene glycoside containing steviol (**11-38**) as the aglycone and β-D-glucose and disaccharide β-sophorose as sugar components. Stevioside is accompanied by other related glycosides, which include rebaudioside A, rebaudioside B, rebaudioside C, rebaudioside D, rebaudioside F, dulcoside A, rubusoside and steviolbioside (Table 11.8). Stevioside occurs in amounts of up to 6% in the leaves of stevia (*Stevia rebaudiana*, Asteraceae); a shrub native to tropical South America (Paraguay), the leaves of which can be used directly for sweetening, but the taste quality is not as good as that of isolated glycosides. Today, stevia is cultivated in the Far East (China, Japan, Korea and Malaysia). In Japan, it has been available to sweeten soft drinks, candy and chewing gums for decades. In some countries, health concerns have limited its availability; for



11-38, steviol ($R^1 = R^2 = H$)

Table 11.8 Structure of stevioside and related substances.

Trivial name	Substituents in steviol (see 11-38)	
	R^1	R^2
Stevioside	β-D-Glc*p*	β-D-Glc*p*-(1→2)-β-D-Glc*p*
Rebaudioside A	β-D-Glc*p*	β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-β-D-Glc*p*
Rebaudioside B	H	β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-β-D-Glc*p*
Rebaudioside C (dulcoside B)	β-D-Glc*p*	β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-α-L-Rha*p*
Rebaudioside D	β-D-Glc*p*-(1→2)-β-D-Glc*p*	β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-β-D-Glc*p*
Rebaudioside E	β-D-Glc*p*-(1→2)-β-D-Glc	β-D-Glc*p*-(1→2)-β-D-Glc*p*
Rebaudioside F	β-D-Glc*p*	β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→2)-β-D-Xyl*p*
Dulcoside A	β-D-Glc*p*	β-D-Glc*p*-(1→2)-α-L-Rha*p*
Rubusoside	β-D-Glc*p*	β-D-Glc*p*
Steviolbioside	H	β-D-Glc*p*-(1→2)-β-D-Glc*p* (β-soforosa)

example, the United States banned stevioside in the early 1990s (because of possible mutagenicity of steviol), but in 2008 it approved rebaudioside A as a food additive. Relatively recently (in 2011), stevioside was approved for use in the EU as steviol glycoside (E960), and maximum content levels for different types of foods and beverages were established.

11.3.2.1.4 Natural nutritional sweeteners

Natural nutritional sweeteners are proteins, but their potency is so high that, if used, they would not be significant sources of energy. All protein sweeteners have a slow onset of sweet taste and the sweetness lingers for some time. They are hydrolysed in acidic media, which results in the loss of the sweet taste. It is expected that sweet proteins are digested just as any other dietary proteins.

Brazzein

Brazzein is a sweet protein composed of 54 amino acids. It occurs in very sweet edible fruits of the plant *Pentadiplandra brazzeana* (Pentadiplandraceae), which is native to West Africa. Brazzein has a slight liquorice-like cooling effect in the mouth and is remarkably heat stable.

Miraculin

The glycoprotein miraculin occurs in small red berries of the West African shrub *Synsepalum dulcificum* (syn. *Richadella dulcifica*, Sapotaceae). Although it is itself tasteless, it adjusts the sour taste of acids to a sweet taste (e.g. taste of lemon juice), and this perception lasts about 1 h. Miraculin occurs as a tetramer (98.4 kDa), where a combination of two monomers forms two dimers linked by disulfide bridges. The relative molecular weight of the monomer is 24.6 kDa. Sugars bound in the glycoprotein (4 kDa, 13.9% of molar weight) are D-glucosamine (31%), D-mannose (30%), L-fucose (22%), D-xylose (10%) and D-galactose (7%). When heated over 100 °C, miraculin loses its taste-modifying property. Miraculin has no importance as a food additive (taste-modifying agent).

Monellin

Monellin is extracted from the fruit *Dioscoreophyllum volkensii* (syn. *D. cumminsii*, Menispermaceae) native to tropical African rainforests. Monellin is a sweet protein with liquorice-like flavour, which consists of two peptide chains, A and B, composed of a sequence of 45 and 50 amino acids, respectively (11.5 kDa). Under food processing conditions it is unstable and has no practical significance as a sweet substance.

Thaumatin

Thaumatin (also called thalin) is a mixture of sweet proteins extracted from the fruit of the tropical West African flowering plant *Thaumatococcus danielli* (Marantaceae), known as miracle fruit or miracle berry. It is the only protein sweetener approved in the EU (E957). The main components with sweet notes resembling liquorice are the proteins thaumatin I and thaumatin II, with a relative molecular weight of about 22 kDa (thaumatin I consists of 207 amino acids and contains one disulfide bond and no histidine). In addition to these proteins, the commercially available preparations contain several other sweet proteins (e.g. thaumatins a, b and c) and small amounts of polysaccharides (arabinogalactans and arabinoglucuronoxylans). Thaumatin is unstable with heat treatment. It is mainly used in food and drinks in combination with other sweeteners, for its flavour modifying properties and not as a sweetener, because it acts synergistically in combination with acesulfame K, saccharin, stevioside and other sweeteners.

11.3.2.2 Legislation

In the EU, most sweeteners are only permitted to be used in certain foods and are subject to specific quantitative limits (Table 11.9). Sorbitol (the correct name is glucitol, E420), mannitol (E421), maltitol (E965), lactitol (E966), xylitol (E967) and erythritol (E968) are approved as food sweeteners, and are described together with other sugar alcohols in Section 4.3.1.3.1. They are permitted to be used in *quantum satis* for confectionery, desserts and similar products. Common carbohydrates occurring in foods (glucose, fructose, sucrose and lactose) and honey are not considered sweeteners.

Sweeteners may be used to sweeten foods and for the preparation of table-top sweeteners, but are not intended to be processed for baby food. Foods and table-top sweeteners containing more

Table 11.9 List of current EU approved sweeteners and their E-numbers.

E-number	Name
E420	Sorbitol and sorbitol syrup
E421	Mannitol
E950	Acesulfame K
E951	Aspartame
E952	Cyclamic acid and its Na and Ca salts
E953	Isomalt
E954	Saccharin and its Na, K and Ca salts
E955	Sucralose
E957	Thaumatin
E959	Neohesperidin dihydrochalcone
E960	Steviol glycoside
E961	Neotame (as a flavour enhancer)
E962	Salt of aspartame-acesulfame
E965	Maltitol and maltitol syrup
E966	Lactitol
E967	Xylitol
E968	Erythritol

Table 11.10 Quantitative limits and applications for synthetic non-nutritional sweeteners.

Maximum usable dose (mg/kg or mg/l)	Sweetener[a]						
	Ac	As	Cy	Nc	Sa	Su	Th
Non-alcoholic beverages	350	600	250	30–50	80–100	200–300	-

[a] Ac = acesulfame K, As = aspartame, Cy = cyclamates, Nc = neohesperidine chalcone, Sa = saccharin, Su = sucralose, Th = thaumatin.

than 10% sugar alcohols must carry a warning on the packaging that excessive consumption may have a laxative effect. Top-table sweeteners and foods containing aspartame must be labelled that they contain a source of phenylalanine. Table 11.10 provides the maximum usable doses of approved sweeteners in some selected foodstuffs.

11.3.2.3 Health assessment

The ADI value was not specified for sugar alcohols derived from monosaccharides (xylitol, glucitol and mannitol) and disaccharides (maltitol, isomaltitol and lactitol).

Acesulfame K does not exhibit mutagenic or other toxic effects. It is rapidly absorbed and excreted mainly in the urine as an unchanged compound. In certain countries (including EU countries), acesulfame K has many uses, but in others it is only used for toothpastes and mouthwashes. The ADI value is 15 mg/kg body weight for children and adults. Acute toxicity in humans may manifest itself by headaches.

Aspartame has been the most controversial artificial sweetener by far because of its potential toxicity. It is hydrolysed to phenylalanine, aspartic acid and methanol and partially metabolised to glutamate. The daily intake of phenylalanine from food, which is estimated at 3.6 g, remains virtually unchanged using aspartame, but in people with impaired phenylalanine metabolism (phenylketonuria) some problems could arise. In some foods, where up to 5% of aspartame may be transformed into 2,5-dioxopiperazine, there has been some doubt about its possible carcinogenic properties. The toxicological data suggest that normal consumption of aspartame is not risky (ADI = 40 mg/kg body weight for aspartame and 7.5 mg/kg body weight for the corresponding 2,5-dioxopiperazine). Acute toxicity may be manifested by headaches, dry mouth, dizziness, mood change, nausea, vomiting, reduced seizure threshold and thrombocytopaenia (an abnormally low number of platelets in the bloodstream).

Cyclamates are partially absorbed in the digestive tract (individually within 1–60%) and the rest is then transformed by intestinal bacteria into cyclohexylamine. Cyclohexanol and cyclohexane are produced in small amounts. Problems arose with cyclamates in 1969, when a single scientific study showed bladder carcinogenicity in rats fed with cyclamates due to the formation of cyclohexylamine, which led to an immediate ban on use of the compounds in many countries. More than two dozen other studies on its safety reportedly failed to show the same results, which has led to re-approval of the use of cyclamates in many countries, including the EU, although they remain banned in the United States (ADI = 11 mg/kg body weight).

Ingested neohesperidin dihydrochalcone is hydrolysed in the same way as other related, naturally occurring flavonoids, yielding sugars and the corresponding aglycone. The aglycone is partly absorbed, metabolised, conjugated and excreted via bile and urine, partly undergoes bacterial ring cleavage (of the C-ring) and subsequently cleavage of the three-carbon bridge. It has been shown that neohesperidin dihydrochalcone can produce some side effects, such as nausea and migraine, at concentrations of around 20 mg/kg and above, but this effect is not well documented (ADI => 5000 mg/kg body weight).

Neotame is recognised as safe and, in toxicological studies, no adverse findings related to neotame were found in clinical observations in test animals. At high doses, acute toxicity may be manifested by headache and hepatotoxicity. The ADI for neotame was set at 2 mg/kg body weight by JECFA (the Joint FAO/WHO Expert Committee on Food Additives) in 2003.

Saccharine is slowly but almost completely absorbed in the digestive tract and is rapidly excreted unchanged in the urine. The unabsorbed portion is excreted in faeces. Some doubts persist about its potential carcinogenicity or co-carcinogenicity (ADI = 5 mg/kg body weight), as saccharin has been shown to produce urinary bladder tumours in rats. This finding has led to a ban in some countries and a proposed ban in the United States, but this phenomenon has not been observed in mice or in any other species, including humans. Acute toxicity may be manifested by nausea, vomiting and diarrhoea.

Sucralose consumption does not have adverse health effects at doses up to 10 mg/kg body weight and repeated doses of up to 5 mg/kg per day for several weeks. The acute toxicity of sucralose

may be manifested by migraine in sensitive individuals and by diarrhoea. The ADI for sucralose was set at 15 mg/kg body weight.

Stevioside is not degraded in the stomach juice and its uptake by the gastrointestinal tract is very low. All the stevioside reaching the colon is degraded by microorganisms into steviol, the only metabolite found in faeces. In urine, no stevioside or free steviol are present, except small amounts of steviol glucuronide. Studies of the toxicity of stevioside found no clinical signs of toxicity or morphological or histopathological changes in test animals. A European Food Safety Authority (EFSA) panel established an ADI for steviol glycosides, expressed as steviol equivalents, of 4 mg/kg body weight.

Thaumatin is not absorbed as such, but is completely hydrolysed in the digestive tract to amino acids (about as fast as egg albumin). Thaumatin is not mutagenic, teratogenic or allergenic and its consumption does not pose any health risk (there is currently no listed ADI for thaumatin).

In the United States, glycyrrhizin is generally recognised as safe. The European Union suggests that an intake of 100 mg/day (equivalent to approximately 50 g of liquorice sweets) would be unlikely to cause adverse effects (pseudohyperaldosteronism leading to hypocalcaemia alkalosis associated with a low serum potassium level and lower aldosterone secretion) in the majority of adults. People suffering from hypertension should avoid excessive consumption of liquorice products. The ADI for glycyrrhizin is suggested at 0.2 mg/kg/ body weight.

11.3.3 Acidulants and acidity regulators

Acidulants used as food additives are inorganic and organic acids generally identical to those that occur naturally in foods. Acids are most commonly used for their sour taste (see Section 8.3.3). They often also have other beneficial properties. Some acids:

- exhibit antimicrobial effects and are therefore used simultaneously as preservatives, such as vinegar– acetic acid (E260), propionic acid (E280) and other acids;
- have significant organoleptic properties (taste and smell) and are used as flavouring agents, for example actic acid (E260), succinic acid (E363), fumaric acid (E297), adipic acid (E355), lactic acid (E270), citric acid (E330) and malic acid (E296);
- act as colour stabilisers, such as ascorbic acid (E300) in meat products and citric acid (E330) in fruit products;
- act as sequestrants and synergists of antioxidants, for example calcium disodium salt of ethylenediaminetetraacetic acid (E385), citric (E330), tartaric (E334), malic (E296), ascorbic (E300) and phosphoric acids (E338);
- are substances that modify the texture, for example citric acid (E330) allows the formation of some pectin gels, milk clotting by chymosin and inhibits the formation of crystals in confectionery;
- suppress the formation of hazes, such as lactic acid (E270) in brine of fermented olives;
- are agents that hydrolyse proteins, such hydrochloric acid (E507) in the production of acidic protein hydrolysates.

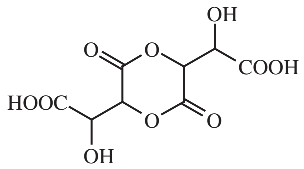
Acidifying agents also include substances that produce acids by hydrolysis or during heating. This group of additives includes salts used as raising agents, such as sodium (E500), potassium (501) and ammonium carbonates (E503) releasing carbon dioxide in the dough. These additives are also used in the production of sparkling beverages. In durable fermented salami, dairy and other products, δ-lactone of D-gluconic acid (D-glucono-1,5-lactone, E575) is used, from which D-gluconic acid arises by hydrolysis (see Section 4.3.2.1).

Acidity regulators or pH regulators maintain the acidity and alkalinity of foods. They mostly include salts of various acids with buffering effects and alkaline agents. For example, dispersion stabilisers for dairy products (melting salts) and meat products (substances that increase meat water holding capacity) are mostly various di-, tri- and polyphosphates (E339, E400, E411, E450–E452). Sodium hydrogen carbonate (E500) is used for pH adjustment in the manufacture of dark, Dutch-processed cocoa powder to neutralise its natural acidity. Sodium carbonate (E500) or sodium hydroxide (E524) are used for neutralisation of acidic protein hydrolysates, while sodium hydroxide (E524) is employed for olive debittering (see Section 8.3.5.2) and for peeling fruits and vegetables.

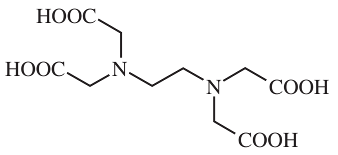
11.3.3.1 Legislation

Many substances may be used in food production only in the amount necessary to achieve the desired effect. Phosphates or mixtures thereof may be only used for listed foods, and their amount is limited.

For example, phosphoric acid (E338) is allowed for flavoured soft drinks (such as cola drinks) in a quantity of up to 700 mg/l, phosphates (as P_2O_5) for soft fresh cheeses (2000 mg/kg), melted cheese (melting salt, 20 000 mg/kg), meat products (for the increase of water binding capacity, 5000 mg/kg) and powder whiteners for beverages (30 000 mg/kg). The lactide metatartaric acid (E353, **11-39**), prepared by heating tartaric acid, is allowed only for wines (100 mg/l), calcium disodium salt of ethylenediaminetetraacetic acid (E385, **11-40**) at a concentration of 75 mg/kg for emulsified sauces, mayonnaises, pickled products from crustaceans, molluscs and fish and up to 250 mg/kg for canned legumes, artichokes and mushrooms. To highlight the colour of black olives, ferrous salts of some organic acids are allowed, lactate (E579) or gluconate (E579 at a level of 150 mg/kg (calculated as iron) that form black complexes



11-39, metatartaric acid



11-40, ethylenediaminetetraacetic acid

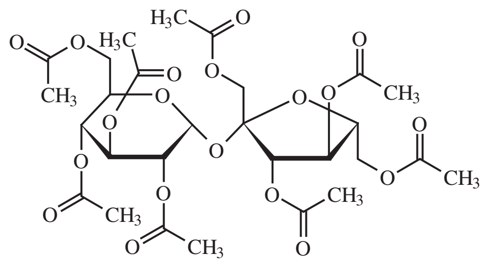
with oxidised fruit polyphenols. Urea (E927) may only be used in food supplements (200 mg/kg), and triethyl citrate only for egg whites (and only in the specified quantity).

11.3.3.2 Health assessment

Acids and their salts are generally considered to be natural food constituents. Citric, fumaric and succinic acid are intermediates of the citric acid cycle, and propionic acid is metabolised like other fatty acids (ADI values are not given). There are, however, reservations over the use of certain acids. Acetic acid induces epidermal reactions and other allergic type symptoms in susceptible individuals. Adipic acid (ADI = 5 mg/kg body weight) may affect the growth of animals. Restrictions also relate to fumaric acid (ADI = 6 mg/kg body weight), racemic malic acid (ADI = 100 mg/kg body weight, but L-isomer is a normal food constituent) and L-tartaric acid (ADI = 30 mg/kg body weight). Racemic and D-lactic acid may cause acidosis in infants, vomiting and dehydration. The ADI value is not set, but it is not recommended to use these acids in infant nutrition.

11.3.4 Bitter substances and stimulants

A large number of organic and inorganic compounds have a bitter taste, and these are discussed in other contexts in Section 8.4.5.1. Bitter tasting substances derived from plant materials (such as hops, wormwood and other herbs), which are used for aromatisation are classified as flavourings, as well as the category of bitter tasting additive substances and stimulants to which the alkaloids caffeine (see Section 10.3.3.1.8) and quinine (see Section 10.3.3.1.5) belong. None of these compounds have E-numbers. Another bitter additive substance is octaacetylsaccharose, better known as sucrose octaacetate (**11-41**). Pesticide products containing sucrose octaacetate as an inert ingredient are used as insect repellents, herbicides, flea and tick sprays and other insecticides. Other commercial uses of sucrose octaacetate include impregnating and insulating papers, as well as in lacquers and plastics.



11-41, octaacetylsaccharose

11.3.4.1 Legislation

In the production of food, caffeine and quinine may be used directly or as components of flavourings. Their amount was limited in the past, but according to new legislation (see Section 10.3.3.1.8) only beverages that contain caffeine concentration higher than 150 mg/l must be labelled as having 'High caffeine content'. The maximum content of quinine in bitter drinks is not limited either. Sucrose octaacetate has been approved by the FDA as a food additive in the US, but not in the EU, where it may be added to foods only in the specified quantities.

11.3.4.2 Health assessment

In the gastrointestinal tract, octaacetylsaccharose is hydrolysed to acetic acid and sucrose, which are metabolised in the normal way. The health evaluation of caffeine and quinine has been described elsewhere (see Sections 10.3.3.1.8 and 10.3.3.1.5, respectively).

11.3.5 Flavour enhancers

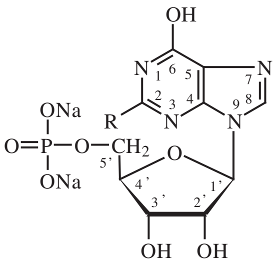
Flavour enhancers are substances that intensify or modify the original flavour of certain foods, even though they do not have their own flavours. Additives of this category include:

- L-glutamic acid (E620) and its salts, sodium hydrogen glutamate (E621), potassium hydrogen glutamate (E622), ammonium hydrogen glutamate (E624), calcium glutamate (E623) and magnesium glutamate (E625);
- purine 5′-nucleotides, which include inosine 5′-phosphate (inosinic acid, IMP, E630), disodium (E631), dipotassium (E632) and calcium inosinate (E633), guanosine 5′-phosphate (guanidylic or guanylic acid, GMP, E626), disodium (E627), dipotassium (E628) and calcium guanylate (E629).

Of particular importance are glutamic acid and sodium hydrogen glutamate. This salt is the active form that shows the taste referrd to as umami (see Section 8.3.4). At concentrations of 0.05–0.8%, in which it is added as an additive, it amplifies and enhances the flavour of meat and vegetable products, such as soups and sauces, meat and vegetable preserves, tomato juice, ketchup, mayonnaise and other products.

Synergistic effects to the taste of glutamate are shown by disodium 5′-ribonucleotides: IMP and GMP (**11-42**), which are added to foods in amounts ranging from 0.001 to 0.2%. When used, the amount of glutamate can be reduced about ten times, while maintaining the same intense umami taste. Commonly used is a mixture containing 95% w/w sodium hydrogen glutamate, 2.5% w/w IMP and 2.5% w/w GMP.

Detection thresholds of IMP and GMP are 250 and 125 mg/l, respectively. The detection threshold of a mixture of these substances (in weight ratio 1 : 1) is 63 mg/l, in combination with glutamate (at a concentration of 8 g/l; its detection threshold is 120 mg/l) it is as low as 0.31 mg/l. All three compounds are common food ingredients (Table 11.11). In some products, however,



11-42, 5′-nucleotides
5′-IMP, R = H
5′-GMP, R = NH_2
5′-XMP, R = OH

Table 11.11 Natural content of glutamic, inosinic and guanylic acids in selected foods.

Food	Content (mg/kg)		
	Free Glu	IMP	GMP
Pork meat	230	1860	37
Chicken meat	440	1150	22
Peas	750	0	0
Tomatoes	2 460	0	0

the glutamate content is very high (e.g. about 40 g/kg in acid protein hydrolysates, which corresponds to 100 g/kg of dry matter). In meat and fish IMP prevails, as it arises from ATP via deamination of AMP *post mortem* (Figure 11.12). IMP is then degraded via inosine, hypoxanthine and xanthine to uric acid. The amount of IMP in meat extracts (highly concentrated meat stocks) used in cooking reaches about 10 g/kg. In the meat of crustaceans, the main nucleotide is adenosine 5′-phosphate (AMP). Some mushrooms and yeast extracts used as food additives (flavourings) and as nutrients for bacterial culture media in microbiology have a higher content of GMP. Xanthosine 5′-phosphate (xanthylic acid, XMP) has similar properties as IMP and GMP.

11.3.5.1 Legislation

Glutamic, inosinic and guanylic acids and their sodium and potassium salts can be used as flavour enhancers, individually or in combination, up to the maximum allowable amount. The permissible amount of glutamic acid in foodstuffs in general (excluding soft drinks) is 10 g/kg. Specified amounts of this amino acid and nucleotides are prescribed for condiment preparations.

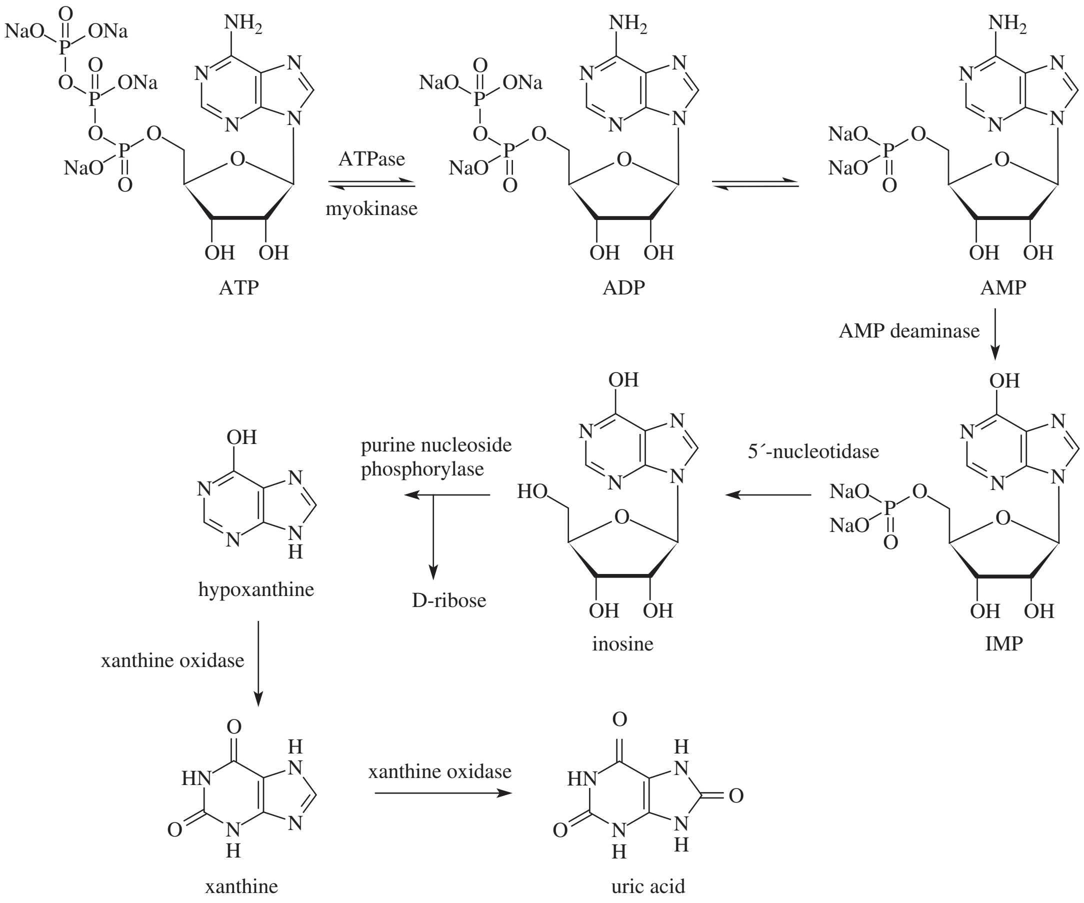


Figure 11.12 Formation and degradation of IMP in meat.

Table 11.12 List of current EU approved natural and natural-identical colours and their E-numbers.

E-number	Name	E-number	Name
E100	Curcumin	E160a	Carotenes
E101	Riboflavin and riboflavin 5′-phosphate	E160b	Annatto, bixin and norbixin
E120	Cochineal, carminic acid and carmines	E160c	Paprika extract, capsanthin, capsorubin
E140	Chlorophylls and chlorophyllins	E160d	Lycopene
E141	Copper complexes of chlorophyll, chlorophyllins	E160e	β-Apo-8′-carotenal
E150a	Plain caramel	E160f	Ethyl β-apo-8′-carotenoate
E150b	Caustic sulfite caramel	E161b	Lutein
E150c	Ammonia caramel	E161g	Canthaxanthin
E150d	Sulfite ammonia caramel	E162	Beetroot Red, betanin
E153	Vegetable carbon	E163	Anthocyanins

11.3.5.2 Health assessment

In the past there have been some reservations over excessive intake of glutamic acid and its salts, because it was associated with the so-called Chinese restaurant syndrome manifested in sensitive individuals by headaches, anxiety, digestive problems and burning in the upper parts of the body, but these side effects have not been scientifically proven. When glutamic acid or glutamates are added to foods, legislation requires that it be listed on the label (see Section 8.3.4). Many countries have restricted the amount of glutamic acid, glutamate and 5′-nucleotides added to foods legislatively. In some countries, however, these substances are not regulated at all (e.g. in Japan). The ADI for sodium hydrogen glutamate is 120 mg/kg body weight, ADI values for 5′-nucleotides are not specified, but salts of IMP (inosinates) may not be used in products intended for children under 12 weeks. As 5′-nucleotides are metabolised to uric acid, they should be avoided by people suffering from the form of arthritis known as gout. However, the concentrations used are generally so low that no effects are to be expected. Asthmatic people should likewise avoid these substances.

11.4 Substances modifying colour

Stabilisation of natural food colours and colouring of food has been carried out since time immemorial for aesthetic reasons, to make food more visually appealing, but the physiological reasons are also significant. Colours are used to restore the original appearance of food, whose pigments have been affected by processing, storage, packaging and distribution, and to give colour to food that would otherwise be colourless, whereby its visual acceptability may be impaired. Another reason is the standardisation of colour, for example the compensation of seasonal fluctuations. The attractive colour of food is related to its likeability, increases the secretion of gastric juices in the consumer and leads to better utility of the food. In some cases, the natural colour may be unwanted and can be removed using bleaching agents.

11.4.1 Colours

11.4.1.1 Classification

Pigments found in foods are divided according to their origin into:

- natural pigments
- natural-identical synthetic pigments
- synthetic dyes.

11.4.1.2 Natural colours

Natural and natural-identical synthetic pigments approved for colouring food are described in detail in Chapter 9 and caramel colours, one of the oldest and most widely-used food colourings, in Section 4.7.6. They are listed in Table 11.12.

11.4.1.3 Synthetic dyes

11.4.1.3.1 Structure and nomenclature

Synthetic dyes generally have more intense colour than natural dyes, are more stable and do not introduce any characteristic odours and tastes into coloured food. Therefore, synthetic dyes are widely used in food practice, mainly for practical and economic reasons. Food colours are contained in many foods, including snack foods, margarine, cheese, jams and jellies, and desserts, drinks and other products.

The following dye classes are recognised according to structure:

- azo dyes (monoazo, bisazo-, trisazo-to polyazo dyes)
- diphenylmethane and triphenylmethane dyes
- pyrazolone dyes

- nitro dyes
- xanthene dyes
- anthraquinone dyes
- quinoline dyes
- indigo dyes.

Other dyes, such as acridine, diazonium, phthalocyanin, tetrazolium and thiazole dyes, are not approved for foods. According to their physico-chemical properties, synthetic dyes may be classified into:

- sour dyes
- alkaline dyes
- neutral dyes.

According to their solubility, synthetic dyes are divided into:

- lyophylic dyes (soluble in water)
- lipophilic dyes (soluble in fats).

The list of synthetic dyes approved in the EU is shown in Table 11.13. All synthetic dyes approved as food dyes are

Table 11.13 Synthetic EU approved food dyes, their E-numbers and some attributes.

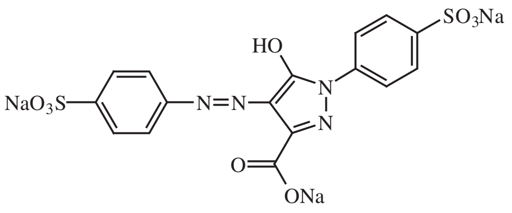
E-number	Name	Other names[a]	Class	Colour
E102	Tartrazine	Acid yellow T, Hydrazine yellow, FD&C Yellow No:5; C.I. Acid Yellow 23	Monoazo	Yellow
E104	Quinoline yellow	Food Yellow-13, D&C Yellow No:10, C.I. Acid Yellow-3	Quinoline	Yellow
E110	Sunset Yellow FCF, Orange Yellow S	FD&C Yellow No:6, C.I. Food yellow 3	Monoazo	Orange
E122	Azorubine, Carmoisine		Monoazo	Blue-red
E123	Amaranth	FD&C Red No. 2, C.I. Acid Red 27, C.I. Food red 9	Monoazo	Blue-red
E124	Ponceau 4R, Cochineal Red A		Monoazo	Red
E127	Erythrosine	FD&C Red No:3	Xanthene	Red
E129	Allura Red AC	FD&C Red No:40	Monoazo	Blue-red
E131	Patent Blue V		Monoazo	Red
E132	Indigotine, Indigo carmine[b]	FD&C Blue No:2	Triphenylmethane	Green-blue
E133	Brilliant Blue FCF	FD&C Blue Dye No:1, C.I. Acid blue 9, C.I. Food blue 2, C.I. Pigment blue 24	Indigo	Dark blue
E142	Green S	C.I. Acid green 50, C.I. Food green 4	Triphenylmethane	Green-blue
E151	Brilliant Black BN, Black PN	C.I. Food Black 1	Triphenylmethane	Green
E154	Brown FK		Bisazo	Black
	Brown HT		Monoazo, bisazo and trisazo	Brown
E180	Litholrubine BK		Bisazo	Brown

[a] FD&C = FD&C numbers indicate that the US Food and Drug Administration (FDA) has approved the colorant for use in Foods, Drugs and Cosmetics). Colorants without FD&C numbers are banned in the United States. Colour additives FD&C Green No. 3 (for general use), Orange B (for casings or surfaces of frankfurters and sausages) and Citrus Red No. 2 (for skins of oranges not intended or used for processing) are approved in the United State, but are not approved in the EU. C.I. = C.I. (Colour Index) number.

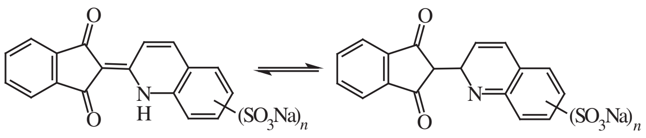
[b] Indigotine occurs as a natural pigment (in shrub *Indigofera tinctoria*), though commercially it is produced synthetically.

water-soluble compounds. The most represented are acidic dyes containing sulfonic groups, carboxyl groups and hydroxyl groups. Most of them belong to the azo dyes; some are di- and triphenylmethane dyes, nitro dyes and xanthene dyes. Basic dyes contain one or more free or substituted amino groups. These include the majority of di- and triphenylmethane dyes and certain azo dyes. All dyes are used in the form of salts (usually sodium, potassium or calcium salts).

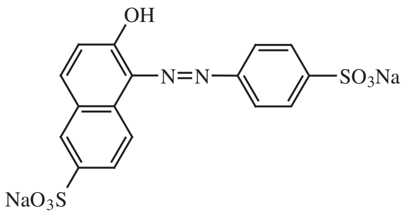
Specific properties of dyes depend on the functional groups present. A characteristic is the presence of two types of functional groups, **chromophores** and **auxochromes**. Chromophore groups are related to the class of dyes (such as azo dyes and nitro dyes) and are responsible for the behaviour of dyes in oxidation and reduction reactions. Auxochrome groups are responsible for the staining properties and behaviour to acids, alkalis, light and heat. The structures of synthetic dyes approved in the EU are given in formulae **11-43** to **11-58**.



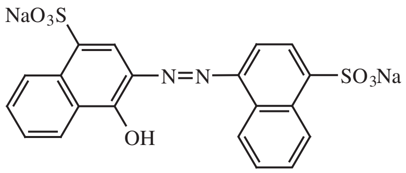
11-43, Tartrazine



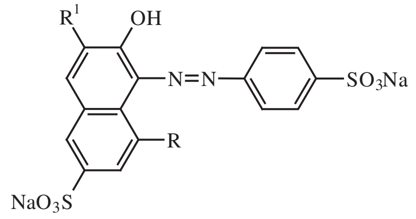
11-44, Quinoline Yellow (n = 1–3)



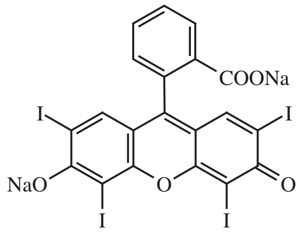
11-45, Sunset Yellow FCF



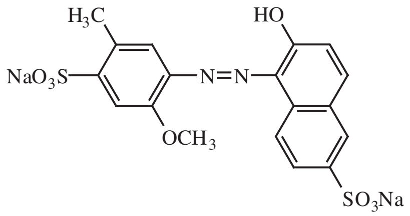
11-46, Azorubine



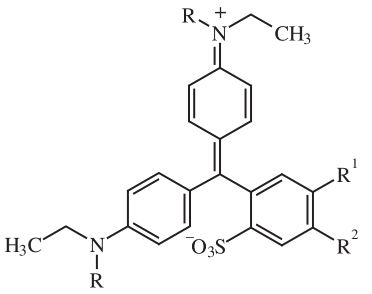
11-47, Amaranth, $R^1 = SO_3Na$, $R^2 = H$
Ponceau 4R,$R^1 = H$, $R^2 = SO_3Na$



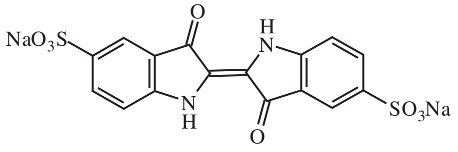
11-48, Erythrosine



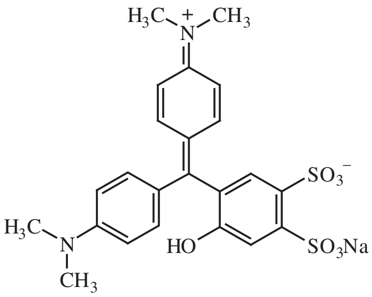
11-49, Allura Red AC



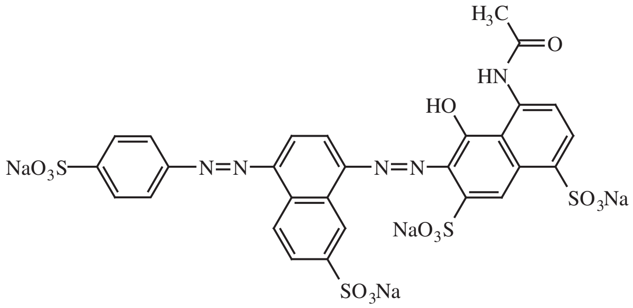
11-50, Patent Blue V, $R = CH_2CH_3$, $R^1 = OH$, $R^2 = SO_3Na$
Brilliant Blue FCF, $R^1 = H$, $R^2 = H$



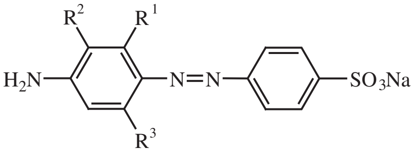
11-51, Indigotine



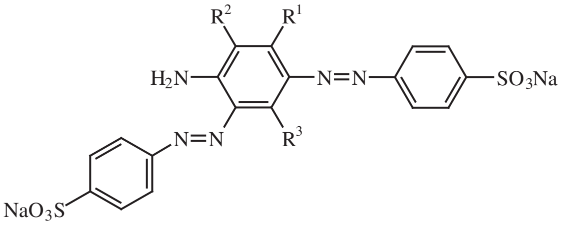
11-52, Green S



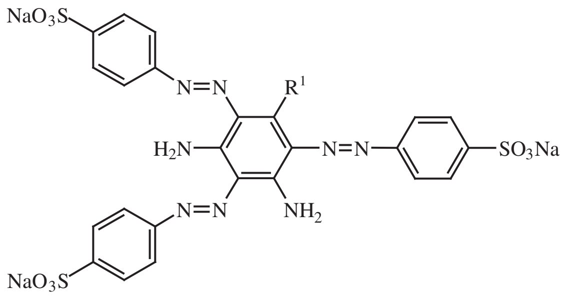
11-53, Brilliant Black BN



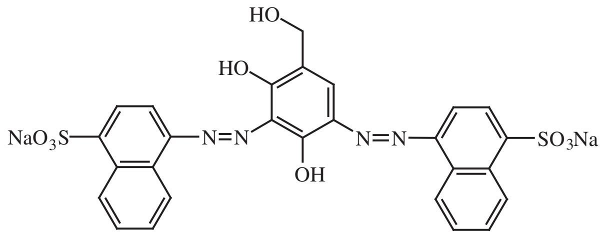
11-54, Brown FK (monoazo components, $R^1 = H$ or NH_2, $R^2 = H$ or CH_3, $R^3 = H$ or NH_2)



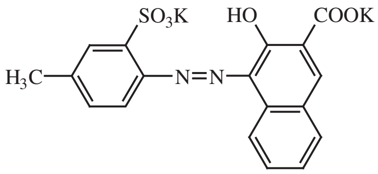
11-55, Brown FK didiazo components, substituents: see monoazo components



11-56, Brown FK (triazo components, substituents: see monoazo components)



11-57, Brown HT



11-58, Lithorubine BK

11.4.1.3.2 Properties and applications

In addition to toxicological criteria, it is required that synthetic dyes have to be chemically pure substances, which do not influence any other organoleptic properties of food (with the exception of colour). They must be stable to changes of pH and on exposure to light. Generally, there is no such dye that is suitable for all applications and situations, therefore the dye used is usually composed of several components and represents a mixture of dyes.

The majority of synthetic dyes have sufficient stability, particularly in dry foods and foods protected from light. Their stability is also sufficient under normal conditions of production, processing and during storage of foods. Azo dyes can relatively easily reduce metal ions and certain reducing agents (such as sulfur dioxide or ascorbic acid present in beverage) yielding colourless products. Triphenylmethane, indigo and xanthene dyes are more stable, but due to UV radiation Indigotine and Erythrosine may be decolourised.

Synthetic dyes are available:

- in the form of dispersions, pastes, aqueous or non-aqueous solutions (mainly in propylene glycol or glycerol) or in the solid state (such as water-soluble granules or powders);

- in the form of water-soluble lake pigments (commonly known as lakes).

Solid products are especially suitable for colouring beverages and emulsions and pastes for colouring confectionery and bakery products, while liquid paints are used for colouring dairy products. Lake pigments are obtained by adsorption of dyes on hydrated alumina. They have different content of dyes, normally 10–40%. The minimum content of dyes in lakes is not prescribed, as the colour is related to the technology of their production, which determines their colouring power, shade and dispersibility. Lakes are not oil soluble, but are oil dispersible. Lakes that contain individual dyes or mixtures thereof are delivered in solid form or as

dispersions in hydrogenated vegetable oils, propylene glycol, and glycerol or sugar syrup. These forms of food colours are more stable than dyes and are ideal for colouring products containing fats and oils or items lacking sufficient moisture to dissolve dyes.

Some dyes, such as azo dyes Amaranth and SunsetYellow FCF, can react in slightly acidic media with bisulfites (sulfur dioxide) to produce coloured products (e.g. a yellow product arises from Sunset Yellow FCF), but some dyes, such as Tartrazine and Azorubine, yield colourless products. The former group of azo dyes have hydroxyl groups in the *ortho*-position to the azo bond as well as unsubstituted *para*-positions in the naphthalene nucleus. Such dyes exist predominantly as hydrazone tautomers rather than strictly azo compounds, which facilitates the addition of bisulfite ion to the *para*-position (Figure 11.13). With Azorubine, the addition of bisulfite ion at the *para*-position appears not to take place, probably as a result of charge delocalisation via the fused aromatic ring of the naphthalene system. It is probable that the dye reacts with bisulfite to form an unstable complex that hydrolyses to a colourless hydrazo product (Figure 11.14).

As with sulfur dioxide, the reaction of ascorbic acid with azo dyes frequently used in combination, for example in fruit drinks, leads to dye degradation. The stability of the most frequently used dyes (at pH 3.0 and 4.0) in the presence of ascorbic acid decreases as follows: Tartrazine > Sunset Yellow FCF = Amaranth, Ponceau 4R > Azorubine > Brilliant Black BN.

11.4.1.4 Inorganic pigments

Inorganic compounds in food are only used in special cases. For example, for the surface treatment and decoration of dragees, candies and similar products, the white pigments calcium carbonate (E170) and titanium dioxide (E171), red, yellow or black iron oxides and hydroxides (E172) and aluminum (173), silver (E174) or gold (E175) pigments are used. Silver and gold pigments are similarly used for decoration of specialty liqueurs (in specified quantities).

11.4.1.5 Legislation

Flavour-active materials with simultaneous colouring effect (such as paprika, saffron and turmeric) are not considered colorants, nor are colorants intended to colour the inedible external parts of foods (such as paraffin wax coatings of cheeses and sausage casings).

Some dyes may only be used for certain purposes and to the maximum amount allowed. For example, Amaranth is allowed for aperitif wines and spirits (30 mg/kg), Erythrosine for cocktail and candied cherries (200 mg/kg) and Litholrubine BK for edible coatings of cheeses (in specified quantities). For meat and meat products only a single dye may be used: Allura Red AC, Brilliant Blue FCF and Brown HT or a mixture of Allura Red AC and Brilliant Blue FCF. For the purpose of food colourings used in the home, the pigments and dyes listed in Tables 11.12 and 11.13 are available, except for annatto, canthaxanthin, Amaranth, Erythrosine, Brown FK, Litholrubine BK and aluminium pigment. The rules also specify foods that can be coloured only by certain dyes. For example, beer, vinegar, spirits of whiskey, brandy and rum-type alcoholic beverages, may be coloured with caramel (in a specified quantity), butter with carotene (10 mg/kg), margarines may be coloured with carotene and curcumin (in specified quantities) or annatto (10 mg/kg). Foods that cannot be coloured are also identified, mostly including unprocessed foods, such as milk, vegetable oils and animal fats, mineral and table water, egg contents, flour, bread, pasta products, sugar, meat, fish, wine, honey, vinegar, fruit and vegetable juices, tomato paste and sauces, coffee, cocoa and chocolate products, infant and child nutrition and others.

11.4.1.6 Health assessment

Food pigments and dyes should not represent any health risk if used up to the maximum amount allowed, as each substance authorised for use in the EU is subject to a rigorous scientific safety assessment. Some dyes can, however, cause health problems. Side effects are known for azo dyes, such as Tartrazine, Sunset Yellow

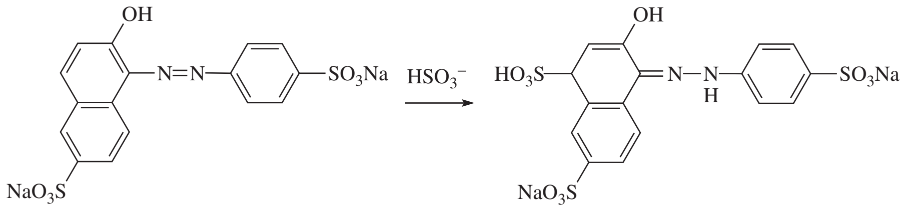


Figure 11.13 Reaction of bisulfite with Sunset Yellow FCF.

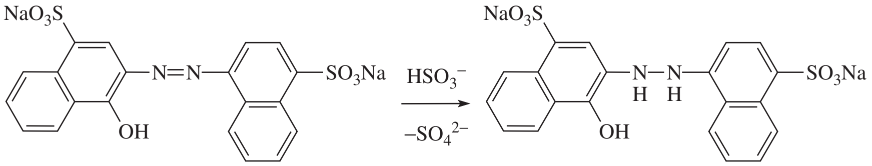

Figure 11.14 Reaction of bisulfite with Azorubine.

FCF, Azorubine and also other azo dyes, in people intolerant to salicylates (aspirin and some fruits). In combination with benzoates, these dyes are implicated in a large percentage of cases of hyperactivity in children, as well as carmine. Asthmatics may also experience symptoms following consumption of azo dyes, as they are histamine-liberating agents. Erythrosine may cause hyperactivity and increased photosensitivity in people with sensitivity to sunlight, and possible mutagenicity has also been reported. In high concentrations, Erythrosine may interfere with iodine metabolism, but these concentrations cannot be reached through the consumption of food. Patent Blue V and Indigotine can function as histamine-liberating agents, and may cause allergic reactions due to coupling of the colour to body proteins as well as Brilliant Blue FCF and Green S. Litholrubine BK is not absorbed and no side effects are known when it is used as a food additive.

A promising solution is the use of natural pigments extracted from tissue cultures. Other encouraging prospects are new dyes, such as high molecular weight pigments non-absorbable in the digestive tract, with chromophores fixed to the polymer so that they pass through the digestive tract in an unaltered state.

11.4.2 Bleaching agents

Bleaching agents include compounds that unwanted dyes:

- reduce
- oxidise to colourless or less intensely coloured products.

11.4.2.1 Reducing agents

Substances with reducing effects are sulfur dioxide and sulfites, which are also used as preservatives, inhibitors of enzymatic browning reactions and inhibitors of non-enzymatic browning reactions. The bleaching activity is mainly based on their ability to reduce the primary products of enzymatic browning reactions – quinones, whose subsequent reactions would otherwise lead to undesirable discoloration in dried fruits, vegetables, potatoes and other products. Furthermore, these compounds are used for the bleaching of hops, lecithin concentrates, mushrooms, nuts and fish products.

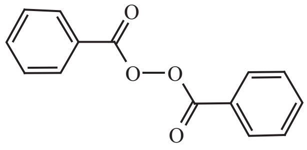
11.4.2.2 Oxidising agents

Substances with oxidising effects (not allowed under EU legislation) include:

- compounds with active oxygen
- compounds with active chlorine.

11.4.2.2.1 Compounds with active oxygen

Halides and peroxides have some importance as bleaching agents with active oxygen. The most widely used agent for bleaching flour is potassium bromate ($KBrO_3$), which has been used for about 90 years. Potassium bromate bleaches carotenoid pigments in flour and simultaneously oxidises gluten and glutathione, thus improving the baking properties of flour (see Section 5.14.6.1.6). It is reduced to bromide. The problem is its toxicity and carcinogenicity, therefore it was never been allowed as a flour improver in a number of countries, but is commonly used in many Latin American and East Asian countries. The suggested quantity of potassium bromate for improving bread flour is 50 mg/kg. Certain other compounds have also been used for the same purpose as potassium bromate. For example, inorganic compounds that are used include potassium and calcium iodates (IO_3^-), cupric sulfate, ammonium and potassium peroxodisulfates (also known as persulfates, $S_2O_8^{2-}$), hydrogen peroxide and ozone. Organic compounds used as bleaching agents and dough conditioners include dibenzoyl peroxide (**11-59**) and azodicarbonamide (azoformamide). Azodicarbonamide releasing nitrogen gas was previously used as a blowing agent in rubber and plastic products that were permitted in food packaging applications. In 2003, the European Food Safety Authority (EFSA) implicated foamed poly(vinyl chloride) cap liners as the source of potentially genotoxic semicarbazide (a group 3 substance not classifiable as to its carcinogenicity to humans according to International Agency for Research on Cancer, IARC). In certain countries, azodicarbonamide is still approved as a food additive up to a maximum of 45 mg/kg in flour, such as in the United States (at levels up to 45 mg/kg), Canada, and Asia, but is banned in Singapore, Australia and Europe. Azodicarbonamide is stable in dry flour, but it reacts in moist flour and yields, as the main reaction product biurea, which is relatively stable during baking, but partly decomposes to urazole, semicarbazide and unstable carbamic acid (Figure 11.15), which yields ethyl carbamate on reaction with the ethanol produced by yeast. Semicarbazide was not detected after room temperature or elevated temperature dough maturation, but only in bread. Commercial bread products show a wide range of semicarbazide concentrations (10–1200 μg/kg).



11-59, dibenzoylperoxide

11.4.2.2.2 Compounds with active chlorine

Gaseous chlorine, chlorine dioxide (ClO_2) and sodium and potassium hypochlorites (OCl^-) are used as bleaching agents and improvers of flour baking properties and also for chemical disinfection of water. The most frequently used agent is chlorine dioxide, in amounts of up to about 30 mg/kg flour in some countries.

The use of compounds with active chlorine is problematic from the hygienic and toxicological perspectives, because their reactions with food components may produce a number of potentially toxic chlorinated products. Chlorine dissolved in water reacts to form hypochlorous acid and hydrochloric acid:

$$Cl_2 + 2H_2O \rightleftharpoons HOCl + H_3O^+ + Cl^-$$

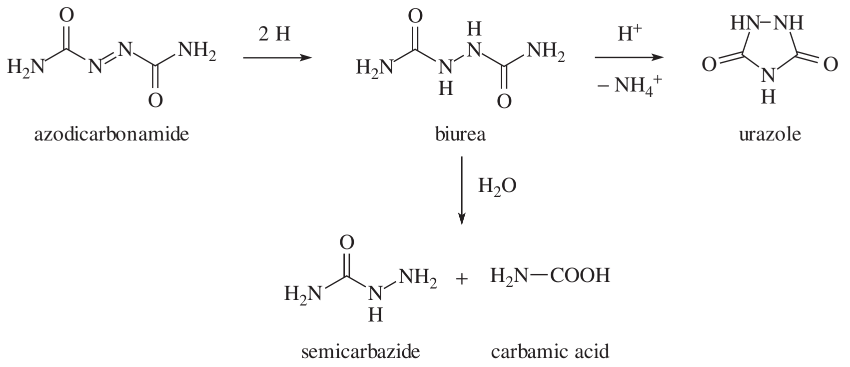


Figure 11.15 Decomposition of azodicarbonamide.

Under acidic conditions, the reaction equilibrium is shifted away from the formation of hypochlorous acid, which explains the formation of hypochlorite and chlorine and also the chlorinating action of chloramines, which are used as disinfectants and sanitising agents in the food industry. In acidic media hypochloric acid cation and chloride arise in the reaction with hydronium ions:

$$HOCl + H_3O^+ \rightleftharpoons H_2OCl^+ + H_2O \rightleftharpoons Cl^+ + 2H_2O$$

Hypochlorous acid dissociates with increasing pH (at pH 4–6 and higher):

$$Cl_2 + 2H_2O \rightleftharpoons HOCl + H_3O^+ + Cl^-$$

Hypochlorous acid and its anion also arise in alkaline media (pH 10.5–12.5):

$$Cl_2 + HO^- \rightleftharpoons HOCl + Cl^-$$
$$HOCl + HO^- \rightleftharpoons ClO^- + H_2O$$

In addition to these reactions, there irreversible reactions also proceed, in which oxygen is formed as the reaction product, which explains the oxidative properties of chlorine, hypochlorites and chloramines:

$$2Cl_2 + 2HO^- + 2H_2O \rightarrow 4Cl^- + 2H_3O^+ + O_2$$
$$\text{or } 2ClO^- \rightarrow 2Cl^- + O_2$$
$$2Cl^+ + 4HO^- \rightarrow 2Cl^- + 2H_2O + O_2$$

In the reaction of chlorine dioxide with water, hypochlorous, hydrochloric and chloric acids are formed temporarily, and in alkaline solutions chlorites (ClO_2^-), chlorates (ClO_3^-) and other products arise. The cation H_2OCl^+ formed in aqueous solutions of chlorine, chlorine dioxide and hypochlorites may react with alkenes and other unsaturated compounds. The electrophilic addition of HOCl to alkenes is an established reaction mechanism for α, β-chloroalcohol (chlorohydrin) and α, β-dichloro derivative formation (Figure 11.16). The reaction yielding chlorohydrins follows the Markovnikov rule with the hydroxyl group adding to the more substituted carbon. Oxidation of chlorohydrins by hypochlorites

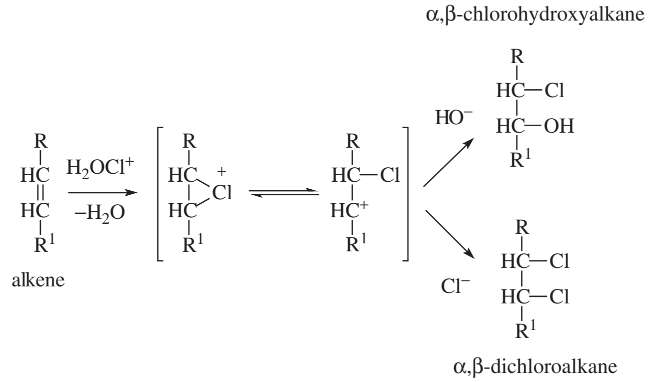

Figure 11.16 Reactions of hypochlorites with olefins.

in acidic media may yield α-oxochloroalkanes, while epoxides arise in neutral (or slightly alkaline) media, by elimination of hydrogen chloride, and are hydrolysed by acids and bases to the corresponding α, β-dihydroxyalkanes.

The reaction of chlorine in flour with unsaturated fatty acids, which are also alkenes, yields a number of fatty acid chlorinated derivatives (dichloroacids and chlorohydroxyacids). Chlorohydroxyacids are formed preferentially with chlorine dioxide. For example, oleic acid produces 9,10-dichlorostearic, 9-chloro-10-hydroxystearic and 10-chloro-9-hydroxystearic acids. From linoleic acid the corresponding disubstituted derivatives of oleic acid or tetrasubstituted derivatives of stearic acid are formed. Their content in flour, depending on the amount of chlorine used for bleaching, is given in Table 11.14. Chlorinated fatty acids are also formed in the fat of chicken carcasses that are cooled in chlorinated water after slaughter.

The use of nitrogen trichloride, also known as trichloroamine (NCl_3), to bleach flour was found to evoke hysteria in experimental animals (dogs), due to the presence of methionine sulfoximine (**11-60**). Methionine sulfoximine, a methionine antagonist, arises in the reaction of methionine with nitrogen trichloride.

Unsaturated terpenes also react with electrophilic reagents, such as hypochlorous acid (HOCl). Reactions of HOCl with a variety of terpenes, including limonene monoxide, α-pinene and α-terpineol, have been reported. For example, limonene, the

(1*R*,2*R*,4*R*)-2-chloro-8-*p*-menthen-1-ol (1*S*,2*S*,4*R*)-2-chloro-8-*p*-menthen-1-ol (1*R*,2*R*,4*R*)-2,9-dichloro-8-*p*-menthen-1-ol

11-61, reaction products of limonene with hypochlorous acid

major component of orange essential oil, reacts with hypochlorous acid found in chlorinated water to form the diequatorially substituted (1*R*, 2*R*, 4*R*)-2-chloro-8-*p*-menthen-1-ol, the diaxial (*E*)-stereoisomer, (1*S*, 2*S*, 4*R*)-2-chloro-8-*p*-menthen-1-ol as the major chlorohydrin and the dichlorohydrin, (1*R*, 2*R*, 4*R*)-2,9-dichloro-8-*p*-menthen-1-ol (**11-61**).

One of the major problems associated with the disinfection of water supplies by chlorination is that the chlorinated water may produce the so-called chlorophenolic taste produced by a reaction between the added chlorine and phenol and some of its homologs that are present in trace amounts. The chlorination of phenol proceeds by the stepwise substitution of the 2-, 4- and 6-positions of the aromatic ring. Initially, phenol is chlorinated to form either 2- or 4-chlorophenol. Then 2-chlorophenol is chlorinated to form either 2,4- or 2,6-dichlorophenol, while 4-chlorophenol forms 2,4-dichlorophenol. Both 2,4- and 2,6-dichlorophenol are chlorinated to form 2,4,6-trichlorophenol, which reacts with aqueous chlorine to form a mixture of non-phenolic oxidation products. 2,4,6-Trichloroanisole was the first compound identified as the source of taints in wines, perceived as musty or mouldy aromas. 2,4,6-Trichloroanisole in wine originates from chlorination of lignin-related substances during bleaching of the cork with chlorine, the product(s) subsequently being leached into the wine during storage. This taint is known as corkiness and is widely attributed to the interaction of bacteria and fungi with constituents of the cork that methylate 2,4,6-trichlorophenol. 2,4,6-Trichloroanisole can be similarly formed during microbial contamination of packaging materials and in soil contaminated with phenols. 2,4,6-Trichlorophenol is also an industrial agent used to decontaminate wooden objects, including the floors, beams and barrels in wine cellars. In addition, 2,4,6-trichloroanisole is produced together with 2,4,6-trichlorophenol by degradation of some pesticides (such as fungicide pentachlorophenol). Pentachlorophenol and the lower chlorinated phenols, tetra- and trichlorophenols, have been used increasingly as fungicides, herbicides, insecticides and precursors in the synthesis of other pesticides since the early 1930s (see Section 12.6.2.1.1).

11.5 Substances modifying texture

Substances modifying and regulating food texture and other physical properties of foods are, in terms of quantity, the main additive substances used. The most important groups are:

- thickeners and gelling agents
- emulsifiers.

Many of these substances can be simultaneously classified into several categories of food additives, because they have different properties and are used for various purposes.

11.5.1 Thickeners and gelling agents

The reason for the use of thickeners and gelling agents is to create and maintain a desirable texture to food. Thickeners are substances that increase the viscosity of food, and gelling agents

produce gels. These additives include natural plant polysaccharides, such as starch (not considered a food additive), cellulose (E460) and pectins (E440), seaweed polysaccharides, such as gum arabic (E414), agar (E406) and carrageenan (E407), extracellular bacterial polysaccharides, such as gellan (E418) and xanthan gums (E415) and modified polysaccharides, such as modified starches (E1404, E1410, E412-E1414, E1420, E1422, E1440-1442) and modified celluloses (E461–E469). Their structure, occurrence, properties and applications are given in the Chapter 4 dealing with polysaccharides. Gels and other food dispersion systems are described in Section 7.8.3.2.2.

11.5.1.1 Legislation

Thickeners and stabilisers of dispersions and emulsions, which can be used to the maximum amount allowed are, for example, karaya gum (E416), konjak gum (E425), sucrose acetate isobutyrate (E444) and glycerol esters of wood rosins (E445). For example, karaya gum (E416) is allowed at levels of 5000 mg/kg for chewing gums, confectionery fillings, toppings for pastries and biscuits, at 6000 mg/kg for desserts and up to 10 000 mg/kg for cold emulsified sauces and egg liqueurs.

11.5.1.2 Health assessment

Some thickeners and gelling agents are considered as food (e.g. starches) and for many others ADI values are not specified, for example for carrageenan (E407), locust bean gum (E410), guar gum (E412), tragacanth (E413), powdered and microcrystalline cellulose (E460), gum arabic (E414) and many others. ADI values are set for karaya gum (20 mg/kg), tara gum (E417, 12.5 mg/kg), methyl, ethyl, hydroxymethyl, hydroxypropyl and sodium carboxymethyl cellulose (25 mg/kg) and dextrins (E1400, 70 mg/kg). The role of thickeners and gelling agents in nutrition and other information are provided elsewhere (see Section 7.8.3.2.2). No side effects of natural polysaccharides, modified starches and celluloses in the concentrations used are known, although high concentrations may bring about flatulence and bloating, due to fermentation by intestinal microflora (in the same way as all indigestible polysaccharides) and high concentrations of cellulose (E460), and modified celluloses can cause intestinal problems, such as bloating, constipation and diarrhoea. Tara gum (E417) and gellan gum (E418) may have laxative properties. Short-chain carrageenans may cause intestinal leakage and are not permitted for use in foods. High concentrations of alginic acid and alginates (E400) could lead to impairment of iron uptake, as iron is efficiently bound by these polysaccharides.

11.5.2 Emulsifiers

Emulsifiers (also known as emulgents) are surfactants enabling the formation of emulsions (especially dispersions of fat in various products). In addition to their ability to form an emulsion, emulsifiers have the ability to interact with other food ingredients. The emulsifier may be an aerating agent, starch complexing agent and/or crystallisation inhibitor. In flours they act as conditioners that soften the crust of pastry, and in confectionery they act as modifiers of crystallisation of fats and have other beneficial properties. Formation of emulsions, their properties and the factors affecting their formation are described in Section 7.8.3.3.

11.5.2.1 Classification

Food emulsifiers are classified according to several criteria. Any emulsifier consists of a hydrophilic head derived from a variety of polar compounds (e.g. glycols and sugar alcohols) and a hydrophobic tail, which is a residue of a fatty acid. The hydrophilic head is directed to the aqueous phase and the hydrophobic tail to the oil. According to the structure of the polar part of the molecule (hydrophilic head), the following groups of emulsifiers are recognised:

- esters of glycols (e.g. esters of propane-1,2-diol)
- glycerol esters and their derivatives (e.g. partial esters of glycerol)
- esters of sorbitans (esters of glucitol dehydration products)
- sucrose esters (partial esters)
- esters of hydroxycarboxylic acids (such as lactic and tartaric acids)
- lecithin and its derivatives.

According to the origin, emulsifiers are identified as:

- natural (such as lecithin and partial esters of glycerol)
- synthetic (other emulsifiers).

According to the properties of hydrophilic and lipophilic moieties (expressed by the so-called HLB value) emulsifiers are recognised as:

- hydrophilic
- lipophilic.

According to their ability to form or not to form ions, emulsifiers are classified into:

- ionogenic also known as ionic (the hydrophilic moiety can be an anion, a cation or may have an amphoteric character)
- non-ionogenic also known as non-ionic (the hydrophilic part of the molecule is not ionised).

Salts of fatty acids are ionogenic emulsifiers and lecithins have an amphoteric character. The most common food emulsifiers (e.g. fatty acid esters of glycerol, sorbitans, sucrose and hydroxycarboxylic acids) are non-ionogenic emulsifiers.

Table 11.15 HLB values and E-numbers of selected emulsifiers.

Substance	HLB	Substance	HLB
Oleic acid	1.0	Polyoxyethylene sorbitan tristearate (Tween 65, E436)	10.5
Sorbitan tristearate (Span 65, E492)	2.1	Polyoxyethylene sorbitan monostearate (Tween 60, E435)	14.9
Monostearoylglycerol (mixture of isomers)	3.4	Polyoxyethylene sorbitan monooleate (Tween 80, E433)	15.0
Sorbitan monooleate (Span 80, E494)	4.3	Polyoxyethylene sorbitan monopalmitate (Tween 40, E434)	15.6
Sorbitan monostearate (Span 60, E491)	4,7	Polyoxyethylene sorbitan monolaurate (Tween 20, E432)	16.7
Sorbitan monopalmitate (Span 40, E495)	6.7	Sodium oleate	18.0
Sorbitan monolaurate (Span 20, E493)	8.3	Potassium oleate	20.0

The applicability of food non-ionogenic emulsifiers greatly depends on their HLB value (Hydrophilic Lipophilic Balance value), which is a measure of the degree to which the emulsifier is hydrophilic or lipophilic. Substances with a low HLB value tend to dissolve in oil (o), but substances with a high HLB value dissolve better in water (w). Numerical HLB values range from 0.0 to 20.0, with a value of 0 corresponding to lipophilic substances and value of 20 to hydrophilic substances – see Table 11.15).

11.5.2.1.1 Lecithin and its derivatives

The term lecithin is used for (3-*sn*-phosphatidyl)choline (1,2-diacyl-*sn*-glycero-3-phosphocholine, or phosphatidylcholine for short) and the mixture of natural phospholipids used as emulsifiers (see Section 3.5.1). Crude food grade lecithins (E322) are mainly obtained from the processing (degumming, also known as hydration) of vegetable oils (soybean, maize, or safflower oils). Almost all of the commercially available lecithin is derived from soybean oil, which contains 1–3% of lecithin. Less important sources include other vegetable oils and eggs. The main component of lecithin is phosphatidylcholine, where the hydrophilic part of the molecule $X = (CH_2)_2N^+(CH_3)_3$. Phosphatidylcholine is accompanied by phosphatidylethanolamine, phosphatidylserine and phosphatidylinositol (see Section 3.5.1). Commercial lecithin may contain up to 35% triacylglycerols.

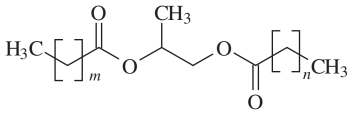
Commercial lecithin is an important product, because of its dietary significance and multifaceted industrial applications. Lecithin products fall into three categories: natural lecithin (such as unbleached and bleached lecithin), refined lecithin and chemically modified lecithin. Bleaching of dark brown crude lecithin is carried out using hydrogen peroxide or benzoyl peroxide to obtain a product of lighter colour, but may result in peroxide oxidation of unsaturated fatty acids. Chemically modified lecithin is more hydrophilic. For example, hydroxylated lecithin is prepared by treating lecithin with hydrogen peroxide and acetic or lactic acid. Two of the earliest applications of lecithin include lowering the viscosity in chocolate and confectionery products, and emulsification/anti-spatter properties in margarine. In addition, its other uses are in the production of bakery goods, pasta products, textiles, insecticides and paints.

11.5.2.1.2 Fatty acid salts

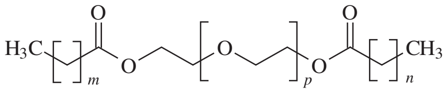
Salts of fatty acids (sodium, potassium and calcium salts, E470a, or magnesium salts, E470b) are produced mainly from vegetable oils, but can also be produced from animal fats. The acids are a mixture of oleic, palmitic, stearic and myristic acids. Salts of fatty acids are used as anti-caking agents in powdered foods to prevent clumping and as emulsifiers.

11.5.2.1.3 Esters of glycols

Fatty acid esters of propane-1,2-diol (E477), also known as propylene glycol (**11-62**), and fatty acid esters of polyethylene glycol 8000 (**11-63**, E1521, the HLB value depends on the degree of ethoxylation) are obtained by direct esterification or by enzymatic reactions. These substances are used for oil-in-water emulsions (o/w emulsions for short).



11-62, propyleneglycol diesters



11-63, polyethyleneglycol diesters

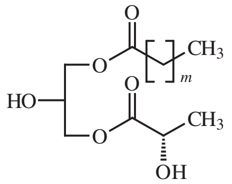
11.5.2.1.4 Esters of glycerol and their derivatives

Monoacylglycerols and diacylglycerols

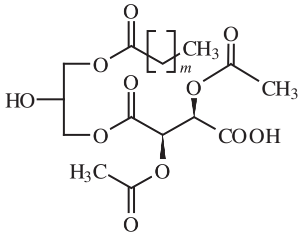
Partial esters of glycerol, mono- and diacylglycerols (E471), are obtained by glycerolysis of fats (usually hydrogenated oils) or by direct esterification of glycerol. The predominant components of monoacylglycerols are 1-acyl-*sn*-glycerols and diacylglycerols are dominated by 1,3-diacyl-*sn*-glycerols. Monoacylglycerols obtained by molecular distillation (containing about 90% of monoacylglycerols) are suitable for most purposes.

Esters of monoacylglycerols and diacylglycerols

The emulsifying efficiency of partial glycerol esters is higher when these esters are esterified with carboxylic acids, such as acetic (E472a), lactic (E472b), citric (E472c), fumaric, succinic, tartaric (E472d), monoacetyl and diacetyl tartaric acids (E472e) or mixtures thereof, such as mixed acetic and tartaric acid esters of mono- and diacylglycerols (E472f). For example, the reaction of 1-acyl-*sn*-glycerols with lactic acid yields a mixture of products containing 1-acyl-3-lactate (**11-64**), its isomer 1-acyl-2-lactate and fully esterified product 1-acyl-2,3-dilactate. Corresponding products are produced with diacetyl tartaric acid (**11-65**). Analogously to these derivatives containing one fatty acid in the molecule, produced for special purposes are esters of glycerol with two fatty acids and one hydroxycarboxylic acid (esters of diacylglycerols with hydroxycarboxylic acids).



11-64, (*S*)-1-acyl-3-lactoyl-*sn*-glycerol

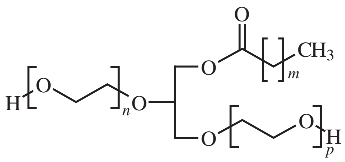


11-65, (2*R*,3*R*)-1-acyl-3-(2,3-diacetyltartaroyl)-*sn*-glycerol

Esters of mono- and diacylglycerols with acetic acid (E472a) are used as substances preventing crystallisation of fats, esters of succinic acid have found use as flour conditioners (enhancers), esters of citric acid as emulsifiers, solvents for antioxidants and fat substitutes in some foods. They also enhance the baking properties of flour.

Ethers of monoacylglycerols and diacylglycerols

Another way of modifying the properties of partial esters of glycerol is their reaction with ethylene oxide in alkaline media (ethoxylation), which yields products with different lengths of side chains (that contain up to 40 residues of ethylene oxide), sometimes branched and therefore of different polarities. The structure of 1-monoacyl-*sn*-glycerol ethers is represented by the formula **11-66**. Instead of ethylene oxide propylene oxide may similarly be used, which gives rise to analogous products. Mixed copolymers may also be obtained. Ethoxylated monoacylglycerols, for example, have good dough strengthening characteristics but very little crumb softening. Dosage of these viscous liquids is rather critical as excess amounts cause excessive expansion which can lead to collapse of the bread when in the oven. Ethoxylated monoacylglycerols are usually combined with monoacylglycerols, but they are not approved for use in the EU.



11-66, polyethyleneglycol ether of 1-monoacyl-*sn*-glycerol

Esters of polyglycerols

Fatty acids can also be esterified by polyglycerols (E475), which are formed from glycerol in alkaline media via 2,3-epoxypropan-1-ol (glycidol, Figure 11.17). Glycidol can isomerise to 3-hydroxypropanal or 1-hydroxypropanone, which give various coloured products in the Maillard reaction. Glycidol additionally condenses with another molecule of glycerol to 1,1-diglycerol (4-oxa-heptane-1,2,6,7-tetrol), to a lesser extent to 1,2-diglycerol (3-oxa-2-hydroxymethylhexan-1,5,6-triol) or, via epoxide, to triacylglycerols (such as 4,8-dioxaundecan-1,2,6,10,11-pentol) and higher oligomers. The dominant products under alkaline conditions are diglycerols, but also common are products that contain 3–6 or more glycerol molecules. In addition to linear products, to a lesser extent (reactivity of secondary hydroxyl groups are lower) branched products are formed. In acidic media various cyclic products are produced, of which the main product is 2,5-bis(hydroxymethyl)-1,4-dioxane formed as a product of diglycerol dehydration. The same products result from glycerol in acid protein hydrolysates.

Phosphatidic acids

Monoacylglycerols and diacylglycerols can also be esterified using phosphorus pentoxide. For example, esterification of 1,2-diacyl-*sn*-glycerol yields phosphatidic (1,2-diacyl-*sn*-glycerol 3-phosphate) and the corresponding bisphosphatidic acid and their positional isomers. Both acids are natural-identical products, which serve as substitutes for lecithin. Ammonium phosphatides (E442) are approved in the EU as emulsifiers.

11.5.2.1.5 Derivatives of sorbitans

Sorbitan esters

An important group of non-ionogenic emulsifiers are esters of sorbitol (correctly D-glucitol) with higher fatty acids. During esterification, sorbitol is simultaneously dehydrated, creating a mixture of free anhydro derivatives called sorbitans, their monoesters, diesters and triesters. The most important products are esters derived from 1,4-sorbitan, 1,5-sorbitan and 2,5-sorbitan (**11-67** to **11-69**). The reaction can be continued to yield a dianhydride ester, which is called isosorbide (**11-70**). The resulting mixtures of

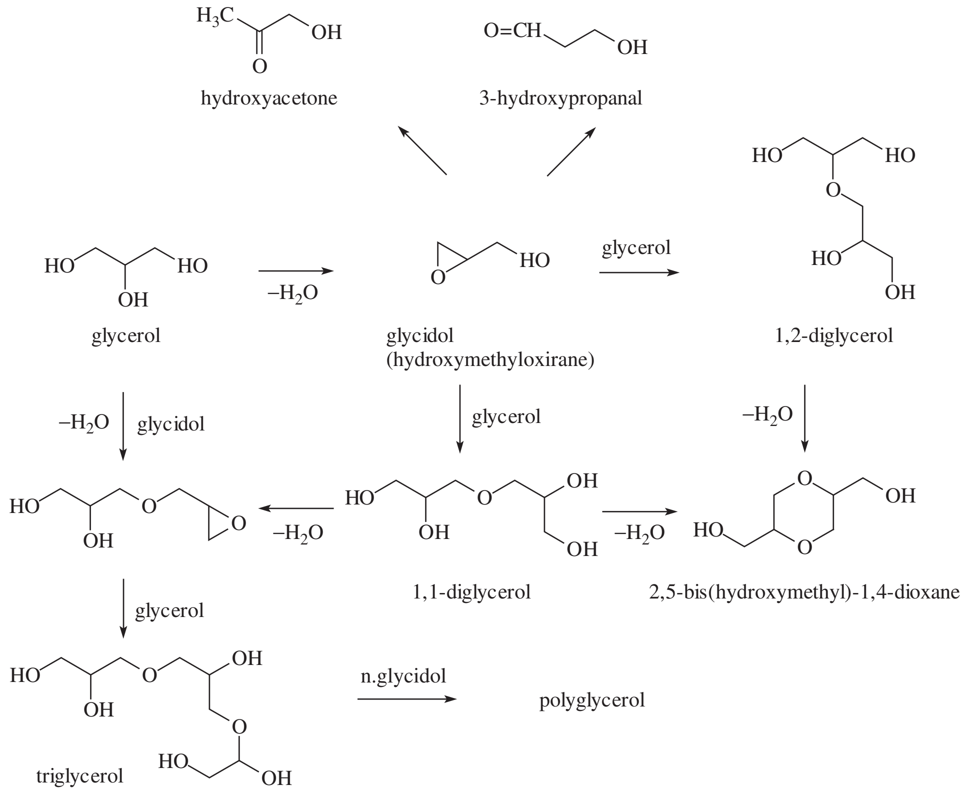


Figure 11.17 Reactions of glycerol with glycidol.

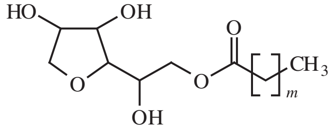
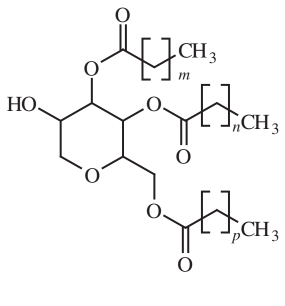
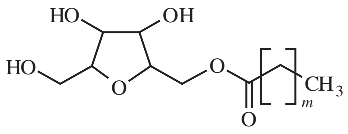
various mono-, di- and triesters of optically active anhydrides (e.g. the corresponding 1,4-sorbitan structure is represented by the formula **11-71** and the isosorbide structure by the formula **11-72**) are known as **Spans**. Their trade names, E-numbers and HLB values are listed in Table 11.15. Spans act as lipophilic emulsifiers with properties similar to those of monoacylglycerols (sorbitan monoesters) and diacylglycerols (sorbitan triesters), but with higher emulsifying ability.



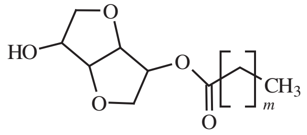
11-67, 1,4-sorbitan ester



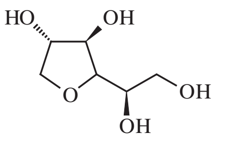
11-68, 1,5-sorbitan triester



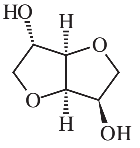
11-69, 2,5-sorbitan ester



11-70, isosorbide ester



11-71, 1,4-sorbitan

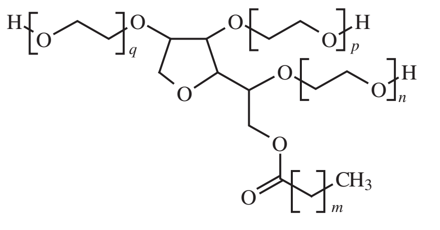


11-72, isosorbide

Acylsorbitan ethers

Partial esters of sorbitans with fatty acids can be modified by reaction with ethylene oxide (under pressure, at elevated temperatures and in the presence of sodium ethoxide or other catalysts), which yields a mixture of products substituted to varying degrees

in free hydroxyl groups, the side chains of which may be branched. These polar emulsifiers are also known as polysorbates or **Tweens** (**11-73**). They are very effective in slowing down the aging of pastry products. Their trade names, E-numbers and HLB values are listed in Table 11.15.

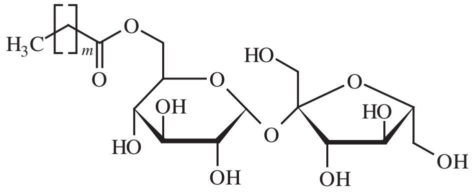


11-73, Tween derived from 1,4-sorbitan

11.5.2.1.6 Sucrose derivatives

Esters

A special group of emulsifiers are sucrose esters of higher fatty acids (E473), which are synthesised from fatty acid methyl esters re-esterified by sucrose (in dimethylformamide or dimethyl sulfoxide under catalysis of alkaline reagents). The most common compounds are strongly polar, water-soluble monoesters (**11-74**) with HLB values > 16, which are used as stabilisers of emulsions, or diesters, which have a wide range of HLB values ranging from 7 to 13 and are used to stabilise the emulsions of the type o/w. Adjusting the reaction conditions can also provide triesters (HLB < 1) and tetraesters. Like sucrose, sucrose esters are easily decomposed on heating to give coloured products.



11-74, sucrose-6-ester

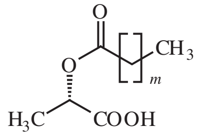
Sucrose esters containing more than five fatty acid residues do not have emulsifying ability, but can be used as low-energy fat substitutes, because they are not absorbed in the digestive tract. Such a product is Olestra, also known by its brand name Olean, which was approved by the US Food and Drug Administration (FDA) as a food additive in 1996. In the late 1990s, Olestra lost its popularity due to the discovery of side effects (including inhibition of absorption of some fat-soluble vitamins) and is not approved for sale in many countries.

Sugarglycerides

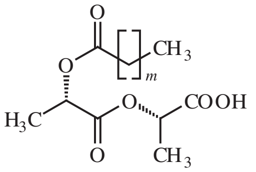
Esterification of glycerol esters by sucrose yields the so-called sugarglycerides (E474), which represent a mixture of various sucrose esters and glycerol esters. Their polarity roughly corresponds to the polarity of monoacylglycerols.

11.5.2.1.7 Hydroxycarboxylic acid esters

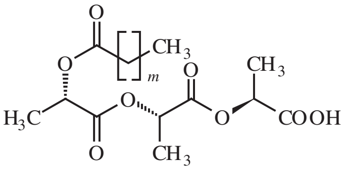
Fatty acids may also be directly esterified by hydroxycarboxylic acids, the most common of which are lactic acid and (2*S*,3*S*)-tartaric (D-tartaric) acid. Lactic acid gives rise to esters called lactylates, at first a monoester (**11-75**), which reacts with another molecule of lactic acid yielding the ester of a dimeric acid (**11-76**), which may arise also by reaction of a fatty acid with lactides. Other reactions can produce emulsifiers in which one molecule of a fatty acid accounts for a greater number of molecules of lactic acid (**11-77**). Stearoyl tartrate, also known as stearoylpalmitoyl tartrate (E483), is approved in the EU as an emulsifier. The main components of this product are distearoyl tartrate, dipalmitoyl tartrate and stearoylpalmitoyl tartrate.



11-75, L-lactic acid ester



11-76, ester of lactic acid dimer



11-77, ester of lactic acid trimer

Esters of lactic acid (lactylates) can be converted into salts and thereby become highly effective polar, anionic emulsifiers. Sodium (E481) and calcium (E482) stearoyl 2-lactylates are approved in the EU as emulsifiers and flour improvers.

11.5.2.1.8 Other emulsifiers

Fatty acids can be esterified by a number of sugar alcohols (such as D-mannitol, maltitol and lactitol) or sugars (D-glucose, D-fructose, maltose and lactose).

11.5.2.2 Properties

For application in food systems and preparation of w/o emulsions, emulsifiers with an HLB value of 3–6 are used, while for the preparation of o/w emulsions substances with an HLB value of 15–18 are used. Emulsifiers with an HLB value of 7–9 are commonly used as moisturisers (emollients). Approximate HLB values of certain emulsifiers and other surfactants are given in Table 11.15. For example, an emulsifier of HLB value 17 is needed for the preparation of an o/w emulsion of oleic acid, an emulsifier of HLB value 9 for beeswax emulsion, an emulsifier of HLB value 6 for rapeseed oil and cocoa butter emulsions and an emulsifier of HLB value 5 for pork lard emulsion. In practice, mixtures of two compatible

emulsifiers in calculated proportions (one with low HLB value and the other with high HLB value) are preferred.

11.5.2.3 Legislation

Emulsifiers which may be used in the necessary quantities are emulsifiers E322, E471 and E472a–f. Polysorbates (E432–E436), sugar esters (E473, E474), stearoyl lactates (E481, E482) and emulsifiers E475, E476, E477, E479b, E483 can only be used up to the maximum amount permitted for certain foods. For example, sugar esters E474 are allowed for fine pastry, biscuits and confectionery products in quantities up to 10 000 mg/kg, for ice creams in quantities up to 5000 mg/kg and for soups and broths in quantities up to 2000 mg/kg. The maximum amount allowed varies according to the type of emulsifier and type of food. For example, for polyoxyethylene sorbitans this amount ranges from 1000 (dietary foods for weight control) to 10 000 mg/kg (emulsified fats for bakery purposes).

11.5.2.4 Health assessment

There is no evidence in the available information on lecithin and lecithin bleached with hydrogen peroxide that demonstrates or suggests reasonable grounds to suspect a hazard to the public when they are used at levels that are now current or that might reasonably be expected in the future. For fatty acid salts, monoacylglycerols and diacylglycerols, esters of mono- and diacylglycerols with acetic, lactic and citric acids, no acute or chronic effects have been observed, and ADI values are not specified.

Certain toxic effects may be observed at higher doses of other emulsifiers, but side effects are not known in the concentrations used. ADI values have been set for the remaining emulsifiers: 25 mg/kg body weight for propane-1,2-diol esters and polyglycerols esters of fatty acids (high concentrations of propyleneglycol can cause eczema in sensitive persons, but not normally from the use in foods), none for esters of mono- and diacylglycerols with carboxylic acids, except 30 mg/kg body weight for tartaric acid esters (E472d-E472f), 30 mg/kg body weight for ammonium phosphatides, 25 mg/kg body weight for sorbitan esters (Spans) and for the entire group of polyoxyethylene sorbitans (Tweens) in the E432–E436 range (people intolerant of propylene glycol should also avoid this group of emulsifiers), 16 mg/kg body weight for sucrose esters and sucroglycerides and 20 mg/kg body weight for stearoyl tartrate and sodium and calcium stearoyl lactates.

11.6 Substances increasing biological value

Important nutritional factors include vitamins, minerals, amino acids, some fatty acids, fibre and other substances with important biological effects. Some of these substances may be used as food supplements that increase the nutritional value of the food or show other beneficial effects, can be also used as food additives and may have a function as pigments (riboflavin) or antioxidants (such as ascorbic acid). The use of substances enhancing the biological value of food closely monitors the development of knowledge in nutrition and is focused to intake of certain essential exogenous substances that may prevent various, previously endemic or just regional, diseases. Two basic reasons exist for the use of dietary supplements:

- they preserve the nutritional quality of food consumed at levels consistent with modern knowledge (such as adding vitamin D to margarines)
- they correct the deficiency of some nutritionally valuable substances in the diet (such as iodination of table salt).

11.6.1 Legislation

The Recommended Daily Allowances (RDAs) for vitamins and mineral elements set in the EU and U.S. are given in Sections 5.0 and 7.0, respectively. According to the European Regulation (EC) No 1925/2006, the enrichment of foods with vitamins and mineral elements is only allowed with approved (listed) vitamins, vitamin formulations, minerals and mineral substances and to a maximum per cent proportion of the reference daily intake. For the majority of vitamins and minerals, Directive 90/496/EEC on nutrition labelling of foodstuffs applies and defines a significant amount as 15% of the RDA.

11.6.2 Health assessment

Medical evaluation and other aspects of dietary supplements are listed in the chapters dealing with main nutrients (amino acids, essential fatty acids), vitamins and minerals.

11.7 Other food additives

In food production many other additives are used that have different properties and effects. Most often, this category of substances is classified into:

- firming agents
- processing aids
- synergists and potentiators
- propellants
- solvents.

Some technologies have identified other groups of additives. For example, for tobacco products combustion modifiers (activated carbon and ammonium chloride), substances for direct printing on cigarette paper, additives for chewing and snuff tobacco and others are used.

11.7.1 Firming agents

Firming agents are those that restore or maintain the texture of food. Generally they are soluble compounds that penetrate well into the material and do not have their own aroma and colour. These substances are mainly used in canned fruits and vegetables, jams and other products of plant origin, but also for animal products (such as cheeses). Typical firming agents are calcium and magnesium salts, such as calcium carbonate (E170), calcium hydrogen sulfite (E227), calcium citrates (E333), calcium phosphates (E341), calcium sulfate (E516), calcium chloride (E509), calcium gluconate (E578), magnesium chloride (E511), magnesium sulfate (E518) and magnesium gluconate (E580). For example, the effect of calcium chloride is based on the interaction of calcium ions with pectin, but it also binds metals and acts as an acidity regulator. The effect of sucrose is based upon its interaction with pectin substances, cellulose and hemicelluloses of plant cell walls by means of hydrogen bonds.

11.7.2 Processing aids

This category of additives includes:

- aroma carriers
- filling agents
- adhesives
- finishing substances
- humectants and plasticisers.

The use of solid aroma carriers facilitates the application of delicate or water-insoluble additives (particularly essential oils and various aroma compositions) in products. Aroma carriers also enhance the retention of aroma, since foods can be flavoured after heat or other treatments, which minimises the loss of aromatic compounds. Examples of aromatic carriers are starch, dextrins (E1400), cellulose (E460), silica (silicon dioxide, E551), and in particular β-cyclodextrin (E459) in quantities up to 1000 mg/kg. Aromatic substances are also applied after dissolution in appropriate solvents.

Filling agents increase the volume or weight of the food and generally do not significantly affect its energy yield. Fillers do not have own flavour and do not change colour of products. Some oligosaccharides and polysaccharides have found use in the manufacture of confectionery, chewing gum, vitamin preparations and cereal mixtures, and especially in various dietary and low-energy products. Fillers can also include some flour conditioners (others than emulsifiers), which increase the volume of bakery products, such as calcium stearoyl 2-lactylate (E482).

Adhesives bind food particles (e.g. reconstituted, poultry and fish meat and the so-called soy meat). They have also found use in extruded foods, production of chewing gum, sweets and tablets. The most commonly used additives are starch, dextrins (E1400), various plant gums, as well as oils and some salts (such as phosphates, which increase the solubility of proteins that denature during subsequent heat treatments and strengthen the material). Various adhesive agents are also used for food packaging.

Films on the food surface are often protection against oxidation by oxygen and slow down other reactions occurring in foods, prevent evaporation of water or (on the contrary) wetting and facilitate dissolution of products. Glossy coatings provide attractive appearances to the food. In some cases these films and coatings are a barrier from the invasion of microorganisms. Edible coatings or coatings which are easily removable are not considered as coatings. Some additives are used as glazing agents for fresh fruits (such as carnauba wax, E903), chocolates (such as a synthetic mixture of hydrocarbons – microcrystalline wax, E905) and eggs (to prevent access of air through pores of the shell – mineral oil, E905a). In the production of milk substitutes (coffee creamers) sodium caseinate for fat encapsulation is used.

Plasticisers are substances that affect the mechanical properties of food. Monoacylglycerols, oils, waxes and resins, and in particular, various wetting agents (humectants) are used as plasticisers. Humectants retain water in the food, prevent foods from drying out, reduce volatilisation of odorous substances or promote the dissolution of some substances in aqueous media. Polyols are mainly used as humectants. For example, glycerol (E422) is used in grated coconut, propane-1,2-diol (E477), glycerol, butane-1,3-diol, triethylene glycol ($HOCH_2CH_2OCH_2CH_2OCH_2CH_2OH$) and triacetin (triacetyl-*sn*-glycerol, E1518) in tobacco products, monoacylglycerols in caramel and margarine and waxes in chewing gums. Related groups are substances that increase the water-binding capacity in foods containing proteins, such as phosphates in dairy and meat products. Softening agents are used for printing inks and varnishes for packaging materials (such as triacetin in paper for cigarette filters).

11.7.3 Auxiliary agents

Auxiliary food additives include:

- anti-caking agents
- clarifying agents
- haze forming agents
- foaming agents
- dispersion stabilisers
- anti-foaming agents
- lubricants and release agents
- sequestrants
- synergists and potentiators
- packaging gases
- catalysts.

Anti-caking agents form coatings on the surface of the food particles and reduce their tendency to mutual adhesion. Potassium (E340) and magnesium phosphates (E343), silicon dioxide (silica, E551), various silicates (E551-E556, E559) and other substances may be used as anti-caking agents.

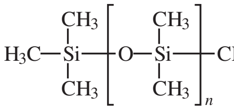
Clarifying agents stabilise beverages by removing hazes (e.g. in beer, wine and fruit juices). Proteins (such as gelatine), polyphenols (such as tannin), polyvinylpolypyrrolidone (E1202), phytic acid and bentonite (E558) can act as clarifying agents. Some enzymes that hydrolyse polysaccharides (such as pectins in fruit juices) are also clarifying agents.

To induce a turbid appearance to non-alcoholic drinks and beverages, especially to citrus fruit beverages, ice creams and other products, vegetable gums or, in the past, brominated vegetable oils (E443) are used. These are no longer approved in the EU. For beverages derived from fruits other than citrus fruits, the pulp and peels of citrus fruits is used.

Foaming agents are surfactants that allow creation of dispersions of gaseous substances in liquid or solid food. Foaming gases are carbon monoxide and carbon dioxide (E290) and in some countries natural saponins.

Dispersion stabilisers help to maintain desirable physical properties of emulsions and other disperse systems. Various polysaccharides, such as gum arabic (E414), are used as dispersion stabilisers.

Anti-foaming agents are food additives that prevent the formation of foam or reduce foaming, for example fatty acid esters of polyoxyethylene sorbitans (E432–E436) and silicone oils (dimethylpolysiloxane, E900, **11-78**).



11-78, dimethylpolysiloxane

Lubricants and releasing agents are applied on the surface of products or on the surface of production equipment. The purpose is to reduce the mutual attractive forces between the individual parts of the products, tack on packaging, production equipment and teeth during chewing and to allow easier handling of products and simplify processing. They are used mainly for dehydrated and frozen vegetables (magnesium silicate, E553a), sweets and chewing gum (starch), milk powder, cheeses, pasta (mono- and diacylglycerols, E471) and roasted nuts (starch). To reduce the stickiness of the product to the manufacturing equipment silicone oils and lecithin may be used. Lubrication of sheets for baking pastry is also done with silicone oil.

Sequestrants (chelating agents) form complexes with metal ions, thus preventing oxidation, undesirable discoloration and turbidity (calcium disodium ethylenediaminetetraacetate, E386 and its salts and phosphates, E450–E452).

Synergists and potentiators are substances that increase the effects of other additives. They are used to increase the activity of antioxidants (polyphenols, E452; citric acid, E330), emulsifiers (phosphates, E450), aromatic compounds (sodium hydrogen glutamate, E621; 5′-nucleotides, such as inosine 5′-phosphate, E630).

Packaging gases (other than air), which are introduced into the containers before, during or after filling with the foods have the role of an inert or modified atmosphere (e.g. nitrogen in ground coffee packaging, E941).

Propellants are substances that expel a food from a container or facilitate the formation of foam. For whipped creams and other dairy products, nitrous oxide (E942) is used. In cases where acidic agents can be used, it is possible to use carbon dioxide (E290) and, if foaming is desired, nitrogen (E941) can be used.

Catalysts speed up chemical reactions in which they do not actually enter. They are typically used in small quantities. Raney nickel is used as a catalyst in hydrogenation of oils and sodium methoxide (sodium methanoate) in the transesterification of fats. Acids are used as catalysts in the production of certain modified starches. Catalysts also include the enzymes used as food additives, such as amylase (E1100), proteases (E1101, for example papain, bromelain and ficin), glucose oxidase (E1102), invertase (E1103) and lipases (E1104).

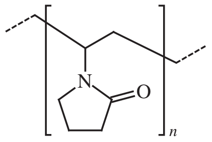
Solvents are additives that allow the extraction of desirable compounds, their dissolution and dilution. They also serve as carriers of aromatic compounds. For the extraction of hops, coffee, tea and spice, hexane, dichloromethane, acetone, trichloroethylene or supercritical carbon dioxide (for the extraction of caffeine from coffee or tea) are most commonly used. Ethanol is used as a solvent of aromatic substances for confectionery; monoacylglycerols are used as solvents for antioxidants and polyols for flavour potentiators.

11.7.4 Legislation

The category of auxiliary agents includes a vast array of food additives. In many cases, it is permissible to use these substances in the amount of *quantum satis* or under good manufacturing practice, but for some commodities maximum levels of additives are set.

Anti-caking agents may be used up to the maximum amounts and only for specified foods. For example, for normal table salt, cocoa powder and potato flakes, silicon dioxide (E551, 20 g/kg) is used as the anti-caking agent. Other agents may be used for coffee and tea whiteners such as silicon dioxide, calcium phosphate (E341), magnesium carbonate (E504) and other agents at levels of 10 g/kg. Talc (E553b) may be added to rice in specified quantities. Dimethylpolysiloxane (E900, **11-78**) may be used as an anti-foaming and anti-caking agent at an amount that does not exceed the specified maximum limits (100 mg/kg in chewing gum and 10 mg/kg in other foods). For the polishing and surface treatment of confectionery, chocolate, walnut kernels, coffee beans and fresh fruits (citrus fruits, melons, apples and pears) some waxes may be used, such as beeswax (E901), candellila wax (E902) and carnauba wax (E903), and shellac (E904). For tableting and coating of tablets, polyvinylpyrrolidone (E1201, **11-79**) and polyvinylpolypyrrolidone (E1202) may be used. For dissolution, dilution and other preparations of additives (colourings, emulsifiers and antioxidants) and flavourings only propane-1,2-diol (propylene glycol, E1520) may be used, the maximum amount of which, except for baby food, is 1000 mg/kg and polyethylene glycol

6000, $HO{-}CH_2{-}(CH_2{-}O{-}CH_2{-})_n{-}CH_2{-}OH$, (E1521). The numbers that are often included in the names of polyethylene glycols indicate their average molecular weights. For antioxidants and fat-soluble pigments, certain salts are allowed as carriers, such as calcium carbonate (E170), calcium acetate (E263), sodium citrates (E331) and numerous others, lecithins (E322), a number of polysaccharides, sugar alcohols and emulsifiers. For food dyes, sorbitan esters (E491–E495) and silicon dioxide (silica, E551) are permitted as emulsifiers. For emulsifiers, colours and flavourings some silicates can be used as anti-caking agents, such as calcium silicate (E552). Beeswax (E901) is only allowed for food dyes. Pyrrolidone polymers polyvinylpyrrolidone (E1201, **11-78**) and polyvinylpolypyrrolidone (E1202), various modified starches and esters, such as triethyl citrate (E1505) and triacetin (E1518), are allowed as stabilisers for sweeteners.



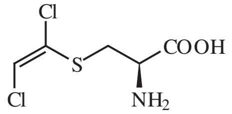
11-79, polyvinylpyrrolidone

11.7.5 Health assessment

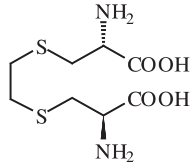
Some food additives are considered as food (such as gelatin, non-fat milk powder, honey, sucrose and starch), and for a number of other food additives ADI values are not specified, for example for various oxides, hydroxides and salts (such as magnesium oxide, silica, calcium chloride and calcium stearate), some polysaccharides (such as carrageenans), glycerol, polyvinylpolypyrrolidone, solvents (ethanol), waxes (beeswax, candilla wax and canauba wax) and others, and no side effects are known. Other substances are considered to be inert (such as dimethyl polysiloxane and polyvinylpolypyrrolidone). Carbon dioxide in concentrations $> 10\%$ by volume is a smothering agent, as is nitrous oxide in high concentrations. Calcium oxide and sodium methoxide are classified as corrosive chemicals.

ADI values are determined for other substances: for phosphoric acid and phosphates (the maximum total intake of phosphorus from phosphates should be 70 mg/kg body weight), calcium D-gluconate and polyvinylpyrrolidone (**11–78**, 50 mg/kg body weight), propane-1,2-diol and ethyl acetate (25 mg/kg body weight) and tannin (0.6 mg/kg body weight). Raney nickel is classified as a possible carcinogen.

Some chlorinated solvents previously used for the extraction of fats, reacted with proteins with the formation of toxic products. For example, soybean meal extracted with trichloroethylene caused, when fed to calves, aplastic anaemia (a condition that occurs when the body does not produce enough new blood cells) caused by toxic (*Z*)- and (*E*)-isomers of *S*-(1,2-dichlorovinyl)-L-cysteine (**11-80**), which arises as a reaction product of protein-bound cysteine with trichloroethylene and subsequent proteolysis. The reaction of 1,2-dichloroethane with proteins in cod fillets did not lead to chlorinated reaction products, but the nutritional value was reduced due to the formation of non-utilisable cysteine, histidine and methionine. Protein-bound cysteine yields, for example, *S*,*S*′-ethylenebiscysteine (**11-81**), which is resistant to proteolysis.



11-80, (*E*)-*S*-(1,2-dichlorovinyl)-L-cysteine



11-81, *S*,*S*′-ethylenebis-L-cysteine

12

Food Contaminants

12.1 Introduction

Food contamination refers to foods that are tainted or spoiled because they contain toxic substances, microorganisms or parasites that make them unsuitable for consumption. Food contamination is a serious issue because it results in food-borne diseases that affect many people worldwide each year. Hence, awareness of potential sources of food contamination is an important component of good nutrition.

Under certain conditions, various substances may arise in food or permeate into food from the external environment that can have a negative impact on human health. Substances that can get into food accidentally during agricultural production (agrochemicals), during technological or culinary processing, as well as during storage, transportation and marketing, or due to environmental pollution, are called food contaminants. Food contaminants also include some toxic secondary metabolites of microorganisms. Food contaminants can be classified according to the source of contamination and the mechanism by which they enter the food product. Important groups of contaminants include:

- **primary** or **exogenous** contaminants originating from external sources

- **secondary** or **endogenous** contaminants, which arise in food due to various physical and chemical factors from natural components of raw materials during food processing operations, better known as **food-borne**, **process-induced**, **processing** or **technological** contaminants.

In principle, the circumstances under which the primary (exogenous) or secondary (endogenous) organic and inorganic contaminants get into the human food chain may be summarised in the following points:

Agricultural production

- use of pesticides (so-called modern pesticides) and plant growth regulators;

- fertilisation (toxic metals, especially cadmium);

- environmental pollution, pollution load, for example the long-range transport (persistent organohalogen compounds) such as polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF), polychlorinated biphenyls (PCBs), DDT group of insecticides, polycyclic aromatic hydrocarbons (PAHs) and phthalic acid esters;

- use of surface water irrigation (especially pesticides and their metabolites, industrial chemicals and toxic metals);

- attack by microorganisms, especially by fungi (mycotoxins);

- veterinary treatment (drugs, hormones, pesticides and other compounds).

Storage and processing

- postharvest application of pesticides (mainly organophosphates and pyrethroids);

- formation of toxic degradation products from relatively non-toxic pesticides (ethylenethiourea, *N*,*N*-dimethylhydrazine);

- attack by microorganisms (bacterial toxins and mycotoxins);

- some technological or cooking procedures (heterocyclic amines, acrylamide, furan, 3-chloropropane-1,2-diol and its fatty acid esters, polycyclic aromatic hydrocarbons and nitrosamines);

- penetration of additives from plastics (such as phthalates and bisphenol A).

A number of exogenous and endogenous chemicals (e.g. PAHs, PCBs, PCDD, PCDF polychlorinated hydrocarbons) are classified as **persistent organic pollutants** (POPs), which are organic compounds resistant to environmental degradation through chemical

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

and biological processes. POPs are typically hydrophobic and lipophilic substances that partition strongly into solids (notably organic matter) in aquatic systems and soils rather than being dissolved in water. They also partition into lipids in living organisms rather than entering the aqueous milieu of cells, are stored in fatty tissue and accumulate in food chains as their metabolism is slow. The fate of persistent organic pollutants (POPs) in the abiotic (consisting of soil, water and air) and biotic (living organisms) components of the environment are related to their physical and chemical properties, such as high melting and boiling points, high vapour pressure (related to the value of Henry's law constant k_H), high lipophilicity (measured by the logarithm of octanal–water partition coefficient K_{OW}), low water solubility and high tendency for adsorption to soil or sediment particles (measured by the logarithm of adsorption coefficient K_{OC} normalised to the organic carbon content).[1]

Contaminants entering into the organism of biota leads to more or less extensive **biotransformation** and **bioaccumulation**. Biotransformation is the process whereby a substance is changed (transformed) into another by a biochemical reaction within the body. Biotransformation is thus a key body defence mechanism, the relative effectiveness of which depends on several factors, including species, age, gender, nutrition and some others. When biotransformation results in metabolites of lower toxicity, the process is known as **detoxification**. In many cases, however, the metabolites may be more toxic than the parent substance. This process is known as **bioactivation**. Bioaccumulation is the process by which contaminants from all sources combined (such as water, food and air) and through any route, including respiration, ingestion or direct contact with contaminated water or sediments, concentrate in tissues of living organisms (biota). **Bioaccumulation factor** (BAF) is the ratio of the contaminant in an organism to the concentration in the ambient environment at a steady state. **Bioconcentration** is the process of accumulation of water-borne chemicals by fish and other aquatic biota through non-dietary routes. A major distinction between bioaccumulation and bioconcentration is that in bioconcentration no dietary intake is involved. The measure of the tendency for a substance in water to accumulate in tissue of aquatic biota is called the **bioconcentration factor** (BCF), defined as the ratio of a contaminant concentration in biota to its concentration in the surrounding medium (water). **Biomagnification**, also known as bioamplification, is the result of bioaccumulation and biotransfer, by which tissue concentration of a contaminant in organisms at one trophic level exceeds tissue concentration in organisms at the next lower trophic level in the food chain. **Biomagnification factor** (BMF) refers to the ratio of contaminant concentration in biota to that in the surrounding water when the biota was exposed via contaminated food.

Among the most observed chemical contaminants are toxic minerals (metals, metalloids and other inorganic compounds), radioactive isotopes, mycotoxins and other microbial toxins, halogenated organic compounds, phytotoxins as representatives of natural contaminants and others. For the selection of contaminants to be covered in this chapter, a number of criteria were taken into account, the most important of which include:

- acute and chronic toxicity determined in toxicological studies (particularly neurotoxicity, carcinogenicity, mutagenicity, teratogenicity, immunotoxicity, interference with hormonal processes and other types of toxicities);
- frequency at which the given contaminant has been proven to be the cause of poisoning of humans or animals;
- frequent occurrence in foods representing important items of the food basket (special attention is paid to breast milk);
- persistence and frequency of occurrence of the given contaminant in the environment, possible conversion to (bio)products with higher toxicity and ability to bioaccumulate in the human food chain;
- massiveness of inputs (emissions) of the given contaminant into the environment from industry, agriculture, urban areas and other sources;
- importance of foods in which the contaminant occurs in terms of international trade.

There are considerable differences between experts and the general public in the perception of health risks associated with consumption of contaminated food. In a survey conducted in the UK in the early 1990s, the professionals put in first place the risks associated with microbial contamination, followed by risks arising from the presence of natural toxins, pollution from industrial contaminants, residues of veterinary drugs, pesticides and the presence of food additives. The general public considered the primary problem pesticide residues, as well as industrial contaminants, additives (so-called 'E additives'), residues of veterinary drugs, microbial contamination: they considered natural toxins the least serious risk. For various reasons, the concerns of ordinary consumers are frequently unfounded, biased and often become the argument in favour of the preference of organic products (organic food). Legislation and practical measures taken to ensure the hygienic and

[1] Values of Henry's law constant ($k_H = p/c$, where p is the partial pressure of the solute in the gas above the solution and c is the concentration of the solute) is a quantity frequently applied in the thermodynamic description of dilute aqueous solutions, which is used in environmental chemistry and atmospheric physics as a major criterion for describing air–water partitioning of solutes at near ambient conditions. It plays a major role in evaluating the transport of pollutants between atmosphere and aquatic systems, rainwater and aerosols. The octanol–water partition coefficient (K_{OW}) is a dimensionless number defined as the ratio of the compound's concentration in a known volume of octan-1-ol (c_O) to its concentration in a known volume of water (c_W) after the octan-1-ol and water have reached equilibrium. It has been found to be related to water solubility, soil/sediment absorption coefficients and bioconcentration factors of pollutants for aquatic life. The adsorption coefficient normalised to the organic carbon content of the soil (sediment) K_{oc} is a useful indicator of the binding capacity of a chemical on organic matter of soil and sediments and allows comparisons to be made between different chemicals. For example, $K_{oc} = c_{soil}/c_{aq} = c_{sediment}/c_{aq}$ where $= c_{soil}$ ($c_{sediment}$) are concentrations of test substance in soil (sediment) in equilibrium and c_{aq} = concentration of test substance in aqueous phase in equilibrium.

toxicological quality of food are applied to contaminants, natural toxins and food additives in the same way.

If the acquired knowledge and available data allow the estimation of health risks, then appropriate measures are incorporated into legislation. This is an important tool to protect the health of consumers, while allowing participants in the process of food production and distribution to set up appropriate conditions which lead to the reduction or elimination of contamination. In this context, episodic crisis should be noted, when the food contains toxic substances which were until then unknown. In many cases the aim of their use is food adulteration. Examples include carcinogenic synthetic Sudan pigments, which have been used frequently to colour spices, such as 1-(2-methoxyphenylazo)-2-naphthol, known as Sudan Red G, as an adulterant in turmeric, or 1-phenylazonaphth-2-ol (Sudan I, also known as Solvent Yellow 14 or Solvent Orange R) found in the United Kingdom in Worcestershire sauce produced by Premier Foods contaminated by adulterated chilli powder (this problem peaked in 2004–2007), or melamine (see Section 12.8.3) used mainly in China in order to increase the apparent protein content in food products including infant formula and milk powder (the scandal broke in 2007).[2] The presence of melamine was then reported in a wide range of products, where the contaminated milk was used as an ingredient.

The control system of residues of contaminants generally takes into account the toxicity of the given compound, the method of its use, the possibility of exposure of humans or livestock to residues and indicators of consumption of potentially contaminated foods. At the international level, the relevant recommendations are formulated by the commission of the Codex Alimentarius Committee and by the International Technical Consultation for Veterinary Drugs Registration. The challenge now is to achieve international harmonisation of criteria, in particular generally accepted maximum residue limits (MRLs).

Ongoing evaluation of the toxicity of pesticides is attended by experts of the Joint Meeting on Pesticide Residues (JMPR) representing FAO and WHO. This body effectively cooperates with the Codex Committee on Pesticide Residues (CCPR) and publishes consensus MRL data, which serve as a basis for the adoption of legislative measures at the international level. At the same time, the CCPR compiles a list of particularly hazardous pesticides, which should be the subject of subsequent JMPR evaluations.

The institution responsible for the common (supranational) registration of veterinary drugs in the EU is the Committee for Veterinary Medicinal Products (CVMP), which is organisationally subordinate to the European Medicines Evaluation Agency (EMEA). The basic principle is that no new veterinary preparation can be registered for use if the manufacturer cannot demonstrate that the drug is not safe to the treated animal (patient), the consumer, the attending person and the environment.

[2]The United Nations' food standards body, Codex Alimentarius Commission, has set the maximum amount of melamine allowed in powdered infant formula to 1 mg/kg and the amount of the chemical allowed in other foods and animal feed to 2.5 mg/kg. The United States does not allow melamine to be used as a food additive.

Major international activity focused on the issue of food contaminants also comes from the Global Environment Monitoring System/Food Contamination Monitoring and Assessment Programme (GEMS/Food), founded by the WHO in 1976 in order to inform governments of the participating countries, the Codex Alimentarius Committee, other interested institutions and the public about typical concentrations of contaminants in foods and their contribution to human exposure. The programme provides globally collected data on the occurrence of selected toxic metals (e.g. lead, cadmium and mercury), pesticides (such as DDT, aldrin and dieldrin), polychlorinated biphenyls (PCBs) and mycotoxins (aflatoxins). In addition to issuing the reports, another aim of the project is to support national monitoring programme projects.

Maximum limits for certain contaminants (nitrates, some toxic trace elements, 3-chloropropane-1,2-diol, polycyclic aromatic hydrocarbons, selected mycotoxins and polychlorinated biphenyls and dioxins) in foods (usually related to the edible part), valid for all EU Member States, are set by Commission Regulation (EC) No. 1881/2006. Products containing contaminants exceeding the maximum levels should not be placed on the market as such either, after mixture with other foodstuffs or used as ingredients in other foods. Foods containing mycotoxins cannot be deliberately detoxified by chemical treatment. Maximum levels of contaminants should always be set at a level that is reasonably achievable by following good agricultural and manufacturing practices. Food business operators have to apply measures to prevent and reduce the contamination as far as possible in order to protect public health, especially of infants and young children.

This chapter is divided into seven main sections. The first of these sections is focused on technological contaminants, namely heterocyclic amines, acrylamide, furan, chloropropanols and their fatty acid esters, polycyclic aromatic hydrocarbons, monocyclic aromatic hydrocarbons, nitroso compounds, and ethyl carbamate. Other sections deal with microbial toxins (mycotoxins and bacterial toxins), persistent organohalogen contaminants (such as polychlorinated biphenyls, dibenzodioxins and dibenzofurans), chlorinated aliphatic hydrocarbons, pesticides (persistent chlorinated hydrocarbons and modern pesticides), veterinary medicines and contaminants from packaging materials. Presented for each of these contaminants are structures, properties, occurrence and the main sources of dietary intake, mechanisms of formation, possibilities of food contamination, prevention and mitigation and health and toxicological evaluations.

12.2 Technological contaminants

Toxic or potentially unsafe compounds can arise even in industrial and culinary processing of common food raw materials and foods from their natural components. One of the oldest ways to ensure the microbiological safety of foods, increase their shelf life and also achieve the desired organoleptic properties (smell, taste, colour and texture) is heat treatment, by methods including smoking. Processes operating at elevated temperatures during various industrial operations or culinary processing induce, depending on the

specific physical conditions and chemical composition, a variety of enzymatic (biochemical) and non-enzymatic (chemical) reactions leading to the formation of new compounds. Many compounds produced in this way have antioxidant and antimutagenic properties, but industrial operations or culinary processing may also lead to the formation of compounds with proven toxic potential, and in some cases these compounds may show mutagenicity and carcinogenicity. This group of contaminants are mostly considered as processing or technological contaminants.

Precursors of these compounds are common amino acids or proteins, reducing sugars (including ascorbic acid), fatty acids, triacylglycerols and other lipids, while some other food components may also be precursors of certain technological contaminants. Often there are multiple precursors. Some additives may also participate in the formation of these contaminants, such as hydrochloric acid (known as protein hydrolysing agent in the production of acid protein hydrolysates and in technological practice considered to be an ancillary material), chlorine (chlorine dioxide) from drinking water and nitrites (used as antimicrobial agents and stabilisers of meat colour).

An example of processing contaminants arising at higher temperatures, which decades ago were considered risky in terms of health effects, are primary aromatic amines (aminoimidazoazaarenes), whose precursor is the amino acid creatinine, Strecker aldehydes and heterocyclic nitrogen compounds arising in the Maillard reaction. Some other amino acids and proteins may also be precursors of aminoimidazoazaarenes.

The list of intensively studied chemical contaminants generated by the Maillard reaction at the beginning of the 21st century has spread to acrylamide and furan. Acrylamide is formed from the amino acid asparagine in reactions with reducing sugars, again in the Maillard reaction. Furan precursors may include some amino acids, carbohydrates (including ascorbic acid), unsaturated fatty acids and other compounds, such as carotenoids. Chloropropanols and their esters with higher fatty acids, in particular 3-chloropropane-1,2-diol and its esters, are another group of processing contaminants. Their precursors in many foods are lipids (especially triacylglycerols, phospholipids and their hydrolysis products) and naturally present or intentionally added sodium chloride (salt). In hydrolysed vegetable proteins, the precursors of chloropropanols are lipids and hydrochloric acid. Nitroso compounds, in particular nitrosamines, are formed from nitrites (and nitrogen oxides) by reaction with amines and amino acids containing secondary amino groups. Precursors of nitrosamines may also become their transformation products and reaction products of the Maillard reaction (glycosylamines, aminodeoxysugars and nitrogen heterocycles), some phospholipids and some other nitrogen-containing substances. Polycyclic aromatic hydrocarbons are formed by pyrolysis of a number of compounds, such as steroids and aromatic hydrocarbons, as well as by pyrolysis of basic nutrients. Ethyl carbamate (urethane) is formed from natural precursors during fermentation processes used in the production of certain spirits and other products. The precursors are cyanides derived from cyanogenic glycosides, the amino acid citrulline, carbamoyl phosphate (an intermediate of the biosynthesis of pyrimidines) and urea or the previously used preservative diethyl dicarbonate. During fermentation processes, biogenic amines are also formed as byproducts of decarboxylation of amino acids (see Section 10.3.3.10).

Some processing contaminants may also be simultaneously classified as exogenous contaminants, but exogenous sources are minimal in comparison with endogenous sources. For example, the exogenous source of polycyclic aromatic hydrocarbons in the food chain may be a contaminated environment or tobacco smoke. Tobacco smoke can also be a source of nitrosamines. Some contaminants classified as exogenous may also arise during food processing in smaller amounts. Typical examples of such contaminants are monocyclic aromatic hydrocarbons, such as benzene, which is produced by decarboxylation of benzoic acid, and styrene, which is a product of cinnamic acid decarboxylation.

A number of other compounds that can be classified as technological contaminants are covered elsewhere in this book, in chapters devoted to proteins, lipids and carbohydrates. For example, thermal processes in alkaline media give rise to unusual amino acids from the proteins, such as lysinoalanine (see Section 2.5.1.3.4) and D-isomers of amino acids (see Section 2.5.1.2), the Maillard reaction gives rise to potentially toxic (mutagenic) compounds, such as methylglyoxal (see Section 4.7.1.2.2) and 5-hydroxymethylfuran-2-carbaldehyde (see Section 4.7.1.1.3), which are formed as transformation products of sugars. Other toxic products may be formed from lipids. Examples of compounds resulting from the oxidation of lipids are acrolein (see Section 3.8.2.2.3), malondialdehyde and 4-hydroxynon-2-enal. Also discussed is the health hazard of transformed glycosylated proteins, known by the acronym AGE, produced in the advanced stages of the Maillard reaction or the products of the subsequent oxidation of lipids (lipoxidation) known as ALE (see Section 3.8.1.12.1).

The following sections deal in detail only with processing contaminants whose occurrence (and amount) in foods is either regulated by EU legislation (for which MRL are set), or with processing contaminants the evaluation of which is subject to various monitoring studies. The aim of these studies is to collect sufficient information to estimate dietary exposure to these substances and evaluate the associated health risks.

12.2.1 Heterocyclic amines

12.2.1.1 Structure and nomenclature

The study of toxic products of the Maillard reaction was initiated in 1977 with the finding that the mutagenicity of charred grilled meat and fish is produced, in addition to neutral polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene, by certain basic compounds. Later research has shown that the basic compounds are mainly primary heterocyclic amines. These substances are divided into two groups:

- non-IQ mutagens
- IQ mutagens.

Non-IQ (also known as aminocarbolines or pyrolytic heterocyclic aromatic amines) and IQ mutagens are typical technological contaminants. More than 20 mutagenic heterocyclic aromatic amines have been isolated from various cooked meats, fish and poultry. Mutagens of the first group are mainly **pyridoimidazoles** and **pyridoindoles**. These substances were first isolated from pyrolysates of amino acids and proteins obtained at temperatures of 300–800 °C. Particularly high mutagenicity is shown by pyrolysates of tryptophan, glutamic acid, lysine, ornithine and phenylalanine and pyrolysates of some proteins (casein, wheat gluten and soy globulin). It was subsequently found that these substances likewise arise during thermal processing of foods, such as roasting, pan frying, grilling or grilling directly over an open flame. The first group of mutagens includes 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole, also known as Trp-P-1 (**12-1**), which was found in tryptophan pyrolysates together with 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2, **12-2**), 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole arising from glutamic acid (Glu-P-1, **12-3**) and further 2-aminodipyrido [1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2, **12-4**), 3,4-cyclopentenopyrido[3,2-*a*]carbazole for lysine pyrolysates (Lys-P-1, **12-5**), 4-amino-6-methyl-1*H*-2, 5,10,10*b*-tetraazafluoranthene from ornithine pyrolysates (Orn-P-1, **12-6**), 2-amino-5-phenylpyridine (Phe-P-1, **12-7**), 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC, **12-8**) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC, **12-8**).

Pyrolysates of aliphatic amino acids, such as alanine, valine, leucine and isoleucine (obtained at 230–250 °C) contained, in addition to the corresponding 2,5-dioxopiperazines (see Section 2.5.1.3.3), compounds of similar structures called **imidazopyrazinediones** (**12-9**) that are formed in the reaction of 2,5-dioxopiperazines with another molecule of amino acid and subsequent cyclisation. **Diimidazopyrazinediones** (**12-10**) are formed analogously. These compounds do not show toxic effects as they are not primary aromatic amines.

12-10, 2,5,7,10-tetrahydrodiimidazo [1,2-*a*:1′,2′-*d*]pyrazine-3,6-dione

Mutagens of the second and most important group include **aminoimidazoquinolines**, **aminoimidazoquinoxalines** and **aminoimidazopyridines**, namely 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ, **12-11**), 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ or 4-MeIQ, **12-11**), 2-amino-3,4-dimethylimidazo[4,5-*b*]quinoline known as IQ[4,5-*b*] (**12-12**), 2-amino-3-methylimidazo[4,5-*f*]quinoxaline (IQx, **12-13**), 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoxaline (4-MeIQx, **12-13**), 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx or 8-MeIQx, **12-13**), 2-amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline (4,8-DiMeIQx, 12-13), 2-amino-3,7,8-trimethylimidazo-[4,5-*f*]quinoxaline (7,8-DiMeIQx, **12-13**), 2-amino-1-methylimidazo[4,5-*g*]quinoxaline (IgQx, **12-14**), 2-amino-1,7-dimethyl imidazo[4,5-*g*]quinoxaline (7-MeIgQx, 12-14), 2-amino-1,6,7-tri methylimidazo[4,5-*g*]quinoxaline (6,7-DiMeIgQx, **12-14**), **2**-amino-1,7,9-trimethylimidazo[4,5-*g*]quinoxaline (7,9-DiMeIgQx, **12-14**), 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP, **12-15**), 2-amino-1-methyl-6-(4-hydroxyphenyl)imidazo-[4,5-*b*]pyridine (4′-OH-PhIP, **12-15**), IFP, 2-amino-(1,6-dimethylfuro[3,2-e]imidazo[4,5-b])pyridine (**12-16**), 2-amino-dimethylimidazopyridine (DMIP, **12-17**) and 2-aminotrimethylimidazopyridine (TMIP, **12-18**). All these IQ mutagens containing imidazole cycle derived from creatine/creatinine and an amino group in the C-2 position of the cycle are often collectively called **aminoimidazoazaarenes**. The remaining parts of their molecules

are formed from the Maillard reaction products. Aminoimidazoquinoline (IQ) and aminomethylimidazoquinoline (MeIQ) were first isolated from broiled sun-dried sardines by Japanese scientists in 1980 and one year later aminomethylimidazoquinoxaline (MeIQx) was also isolated from fried beef.

12.2.1.2 Occurrence, main sources and dietary intake

The exposure to aminoimidazoazaarenes primarily occurs through meat and fish, but small amounts of these compounds may also be present in flavourings, beer, wine and cigarette smoke. The exposure can similarly occur by inhalation of aerosol particles generated during cooking or that are present in the combustion gas, especially in diesel engine exhaust gas. In foods, PhIP is found in the highest levels, followed by MeIQx, MeIQ and IQ. Their total amount in thermally processed meat varies by meat type, cooking method and 'doneness' level (rare, medium or well done) and usually ranges from <1 to about 500 μg/kg and the current average concentrations are lower than 100 μg/kg. Total daily intake of aminoimidazoazaarenes is within the limits of 160–1800 ng and the dietary exposure is estimated to be 1–17 ng/kg body weight per day.

PhIP is the main aromatic amine formed in very well done barbequed chicken (up to 305 μg/kg), oven-broiled bacon (16 μg/kg), pan-fried bacon (4.9 μg/kg), oven-broiled ground beef (0.04–2.9 μg/kg), pan-fried beef steak (0.04–12.46 μg/kg). The amount of PhIP in meat depends greatly on its type and the method of heat treatment. Available data vary widely. For example, salmon cooked in a pan, in a convection oven or grilled at 200 °C may contain PhIP at the level of 0.02–2.2 μg/kg and in extreme cases even 73 μg/kg. PhIP has also been identified in flavourings, beer and wine (0.01–480 μg/kg), cigarette smoke, in the air and surface waters. Daily intake of PhIP varies from 286 to 458 ng, and its dietary exposure is estimated at 17 ng/kg body weight. Cooked meats also contain 4′-hydroxy analogue of PhIP, 4′-OH-PhIP. For example, the highest content of 4′-OH-PhIP was found in fried and griddled chicken breast, the concentration being 43.7 and 13.4 μg/kg, respectively, whereas the corresponding PhIP concentrations were 19.2 and 5.8 μg/kg. MeIQx was found in beef, pork and chicken meat and in fish. The highest amount in beef (steaks) reached 8.2 μg/kg, in hamburgers 4.6 μg/kg, but in pork the concentrations of MeIQx are relatively low (except for bacon, 0.9–27 μg/kg). Concentrations in grilled chicken and in chicken roasted in the oven or in a pan were 9 μg/kg, and in fish about 1.2 μg/kg. MeIQx was also found in thickened meat broth, wine, surface water and air. Its daily intake is estimated at 33–44.8 ng and dietary exposure to 2.61 ng/kg body weight.

MeIQ occurs less frequently and at lower concentrations as compared with other aminoimidazoazaarenes. The highest concentrations (0.03–72 μg/kg) have been found in fish, at the upper limit in grilled sardines and at the lower limit in baked fish. It is found in low or undetectable quantities in beef, pork (0.02 μg/kg in roasted meat, 1.7 μg/kg in bacon) and chicken. MeIQ was also identified in thickened meat broth, roasted coffee beans and cigarette smoke. Dietary exposure is estimated at 0.6 ng/kg body weight.

IQ was first found in grilled fish, fried minced beef and beef extracts, and later in many other foods (steaks, roasted chicken, fried minced pork and fried eggs) and cigarette smoke. Its concentrations range from <0.1 to >150 μg/kg, but usually do not exceed 1 μg/kg. For example, its concentrations in oven-broiled ground beef range from 0.01 to 0.1 μg/kg and in barbecued chicken 0.02–0.91 μg/kg.

Dietary exposure to IQ is estimated to be 0.28 ng/kg body weight per day.

The other aromatic amines are generally found in variable amounts. For example, well done pan-fried beef steak may contain 23.7 μg/kg 7-MeIgQx, 6.31 μg/kg 7,9-DiMeIgQx, 4.03 μg/kg IgQx and IFP (well-done meats may contain IFP at levels of from 1.4 to 46 μg/kg, 2.06 μg/kg 4,8-DiMeIQx, 0.68 μg/kg 6,7-DiMeIQx and 0.16 μg/kg IQ[4,5-*b*], while AαC and MeAαC are not present.

12.2.1.3 Formation

Heterocyclic amines known as aminoimidazoazaarenes are formed during thermal processing of meat of warm-blooded animals, poultry and fish by reactions of creatine/creatinine (**2-118**) with certain products of the Maillard reaction, but detailed mechanisms of their formation are not yet fully understood. Creatine was postulated to form the 2-amino-3-methylimidazo (2-aminoimidazo) moiety of aminoimidazoazaarenes by cyclisation and water elimination, a reaction that takes place spontaneously at temperatures above 100 °C. This part of the molecule (especially its 2-amino group) is a common moiety of all aminoimidazoazaarenes and is also responsible for their mutagenicity. The remaining parts of their molecules are assumed to arise from the Maillard reaction between sugars and amino acids, which produces various reactive intermediates for the formation of pyridines and pyrazines, such as glycolaldehyde and glyoxal imines, pyridinium cation, pyrazinium cation radical and pyrazinium dication. Aldol condensation of Strecker aldehydes is believed to link the two parts of aminoimidazoazaarenes together (Figure 12.1).

During cooking, heterocyclic amines can react with proteins (and free amino acids) by condensation of the amino groups of heterocyclic amines (such as PhIP) and carboxyl groups of proteins yielding the corresponding amides. The presence of such adducts may be an important factor in evaluating the carcinogenic risk of heterocyclic amines, because a portion of these mutagens formed by cooking change into non-mutagenic adducts. However, the parent heterocyclic amines can be released from high molecular weight compounds by acid hydrolysis or proteolytic digestion in the gastrointestinal tract and may influence human exposure to heterocyclic amines and carcinogenic risk.

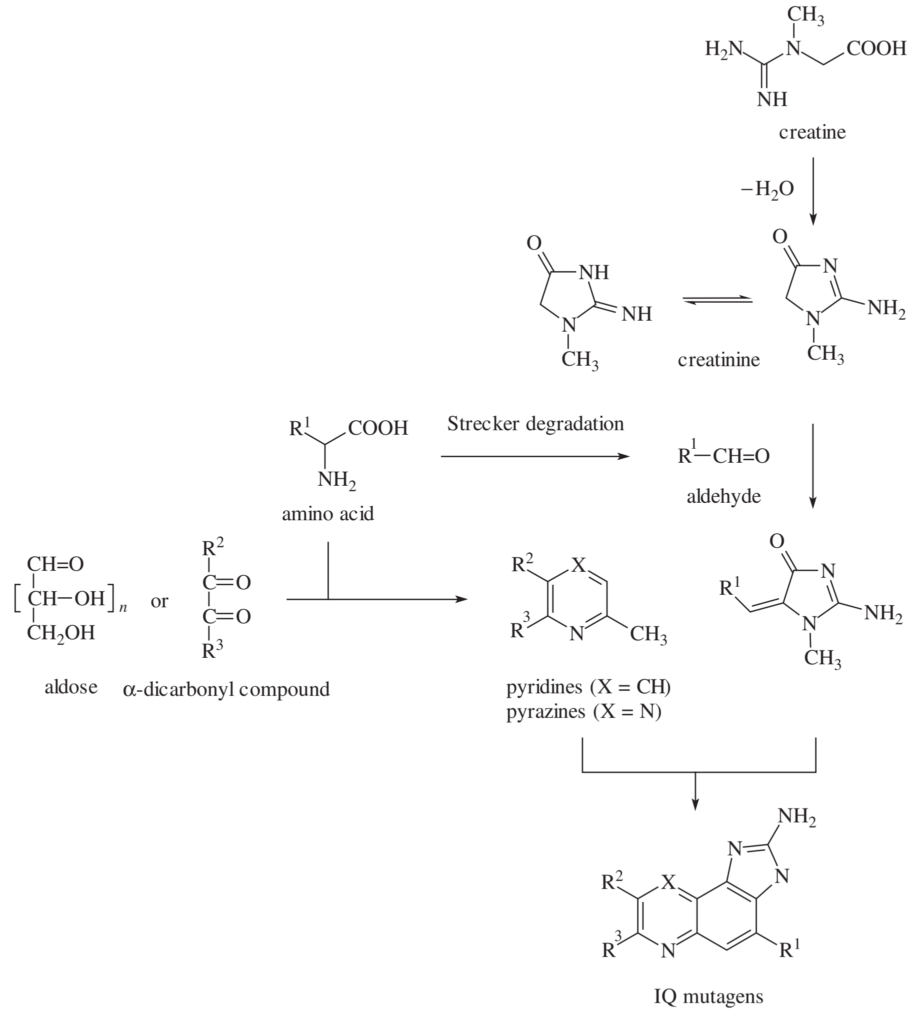

Figure 12.1 Formation of aminoimidazoazaarenes.

12.2.1.4 Health and toxicological assessment

Four compounds show high specific mutagenicity and carcinogenicity, namely 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ, **12-11**), 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (4-MeIQ, **12-11**), 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (4-MeIQx, **12-13**) and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP, **12-15**). In comparison with known mutagens and carcinogens, such as benzo[*a*]pyrene, these compounds cause more serious DNA damage and induce chromosome aberrations (changes in structure and number). They are easily absorbed and distributed in the tissues. IQ mutagens are metabolised by the phase I enzymes (activation by *N*-hydroxylation) and by the phase II enzymes (further activation by the formation of arylnitrenium ions and conjugation with DNA). DNA adducts have been detected in various tissues, such as from the colon and prostate. The risk of carcinogenesis from the intake of individual aminoimidazoazaarenes is difficult to estimate, because there are always mixtures of several compounds in meat, along with other contaminants (polycyclic aromatic hydrocarbons, nitrosamines and other carcinogens).

12.2.1.5 Mitigation

The content of aminoimidazoazaarenes in foods is highly dependent on the particular temperature and time of heat treatment and also on the water content, pH and concentration of precursors. Higher temperatures and longer processing times generally result in higher quantities of aminoimidazoazaarenes. The contents of these contaminants also depend on the type of heat treatment. Direct heating operations or operations with efficient heat transfer, such as grilling, produce higher amounts of aminoimidazoazaarenes than indirect methods, such as cooking in water or steaming. The highest amount of aminoimidazoazaarenes is therefore formed in the surface layers of food exposed to higher temperatures (especially during grilling and roasting) that have lower water content. During cooking in water, these mutagens are either not formed or arise in low quantities. Their concentrations in commercially prepared foods are therefore very low.

The formation of heterocyclic amines of the IQ type is effectively inhibited by antioxidants. The presence of phenolic compounds such as flavanones and flavan-3-ols significantly inhibits their formation. The mechanism of the inhibitory effect is partly based on the elimination of Strecker aldehydes, precursors of IQ mutagens, by condensation with phenols. For example, phenylacetaldehyde, a decarboxylation product of phenylalanine and a precursor of PhIP, produces two adducts, (*E*)-8-(phenylethenyl)naringenin and (*E*)-6-(phenylethenyl)naringenin with naringenin (Figure 12.2).

12.2.2 Acrylamide

12.2.2.1 Structure and nomenclature

Acrylamide, also known as acrylic acid amide or prop-2-enamide (**12-19**) occurs in a wide range of fried, roasted, baked or toasted foods, especially in foods prepared from raw materials of plant

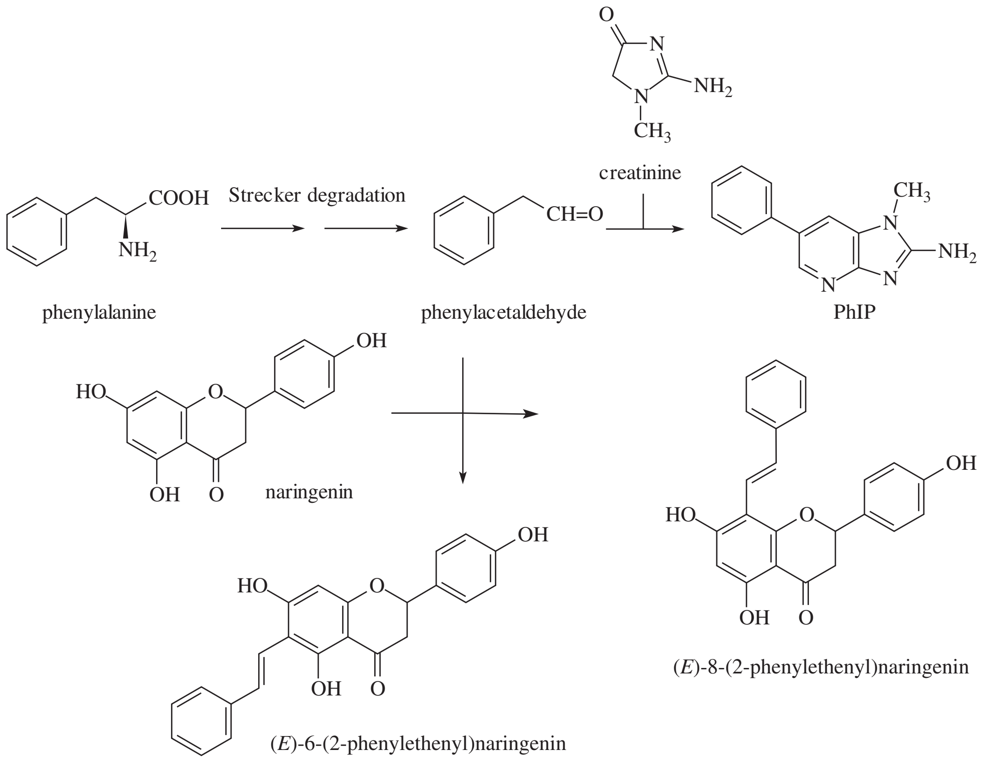

Figure 12.2 Inhibition of PhIP formation by naringenin.

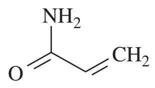

12-19, acrylamide

origin and rich in starch. Although acrylamide has long been a normal component of the human diet, the identification of this contaminant in foods by Swedish scientists in 2002 was a surprise for professionals. This discovery of acrylamide in food is primarily associated with an accident that occurred in Sweden during the construction of a railway tunnel. Dissemination of synthetic acrylamide into the environment due to a technical error induced acute neurotoxic symptoms in construction workers. Livestock and other animals in the area were also affected and surface water contamination led to the death of huge numbers of fish. In the extensive investigations that followed, concentrations of the exposure marker were monitored, which is an acrylamide–haemoglobin adduct. The surprising findings were that there were relatively high levels of that biomarker in unexposed persons from the reference remote locations, which led to identification of thermally processed foods with high starch content as the acrylamide source. Until then, the primary known potential sources of acrylamide had been drinking water and tobacco smoke.

New findings about the presence of this substance in a number of food items, inevitably provoked intense international research, aimed not only to clarify the mechanism of acrylamide formation and evaluation of the health risks from dietary exposure for consumers, but also focusing on finding appropriate strategies to minimise food contamination.

12.2.2.2 Occurrence, main sources and dietary intake

Based on the evaluation of an extensive set of available data, it is assumed that the dietary exposure of western populations to acrylamide is mainly contributed to by fried potato chips (16–30%), potato crisps (6–46%), coffee (13–39%), pastry and sweet biscuits (10–20%), bread and crisp bread (10–30%) and to a lesser extent other foods (<10%). Significant differences in contributions to the total intake of acrylamide depend on the composition of the food basket in different countries. For example in Sweden, the proportion of coffee in the total exposure is estimated at 39%, while in the Netherlands the level is only 13%. In the United States 35% of exposure is attributed to fried potato products, but only 7% to coffee. Exposure to acrylamide in Central Europe is mainly associated with the consumption of fried and roasted potato products.

According to the Joint FAO/WHO Expert Committee on Food Additives (JECFA), the daily intake of acrylamide for the general population is estimated to be between 0.3 and 2.0 μg/kg body weight. It is expected that the daily intake of acrylamide in children may be two to three times higher than in adults. The average daily intake for the general population is estimated at 1 μg/kg body weight. For populations with a high intake of acrylamide and for children, the average daily intake is estimated at 4 μg/kg body weight.

Table 12.1 presents summary data collected in the monitoring implemented in 2002–2008 in EU Member States. The database is managed by the European Commission – Joint Research Centre, Institute for Reference Materials and Measurements. Concentrations of acrylamide fluctuate over a wide range, depending on the raw materials, recipes and methods of culinary or industrial processing. Raw or cooked foods (if temperatures do not exceed 100 °C) usually do not contain acrylamide at all, or contain only very small quantities. Surprisingly high concentrations were found in some types of dried fruits, such as pears and plums, where the concentrations of acrylamide were more than 1000 μg/kg, although the processing temperatures did not exceed 80 °C.

12.2.2.3 Formation

Acrylamide is formed primarily in the Maillard reaction, where the key precursors are the amino acid asparagine, from which is derived the acrylamide skeleton, reducing sugars and various carbonyl compounds resulting from sugar degradation and lipid oxidation that enable the decarboxylation of asparagine. In the absence of reducing sugars, α-hydroxycarbonyl, α-dicarbonyl and other active compounds, only deamination of asparagine proceeds, producing fumaric acid monoamide known as fumaramic acid. The general reaction scheme of acrylamide formation in foods,

Table 12.1 Typical concentrations of acrylamide in various foods in the European market.[a]

Food	Mean value (μg/kg)	Maximum (μg/kg)	Food	Mean value (μg/kg)	Maximum (μg/kg)
Cookies	313–317	4200	Potato chips	348–350	2668
Bread	126–136	2430	Potato crisps	626–628	4180

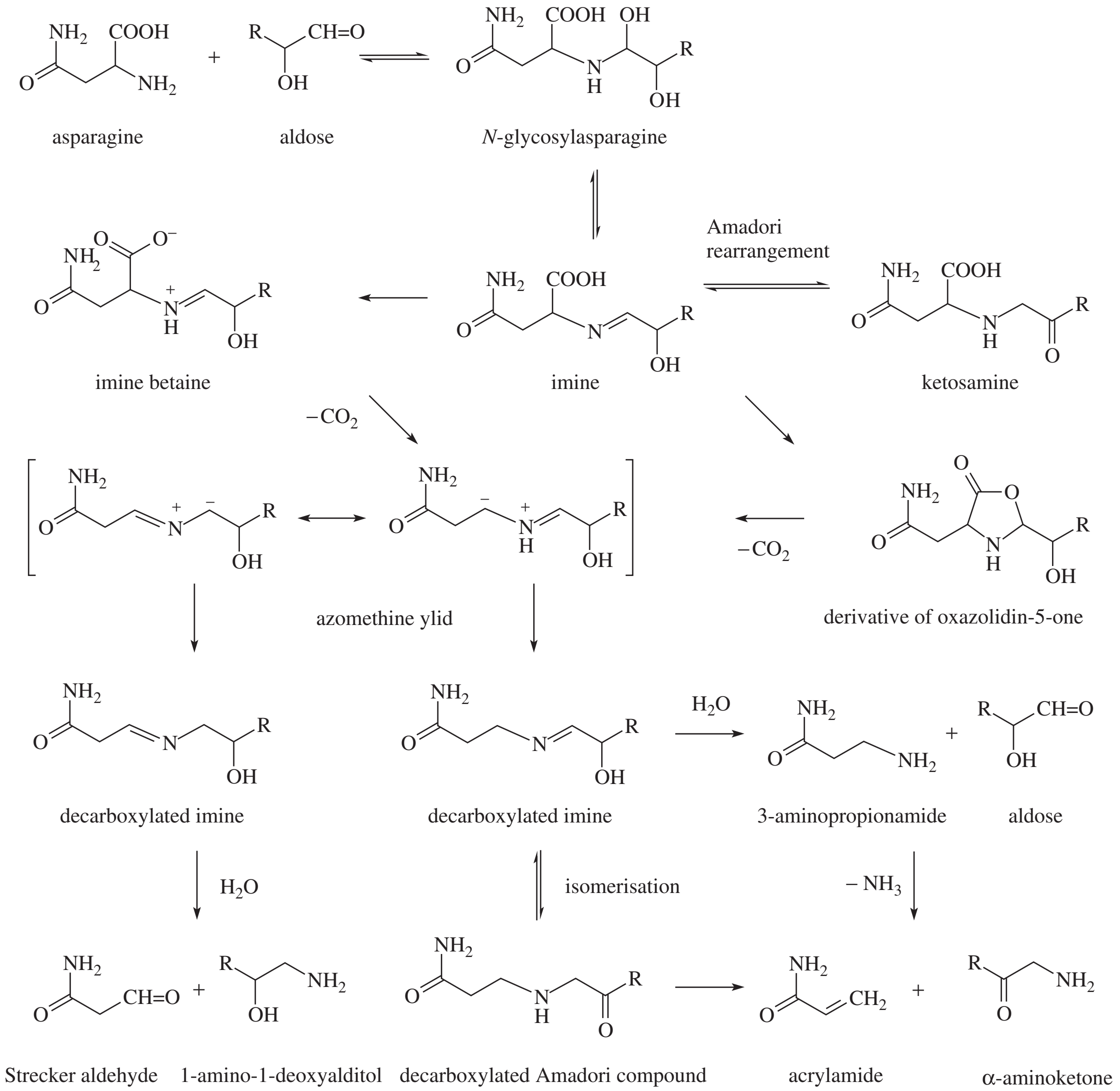

Figure 12.3 Mechanism of acrylamide formation in the presence of α-hydroxycarbonyl compounds.

reflecting current knowledge, is shown in Figure 12.3. A primary product of the reaction is carbinolamine *N*-glycosylasparagine, which dehydrates to form the corresponding imine. In media with low water content, *N*-glycosylasparagine and imine are relatively stable, but in aqueous media imine is hydrolysed or may be rearranged (Amadori rearrangement) to ketosamine (oxoform of 1-amino-1-deoxysugar). Ketosamine is not too significant as a precursor of acrylamide as it is degraded to produce numerous compounds involved in the formation of coloured and flavour-active products in media of low water content.

Decarboxylation of imines derived from α-hydroxycarbonyl compounds, having a free hydroxyl group in the β-position relative to the nitrogen atom, yields the corresponding azomethine ylid. Another alternative of the imine conversion is the formation of imine betaine and intramolecular cyclisation of the product to an oxazolidin-5-one derivative. Both of these compounds provide by decarboxylation azomethine ylid, which can exist in two forms stabilised by resonance that differ in the position of the C=N bond. Both forms of azomethine ylid yield the corresponding imine by decarboxylation. The imine with a double bond between nitrogen and carbon coming from the sugar may be hydrolysed to the parent sugar and 3-aminopropionamide, but may also isomerise to produce a decarboxylated Amadori compound. Acrylamide is then formed, together with an aminoketone, by cleavage of the covalent bond between carbon and nitrogen. The imine double bond between nitrogen and carbon from the asparagine can only be hydrolysed to the Strecker aldehyde of asparagine and 1-amino-1-deoxyalditol, but the decarboxylated Amadori compound does not arise in this case. Another portion of acrylamide may be produced by enzymatic deamination of 3-aminopropionamide.

The amount of acrylamide formed in the reaction mixtures containing α-hydroxycarbonyl compounds, such as glucose, fructose or hydroxyacetone (acetol), is generally much higher than in the case of α-dicarbonyl compounds represented, for example, by butane-2,3-dione (biacetyl) or 2-oxopropanal (methylglyoxal) and other substances. It should also be noted that trace amounts of

acrylamide may result from precursors other than asparagine, such as acrolein and acrylic acid. The thermal degradation of gluten in the production of wheat bread may also give rise to marginal amounts of acrylamide.

12.2.2.4 Health and toxicological assessment

Acrylamide is a neurotoxic compound with genotoxic potential, and according to the IARC (International Agency for Research on Cancer) is classified as a potential human carcinogen (Group 2A).[3] In the organism, acrylamide is rapidly absorbed and evenly distributed. The primary metabolites are glutathione conjugates and the oxidation product glycidamide. Acrylamide and glycidamide can react (form adducts) with macromolecules such as haemoglobin or DNA (Figure 12.4). It is mainly glycidamide that is responsible for the carcinogenic and genotoxic effects, which is, thanks to its epoxy group, much more reactive. The determination of acrylamide adducts with haemoglobin is used in practice to estimate acrylamide exposure. Glycidamide may also be formed by oxidation of acrylamide by fatty acid hydroperoxides.

Current scientific knowledge and epidemiological data have not clearly assessed the cancer risk that may be due to dietary exposure to acrylamide in the general population. An EFSA (European Food Safety Authority) panel on contaminants in the food chain (CONTAM) dealing with various contaminants, confirmed the JECFA 2005 conclusions that consider the acrylamide intake by foods as relatively low. There was an emphasis, however, on the need for ongoing data collection and retrieval of data for further evaluation. The European Commission has not yet set limits for acrylamide, but has issued a recommendation (2007/331/EC) on the monitoring of acrylamide levels in food. To ensure the comparability of analytical results, the chosen methods have to achieve limits of quantification at levels of 30 μg/kg for bread and foods for infants, and 50 μg/kg for potato products, cereal products and coffee.

[3]The International Agency for Research on Cancer (IARC), a part of the World Health Organization (WHO), recognises the following groups of carcinogenic substances: Group 1 – carcinogenic to humans, Group 2A – probably carcinogenic to humans, Group 2B – possibly carcinogenic to humans, Group 3 – unclassifiable as to carcinogenicity in humans and Group 4 – probably not carcinogenic to humans.

12.2.2.5 Mitigation

Acrylamide is an unstable compound and may undergo, for example, the addition of nucleophilic amino or sulfhydryl groups of amino acids and other nucleophiles (Michael addition), which can cause its elimination. Therefore, the reported amounts of acrylamide are the result of simultaneous formation and elimination reactions. Outputs of extensive studies aimed at elucidating the mechanisms of acrylamide formation in thermally processed products identified the following critical factors that influence the level of contamination of the final products:

- reducing sugars, asparagine and other free amino acids contents in the starting raw material
- temperature profile applied during processing/production
- pH
- water content
- use of additives in the given recipe.

Reduction of acrylamide content can be achieved by modifying the processing conditions or choosing less risky cooking procedures, but the selection of suitable raw material is not simple, because

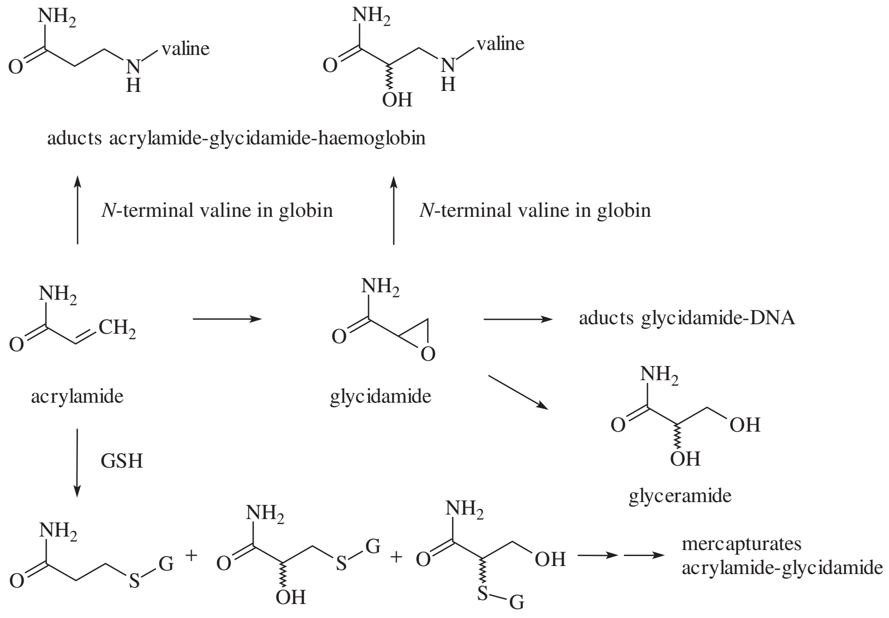

Figure 12.4 Metabolism of acrylamide in organism (GSH = reduced glutathione).

the levels of acrylamide precursors in crops are dependent on the particular cultivar, pedological and climatic conditions in a given locality and on the conditions used for storage of the raw materials.

Asparagine is an amino acid essential for plant growth, and reducing sugars are natural products of plant metabolism, but their concentrations are highly variable. While the molar ratio of sugars to asparagine in potatoes is relatively low, in cereals, which are materials with relatively high carbohydrate contents, free asparagine is a limiting component. Storage conditions do not significantly affect the asparagine content, but in potatoes temperature plays an important role. It is known that long-term storage of potatoes below about 4 °C increases the level of reducing sugars (see Section 4.2.2.6).

The strategy applied to reduce the formation of acrylamide during thermal operations is based on knowledge of the Maillard reaction mechanisms. For instance, the fermentation processes in the production of bread and pastry, leading to a decrease of dough pH, reduce the acrylamide formation during baking (the effect is based on protonation of asparagine amino group, which inhibits the reaction with carbonyl groups of sugars), but at the same time can intensify the formation of another technological contaminant, 3-chloropropane-1,2-diol (3-CPD, see Section 12.2.4). Table 12.2 illustrates the complexity of the optimal strategy suitable for reducing levels of technological contaminants.

Knowledge of acrylamide precursors also led to an urgent recommendation not to use rising agents based on ammonium carbonate in the production of bakery products, as the products (such as gingerbread) may contain high concentrations of this contaminant.

Table 12.2 Effect of dough acidity on the contents of acrylamide and 3-chloropropane-1,2-diol (3-CPD) in backery products.

Dough pH	Acrylamide (μg/kg)	3-Chloropropane-1,2-diol μg/kg)
3.1	93	40
4.0	105	27
5.0	125	19
6.0	145	14
7.0	163	11
8.0	187	9

Important information was also obtained from kinetic studies on acrylamide formation. When frying potato chips, the acrylamide formation correlates with temperature, its duration and colour of products (Table 12.3).

The changes in the amount of acrylamide produced during the course of the roasting of coffee is quite different. After a sharp increase in its content to about 12 500 μg/kg in about 4–5 min of roasting at 230 °C, a gradual decrease in acrylamide content follows, and after 25 min of roasting the acrylamide content is 6000 μg/kg, and after 50 min only 2000 μg/kg, which could be partly due to acrylamide losses caused by its volatilisation, but the main losses may be attributed to acrylamide reactions with components of roasted coffee beans. The decrease of acrylamide content continues during coffee storage and in ground roasted coffee, and results in a loss of 40% of acrylamide during 6 months of storage.

Many original solutions have been designed to reduce the formation of acrylamide. For example, the fortification of raw materials with common amino acids, such as glycine, reduces the overall yield of acrylamide, due to glycine competition in the Maillard reaction. Practical applications, especially in the production of biscuits and other bakery products, have also been found for commercial preparations of asparaginase, an enzyme that effectively breaks down the key precursor of acrylamide asparagine. An important criterion for assessing the effectiveness of measures to increase the safety of the product is an assessment of their impact on the sensory quality of products. The extensive scientific knowledge on the formation of acrylamide has resulted in a number of recommendations for food producers and for consumers, the most important of which are summarised, as an example, in Table 12.4. Compliance with these recommendations can contribute to a reduced dietary intake of acrylamide.

Under certain circumstances, acrylamide may infiltrate into drinking water treated using polymers based on acrylamide, which are used as flocculants. With regard to the toxicity of acrylamide and health risks associated with its intake, the hygienic limit for water intended for human consumption is 0.1 μg/l (European Council Directive 98/83/EC).

12.2.3 Furan

12.2.3.1 Structure and nomenclature

Furan is a simple heterocyclic compound (**12-20**), which typically arises by thermal decomposition of natural materials containing

Table 12.3 Changes of acrylamide concentrations in potato chips, depending on the temperature and time of frying.

Temperature (°C)	Time (min)	Acrylamide (μg/kg)	Temperature (°C)	Time (min)	Acrylamide (μg/kg)
130	7.0	12 000	170	2.3	26 000

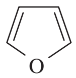
150	4.7	18 000	190	1.6	38 000
160	3.0	22 000	200	1.3	47 000

Table 12.4 Measures to minimise acrylamide levels in different foods.

Food	Growing	Recipe	Processing
Potato chips	Selection of varieties with a low content of reducing sugars; storage at temperature >6 °C; control of reducing sugars contents		Thicker fries; blanching of raw fries in hot water to remove reducing sugars; control of temperature and frying time; frying at <170 °C; during frying of smaller batches reduce frying time; frying to a lighter surface colour
Bread	Important is sulfur fertilisation	No adding of reducing sugars; addition of calcium salts (carbonate, sulfate) can help	Control of temperature and cooking time; bake to a lighter crust colour



12-20, furan

cellulose and pentoses. It is a starting material for a number of industrial organic syntheses. Hydrogenation of furan, for example, yields tetrahydrofuran, which is used as a solvent.

The presence of this toxic substance in foods was demonstrated in the 1970s in studies of volatile compounds produced during the cooking of food. With regard to the low boiling point of furan (34.1 °C), its concentrations were not often quantified, as attention was mainly focused on the flavour and biologically active derivatives of furan formed mainly in the Maillard reaction. In this context the results presented in 2004 by the U.S. Food and Drug Administration (FDA), which documented relatively high levels of furan in various heat-processed food products, especially in roasted, pasteurised and sterilised foods, were very surprising. Information on the occurrence of this potentially carcinogenic technological contaminant inevitably led to a number of related studies and in the European Union, at the request of the European Food Safety Authority (EFSA), a working group was established by the Scientific Committee on Contaminants in the food chain (CONTAM), which was designed to gather information on this contaminant.

12.2.3.2 Occurrence, main sources and dietary intake

The highest furan concentrations were found in roasted coffee, caramel, canned baby foods (mainly vegetable foods) and many other canned foods. Examples of typical amounts of furan in a variety of foods are presented in Table 12.5.

The average daily exposure in babies is estimated to be 0.9 μg/kg body weight, in children up to 2 years of age it is 0.41 μg/kg body weight and in older children and adults it is 0.26 μg/kg body weight. The contributions of different foods to the total exposure of furan for adults are shown in Table 12.6.

12.2.3.3 Formation

The presence of furan has been demonstrated in many foods of very different composition, which shows that there are multiple possibilities for its formation. It has been found that the precursors of furan in foods may be various food components, including amino acids, carbohydrates and ascorbic acid, as well as unsaturated fatty acids and carotenoids.

12.2.3.3.1 Amino acids

The most important precursors of furan are amino acids that yield acetaldehyde and glycolaldehyde on degradation. Acetaldehyde is produced in the Strecker degradation of alanine (alanine is also the product of aspartic acid decarboxylation) or by decarboxylation and deamination of serine (see Section 2.5.1.3.2); glycolaldehyde results from the Strecker degradation of serine. Furan arises from these reactive intermediates by aldol condensation via 2-deoxyaldotetrose, which undergoes cyclisation and dehydration (Figure 12.5). Glycolaldehyde is additionally produced by fragmentation of reducing sugars.

12.2.3.3.2 Lipids

Furan precursors are oxidation products of polyunsaturated fatty acids, in particular of α-linolenic acid and linoleic acid. In the case of linolenic acid, the C–H bond cleavage at C-17 of (9*Z*,12*Z*,15*Z*)-17-hydroperoxyoctadeca-9,12,15-trienoic acid yields (9*Z*,12*Z*,15*Z*)-17-oxoheptadeca-9,12,15-trienoic acid. Subsequent autoxidation (primarily cleaved is the C–H bond at C-11 and the free radical isomerises) produces (9*Z*,11*E*,15*Z*)-13-hydroperoxy-17-oxoheptadeca-9,11,15-trienoic acid, which subsequently decays to form (*E*)-but-2-enal, which can isomerise to (*Z*)-but-2-enal (crotonaldehyde, Figure 12.6). In model experiments, the amount of furan increased by several orders of magnitude in the presence of iron ions.

Autoxidation of linoleic acid gives rise to (10*E*,12*Z*)-9-hydroperoxyoctadeca-10,12-dienoic acid as one of the major products, which is degraded to give (2*E*,4*Z*)-deca-2,4-dienal.

Its isomer (2*E*,4*E*)-deca-2,4-dienal, formed by isomerisation, decomposes to (*E*)-but-2-enal and other products (Figure 12.7). A likely intermediate in polyunsaturated fatty acids, as well as in amino acids, is 4-hydroxybut-2-enal formed by oxidation of (*E*)-but-2-enal, which provides furan after cyclisation, isomerisation and subsequent dehydration.

12.2.3.3.3 Saccharides and related compounds

A Maillard reaction is another possibility for the formation of furan and its substituted derivatives. The highest amounts of furan were produced in model mixtures of alanine with glycolaldehyde heated to 250 °C. Serine in mixtures with ribose and sucrose gave 30%, and in mixtures with ribose or glucose there was only 10–25% formed. In the reaction mixture with erythrose there originated about an eight times higher amount of furan than in mixtures with glucose or fructose, as tetroses (their degradation products) are immediate precursors of furan. In terms of their potential to form furan, the following order of sugars can be compiled: D-erythrose > D-ribose > sucrose > D-glucose = D-fructose. The expected reaction mechanisms are summarised in Figure 12.8.

Four-carbon furan precursors are formed from hexoses in essentially three ways: via 1-deoxyhexo-2,3-diulose and aldotetrose, respectively), from 2-deoxytetros-3-ulose and 3-deoxyhexos-2-ulose. The most common 1-deoxyhexo-2,3-diulose is 1-deoxy-D-*erythro*-hexo-2,3-diulose, which is produced by 2,3-enolisation of ketosamines derived from glucose as the major intermediate and furan is also produced in a small amount from fructose in

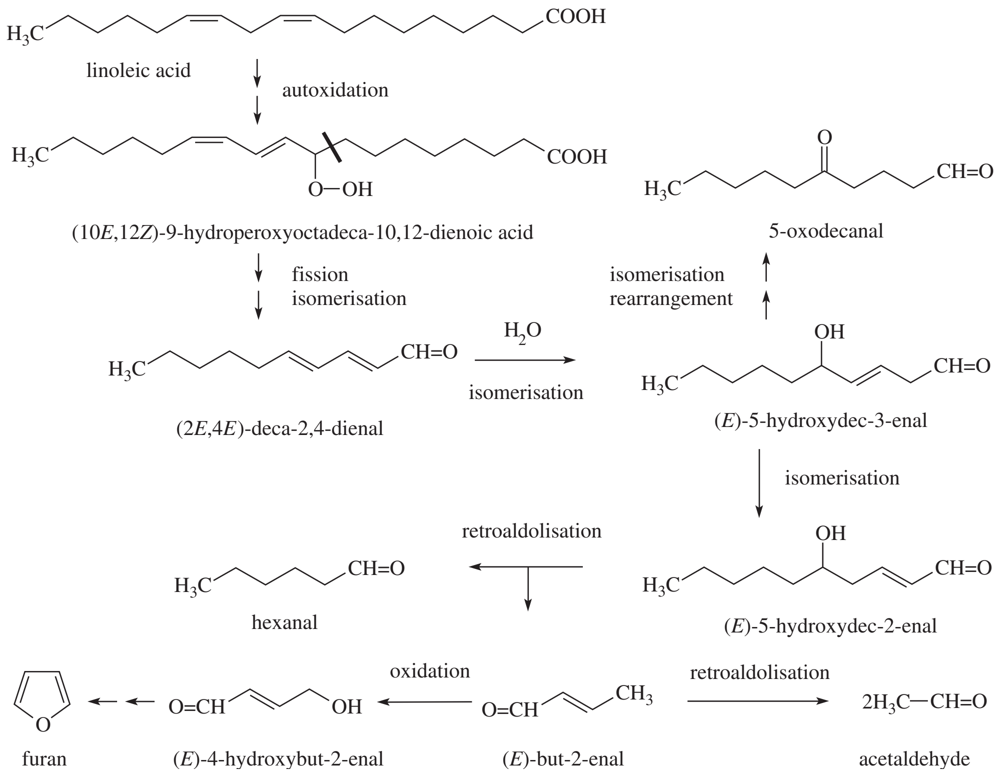

Figure 12.7 Formation of furan from linoleic acid.

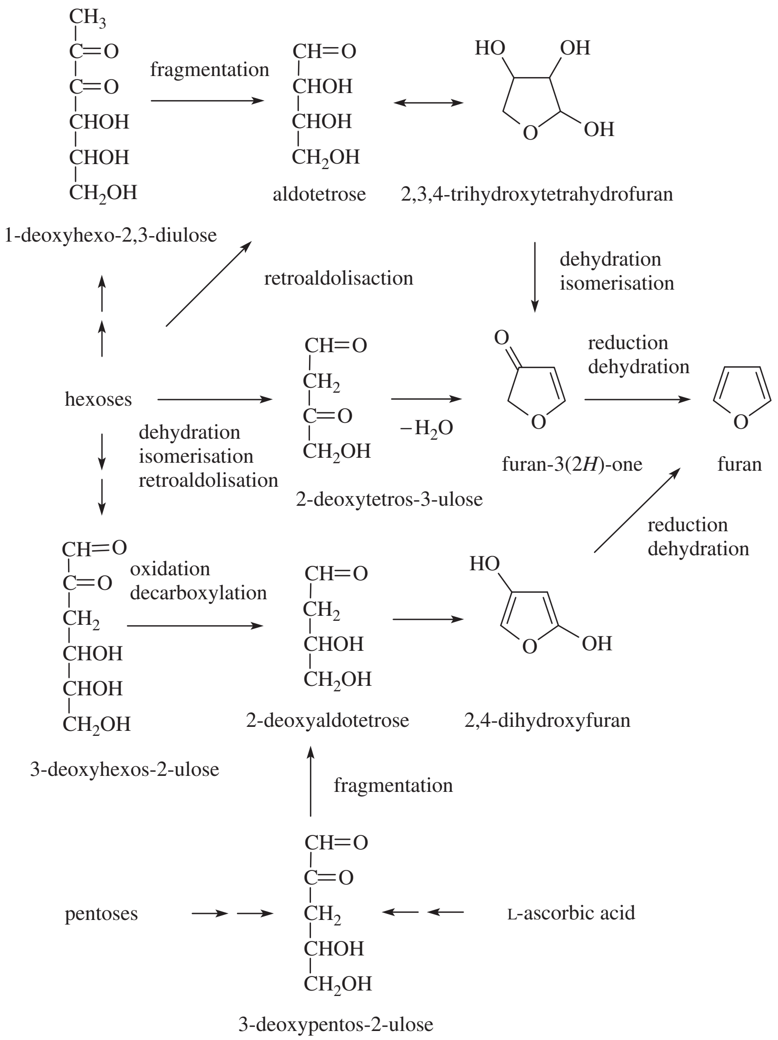

Figure 12.8 Formation of furan from saccharides and ascorbic acid.

the absence of amino compounds. Fragmentation of 1-deoxyhexo-2,3-diulose or hexose yields aldotetrose (carbons C-3, C-4, C-5 and C-6). Ribose gives rise to 1-deoxy-D-erythro-hexo-2,3-diulose, glucose or fructose. This pathway seems to be the most important pathway, since it provides approximately 50% of furan. Another precursor of furan, 2,3-deoxytetros-3-ulose, is produced as one of many products of the transformation (dehydration and retroaldolisation) of hexoses. The molecule of 2,3-deoxytetros-3-ulose contains the carbons C-1, C-2, C-3 and C-4 from the original skeleton of the hexoses. This pathway produces about 10% furan. From 2-deoxyaldotetrose, which is formed by oxidation, decarboxylation and cleavage of hexoses, carbon atoms C-2, C-3, C-4 and C-5 are incorporated into the furan molecule. This pathway produces about 10% furan.

Another natural furan precursor is L-ascorbic acid (the potential of dehydroascorbic and isoascorbic acids found in model experiments were still one order of magnitude higher). The reaction mechanism of furan formation from ascorbic acid is not yet fully understood. The expected precursor is 3-deoxypentos-2-ulose, which is in this case 3-deoxy-L-*glycero*-pentos-2-ulose, also known as 3-deoxy-L-xylosone (see Section 5.14.6.1.5).

12.2.3.4 Health and toxicological assessment

Furan is rapidly absorbed by the body due to its easy penetration across biological membranes. Its excretion from the body is also relatively fast. In the mammalian organism, furan is transformed under catalysis of cytochrome P450 complex. It seems that it is first oxidised (epoxidation of one double bond) and the oxidation product is then rearranged with opening of the cyclic structure. The reactive (*Z*)-but-2-ene-1,4-dialdehyde (**12-21**) formed is a strongly cytotoxic substance that can bind to proteins and nucleosides. An alternative metabolic pathway is its conjugation with glutathione. The resulting product is then expelled from the body through the urine.

12-21, (*Z*)-but-2-ene-1,4-dialdehyde

Based on toxicological studies in rodents, the IARC classified furan as a potential human carcinogen of Group 2B. The existing experimental data show the relationship between liver cancer and the exposure dose. As is apparent from the EFSA documents, it is necessary to collect additional data for the critical risk assessment of dietary furan and to clarify the toxicity of intermediates produced by furan biotransformation.

12.2.3.5 Mitigation

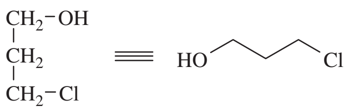
As mentioned above, the dietary sources of furan are mainly two groups of foods: cooked foods with relatively high water activity (products in cans or jars) and foods with low water activity processed by roasting or baking (such as coffee and bread).

The assumption that, after opening the cans or glass containers, furan quickly escapes into the atmosphere, due to its low boiling point, has proved to be untrue. During normal culinary procedures, furan has a relatively high retention in food, and a decrease of its concentration only occurs during intense boiling, when it is removed with the large volume of water vapour. The amounts of furan in different types of heat treatment have also been compared. Furan concentrations in industrially manufactured products were considerably higher than in home-made products, probably due to a diminished possibility of vapour release from the equipment. The research also showed that the furan content in industrially produced vegetable meals is significantly higher than that in fruit mixtures. When assessing these differences it is necessary to take into account the nature of the heat treatment and the content of furan precursors.

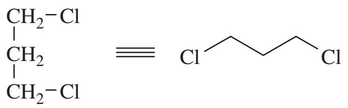
12.2.4 Chloropropanols and their esters

12.2.4.1 Structure and nomenclature

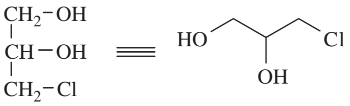
Chloropropanols (chlorinated propanols) are a group of three-carbon alcohols and diols with one or two chlorine atoms, which are hypothetically derived from glycerol. Six compounds, one chloropropanol (3-chloropropan-1-ol, **12-22**), two dichloropropanols (1,3-dichloropropan-2-ol, for short 1,3-DCP, **12-23** and 2,3-dichloropropan-1-ol, 2,3-DCP, **12-24**), two chloropropanediols (3-chloropropane-1,2-diol, 3-CPD, also known as 3-MCPD from 3-monochloropropane-1,2-diol, **12-25**, and 2-chloropropane-1,3-diol, 2-CPD or 2-MCPD, **12-26**) and structurally related 1,3-dichloropropane (**12-27**) arise as technological contaminants in acid protein hydrolysates (hydrolysed vegetable protein) and probably also in foods during the culinary and technological processing.



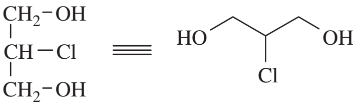
12-22, 3-chloropropan-1-ol (1-chloro-3-hydroxypropane)



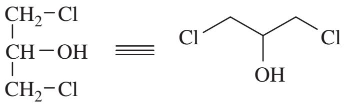
12-23, 1,3-dichloropropane (trimethylenedichloride)



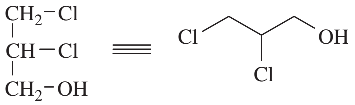
12-24, 3-chloropropane-1,2-diol (glycerol-1-chlorohydrine)



12-25, 2-chloropropane-1,3-diol (glycerol-2-chlorohydrine)



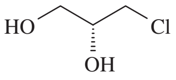
12-26, 1,3-dichloropropan-2-ol



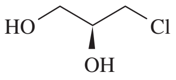
12-27, 2,3-dichloropropan-1-ol

1,3-DCP and its isomer 2,3-DCP were identified in hydrolysed vegetable protein in 1978, while the main chlorine-containing substance, 3-CPD, was found in 1982 and its 2-CPD isomer was identified in 1987 by Czech scientists. At the beginning of the 1990s, some CPD and DCP isomers were found in soy sauces, where hydrolysed vegetable proteins were used in the manufacture. A surprising finding was that these contaminants occur in a number of common foods where hydrolysed vegetable proteins are not used in the production.

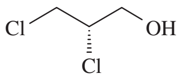
3-CPD and 2,3-DCP are chiral compounds, which occur in protein hydrolysates and foods as racemic mixtures of corresponding enantiomers (−)-(*R*)-3-chloropropane-1,2-diol (**12-28**), (+)-(*S*)-3-chloropropane-1,2-diol (**12-29**), (*R*)-2,3-dichloropropan-1-ol (**12-30**) and (*S*)-2,3-dichloropropan-1-ol (**12-31**), respectively.



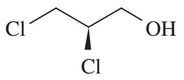
12-28, (*R*)-3-chloropropane-1,2-diol



12-29, (*S*)-3-chloropropane-1,2-diol



12-30, (*S*)-2,3-dichloropropan-1-ol



12-31, (*R*)-2,3-dichloropropan-1-ol

In 1980, it was found that hydrolysed vegetable proteins contain esters of chloropropanols with higher fatty acids. As examples, structures of esters derived from 3-CPD are shown in formulae **12-32** to **12-37**. Monoesters (alkanoic acid 2-chloro-2-alkanoyloxymethyl ethyl esters) and diesters (alkanoic acid 2-chloro-1-alkanoyloxymethyl ethyl esters) of 3-CPD were found in one sample of goats' milk in 1984, but it was understood that they were exogenous contaminants. The current research, focusing on DCP and CPD esters in foods, began in 2004.

12.2.4.2 Occurrence, main sources and dietary intake

12.2.4.2.1 Protein hydrolysates

Protein hydrolysates used for flavouring dishes are basically divided into two large groups:

- chemical (acid) hydrolysates originating from Europe
- enzymatic hydrolysates originating from the Far East.

The first commercial acid protein hydrolysate, known as soup seasoning, was manufactured in Switzerland by J.M.J. Maggi in the early 1920s. Acid hydrolysed proteins are traditionally prepared by hydrolysis of vegetable materials rich in proteins (oilseed extraction meals, wheat gluten and other materials) with about 20% HCl, typically at temperatures exceeding 100 °C (at atmospheric or slightly elevated pressure) for about 8 h. Nitrogen contained in amino acids resulting from the hydrolysis of proteins represents 35–55% of the total nitrogen content. After cooling to 90–100 °C, the crude hydrolysate is neutralised with sodium carbonate or sodium hydroxide over 1.5–3 h so that the final pH is 4.5–7. The insoluble hydrolysate portion, known as humins, is then removed by filtration and the filtrate is allowed to stand for several weeks and, after maturation, is filtered again. The resulting product (30–40% dry matter, 2–3% total nitrogen, usually about 20% sodium chloride) is used directly as a seasoning and also for the production of soup cubes, bouillons, dehydrated soups and certain types of soy sauces.

The best-known enzymatic hydrolysate is soy sauce, which originated in China around 500 BC. The Chinese priest Zen reportedly introduced its production in Japan in 1250 AD. Japanese soy sauces known as honjōzō hōshiki are produced exclusively by fermentation, shinshiki hōshiki sauces contain 30–50% of enzymatic hydrolysate and 50–70% of acid hydrolysate, and aminosanekikongō hōshiki sauces are pure acid protein hydrolysates.

The major contaminant in acidic protein hydrolysates is 3-CPD. Other contaminants are mainly 2-CPD, 1,3-DCP and 2,3-DCP. Employing the above-described conventional technological processes of hydrolysate production, the ratio of these contaminants is roughly as follows: 3-CPD : 2-CPD : 1,3-DCP : 2,3-DCP = 1000 : 100 : 10 : 1. The resulting hydrolysates contained 100–800 mg/kg of 3-CPD, 10–90 mg/kg of 2-CPD, 0.1–6 mg/kg of 1,3-DCP and 0.01–0.5 mg/kg of 2,3-DCP. Their actual amounts depend primarily on the content of lipids in the raw proteinaceous material, the concentration and amount of hydrochloric acid and the temperature during hydrolysis. Chloropropanols are also found in soy sauces made from mixtures of acid and enzymatic protein hydrolysates. Soy sauces produced exclusively by traditional fermentation do not contain chloropropanols.

Since the 1980s, new technological processes have gradually been introduced as substitutes for conventional ones, which have led to a decrease of the chloropropanols content in acid protein hydrolysates and simultaneously in soy sauces. This trend is documented in the results of controls carried out by MAFF (Ministry

Table 12.7 Content of 3-CPD and 1,3-DCP esters in raw neutralised hydrolysate and humins.

Esters	Content (mg/kg)	
	Raw neutralised hydrolysate	Humins
3-CPD diesters	4	35
3-CPD monoesters	35	205
1,3-DCP esters	8	65

of Agriculture, Fisheries and Food) in the United Kingdom in 1990, when 23 out of 39 hydrolysates had a 3-CPD content higher than 10 mg/kg and 33 had greater than 1 mg/kg. In 1992, 17 out of 34 hydrolysates had a 3-CPD content lower than 1 mg/kg, and four hydrolysates analysed in 1998 had a content of 3-CPD within the limit of determination, to 0.428 mg/kg. Of the 50 hydrolysates analysed in 1999, 3-CPD was detected in 21 samples, nine of them contained amounts from 0.01 to 0.02 mg/kg, eight from 0.02 to 0.05 mg/kg, three from 0.05 to 0.1 mg/kg and concentrations higher than 0.1 mg/kg were found in nine samples. The highest amount of 3-CPD, however, was only 2 mg/kg. In the hydrolysates and soy sauces analysed in 2000, 3-CPD was found in amounts higher than 0.02 mg/kg in 25 cases, and in quantities of more than 1 mg/kg in 16 cases. The highest amount of 3-CPD was 82.8 mg/kg. 2-CPD was found at a level of 17.6 mg/kg in 26 samples. 1,3-DCP was detected in 17 cases (its concentration ranged from 0.006 to 0.345 mg/kg), 2,3-DCP was present in 11 samples and its amount ranged from 0.006 to 0.043 mg/kg. The same commodities analysed in 2002 contained 0.02 mg/kg of 3-CPD or higher in only seven cases, and the highest concentration was 35.9 mg/kg. A concentration of 1,3-DCP of 0.017 mg/kg was found only in the sample with the highest content of 3-CPD.

DCP and CPD esters of fatty acids (palmitic, stearic, oleic, linoleic and linolenic) were detected only in the crude neutralised hydrolysates (Table 12.7). These lipophilic compounds (the main fatty acid was oleic acid) in neutralised hydrolysates form a layer on the surface that is easily removed by filtration and goes to the waste humins, so that in the commercial products obtained from the crude hydrolysate they may be present only in traces.

12.2.4.2.2 Foods

Chloropropanols

Recent findings indicate that chlorinated propanols, especially 3-CPD and its positional isomer 2-CPD, are present in a number of common foods. Their amount in foods is generally lower than in acid protein hydrolysates. CPD isomers are present mainly in foods with lower water content, which have undergone industrial and culinary processing at higher temperatures (such as bread crust, toasted bread, roasted malt, barley and coffee). In other foods, such as processed and grilled cheese, meat products (such as fermented sausages) and fish, CPD isomers are present in smaller amounts. Relatively higher levels of these esters are present in smoked products (Table 12.8).

CPD may not always be simply an endogenous contaminant: for example, in smoked products it can be a component of liquid smoke preparations, which contain 200–760 μg/kg of CPD. It may also originate from acid protein hydrolysates used as condiments. High concentrations of 3-CPD (up to 1150 μg/kg) were, for example, found in chicken steaks. CPD can also migrate from some types of

Table 12.8 Content of 3-CPD in selected foods and other products.

Food	3-CPD (μg/kg)	Food	3-CPD (μg/kg)
Cereal products		***Meat products***	
Bread (white)	<10–55	Ground beef	<5
Bread crust	24–275	Regular patty (hamburger)	<10–71

Fish (baked)	<5–83	Coffee	<9–19
Fish (smoked)	<10–191	Malt	<10–850
Cheese	<10–95	Modified starches	<10–488
Fats and oils	<5–12	Garlic (thermally processed)	5–690

packaging that have been manufactured using chloromethyloxirane (also known as epichlorohydrin or 1-chloro-2,3-epoxypropane). In liquid smoke and garlic, CPD arises from unusual precursors. In the cellulose pyrolysates, acetol (3-hydroxyacetone) acts as a precursor, and in garlic CPD arises from allyl alcohol, which is a degradation product of alliin.

The amounts of other chloropropanols (2-CPD, 1,3-DCP and 2,3-DCP) are lower than the 3-CPD content. Higher levels of these contaminants are found sporadically, for example the concentration of 1,3-DCP in a sample of ham was <3–21 mg/kg, in beef steak 70 μg/kg and in various sausages ranged between <3 and 69 mg/kg.

Esters of chloropropanols

Mono- and diesters of 3-CPD with fatty acids occurring in foods represent a new group of contaminants, because they may release free 3-CPD by both chemical and enzymatic hydrolysis during food processing and possibly also by the action of lipases *in vivo*. In most cases, the content of 3-CPD esters is much higher than the amount of free 3-CPD (Table 12.9). Esters of 2-CPD have not been studied, but it is possible that they are likewise present in foods.

The highest amounts of 3-CPD esters (2500 mg/kg and more) undoubtedly occur in refined palm and olive oils, which are obtained from the pericarp of fruits (the outer and often edible layer in the fleshy fruits). The main proportion of 3-CPD esters arises in the deodorisation step, which takes place at temperatures exceeding 200 °C (see Section 3.4.3.7). Lower concentrations of 3-CPD esters occur in refined vegetable oils obtained from oilseeds, and the lowest amount of 3-CPD esters is found in virgin vegetable oils. Palm oil or mixtures of vegetable oils with palm oil are also used for frying foods, such as potato chips, crisps, cheeses and meat. Products containing refined palm oil include, for example, substitutes for milk powder (creamers), whipped creams in sprays, various biscuits, sweet spreads, soup cubes (broth) and other products, including infant and follow-on formulae. For example, the maximum measured levels of 3-CPD esters in infant formulae were 4196 μg 3-CPD/kg fat content, which corresponds to a concentration of 156 μg 3-CPD/l in ready-to-drink milk. Infants then could have a 3-CPD exposure of 25 μg/kg body weight per day, which is 12.5 times the TDI. During the examination of samples of follow-on formulae, a maximum level of 8467 μg 3-CPD/kg fat content was found, corresponding to 250 μg 3-CPD/kg in ready-to-drink milk. This can lead to intakes of 20 times the TDI. In the case of adults, the

[b]Mean value.

daily intake could be up to five times the TDI in cases of high daily consumption of vegetable oils and margarines, which may contain up to 7356 μg 3-CPD/kg fat content.

Virgin oils from seeds (such as rapeseed, soybean and sunflower oils), by contrast, contain 3-CPD esters only at the level of <100–337 mg/kg, and virgin olive oils contain relatively very low amounts of 3-CPD esters (<100 to <300 mg/kg). The content of 2-CPD esters in fats and oils represents about 20–60% of the 3-CPD amount (palm oils usually contain more than 1000 mg/kg and seed oils less than 150 mg/kg of 2-CPD esters). Oils with a high content of 3-CPD esters may rarely also contain 1,3-DCP esters (up to 11 mg/kg).

Esters of glycidol and related compounds

In addition to esters of chloropropanols, commercially refined palm oils with higher 3-CPD content, contain esters of glycidol, also known as 2-(hydroxymethyl)oxirane or 2,3-epoxypropan-1-ol. Their amount increases with temperature during deodorisations. For instance, deodorising of palm oil for 6 h at 210 °C gives rise to 2800 μg/kg of 3-CPD esters and 300 μg/kg of glycidyl esters, deodorising at 250 °C for the same period yields 3300 μg/kg of 3-CPD esters of 2900 mg/kg of glycidyl esters. Glycidyl esters may become precursors of CPD esters and free CPD, respectively. Generally, the amount of glycidyl esters in refined oils and possibly also in other foods ranges from <100 to 4100 μg/kg, in refined palm oils they may occur at a level of 300–10 000 μg/kg, in margarines their amount ranges from <150 to 5000 μg/kg and in the fat of infant formulae they occur at a level of <150–3000 μg/kg.

12.2.4.3 Formation

The precursor of chloropropanols in acid protein hydrolysates is hydrochloric acid, which is used to hydrolyse the proteinaceous materials. Other precursors are residual lipids of the raw material and glycerol arising by hydrolysis of lipids (acylglycerols) with hydrochloric acid. Wheat gluten, which is often used as a raw material, contains, for example, 0.5–3.0% residual lipids, of which 30–36% are neutral lipids, mainly triacylglycerols, and about 60% are phospholipids. Soybean meal contains 1.0–3.0% lipids (of which about 30% represent neutral lipids and 60% phospholipids). The main precursors of chloropropanols are triacylglycerols, followed by phospholipids and glycerol. The content of glycerol in acid protein hydrolysates ranges from 200 to 3000 mg/kg.

The precursors of chloropropanols in common foods are naturally present or intentionally added chlorides (sodium chloride) and lipids and in some products also glycerol, which arises, for example, in dough as a result of the activity of yeast lipases. The primary reaction products are CPD diesters, which are hydrolysed to CPD monoesters. Esters of DCP are formed from CPD esters by reaction with chlorides. Free chloropropanols are then formed by hydrolysis of esters.

Exogenous sources of chloropropanols may be packaging materials containing epichlorohydrin copolymers with polyamines or polyamides that are used for the manufacture of tea bags, coffee filters and absorbents of packaged meat juices. Other exogenous sources of chloropropanols may be starches modified with epichlorohydrin, copolymers of epichlorohydrin with dimethylamine (used during sugar refining as flocculants or for the immobilisation of glucose isomerase in manufacturing of fructose syrups); polyelectrolytes based on epichlorohydrin and polyamines, which are used as flocculating and coagulating agents in the production of drinking water, are only relevant in certain cases.

12.2.4.3.1 Formation from acylglycerols

In acidic solutions, triacylglycerols are gradually hydrolysed to diacylglycerols, the diacylglycerols to monoacylglycerols and the final product is glycerol (Figure 12.9). A simplified sequence of reactions that lead from triacylglycerols through partial glycerol esters and 3-CPD and DCP esters to free CPD and DCP is shown in Figure 12.10. The main reaction that leads to DCP and CPD esters and also to free chloropropanols in acid protein hydrolysates and foods is the formation of reactive intermediates (cyclic acyloxonium cations), preferably from diacylglycerols (acyloxonium ions A and B in Figure 12.10) and monoacylglycerols. In particular, higher amounts of partial glycerol esters (diacylglycerols and monoacylglycerols) occur in oils obtained from seed pericarps (palm and olive oils), which is due to higher activity of naturally occurring lipases. Ring opening of cyclic acyloxonium cations with chloride ions yields 3-CPD and 2-CPD diesters, which may split off fatty acid(s) and yield cyclic acyloxonium ions and the corresponding hydroxy derivatives, respectively. Acyloxonium ions can also be formed by the elimination of fatty acids from monoacylglycerols. Reaction with chloride ions then leads to 3-CPD (2-CPD) monoesters and 1,3-DCP and 2,3-DCP esters. In the absence or depletion of chloride ions, the pathway leading from diacylglycerols is believed to end at the stage of glycidol esters. The ratio of 3-CPD and 2-MCPD arising from acylglycerols in acid protein hydrolysates depends on steric and other effects (terminal ester group), and is approximately 10 : 1. During the refining of vegetable oils (and possibly in foods) 3-CPD diesters, 3-CPD monoesters, 2-CPD diesters, 2-CPD monoesters and glycidol esters are produced at the ratio of about 49 : 14 : 28 : 7 : 7.

Glycidol esters are found in particularly high amounts in refined palm oil and palm oil-based fractions. Palm oil contains relatively high amounts of diacylglycerols (ranging from 2.3 to 4% in freshly extracted oils and from 4.0 to 7.8% in commercial oils) and monoacylglycerols (0.4–0.5%), therefore these acylglycerols are supposed to be the main precursors of glycidol esters. The formation of glycidol esters proceeds at high temperatures by an intramolecular rearrangement, followed by elimination of a fatty acid molecule that can be initiated by abstraction of the hydroxyl group's proton by the vicinal carboxyl group. The generated acyloxonium intermediate can then rearrange through charge migration, resulting in the release of a fatty acid and the oxirane ring formation by nucleophilic reaction of the alkoxide group. Analogous reaction (with elimination of water) may proceed with monoacylglycerols (Figure 12.10). In addition to glycidol esters, diacylglycerols heated at temperatures exceeding 140 °C in refined palm oil yield the

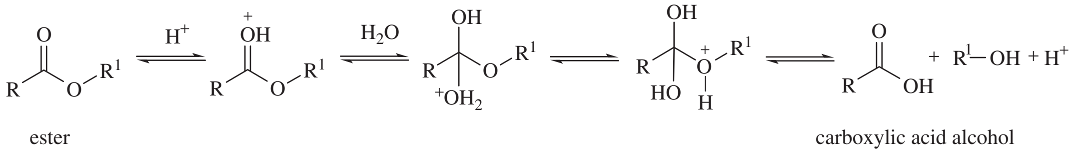

Figure 12.9 Mechanism of ester hydrolysis in acidic media.

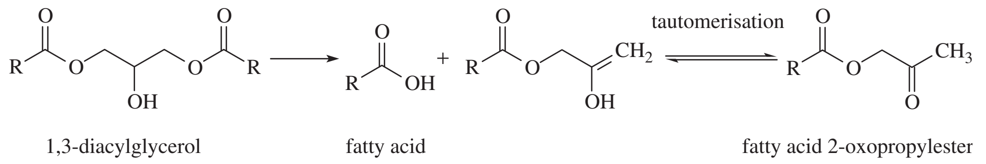

Figure 12.11 Formation of 2-oxopropyl fatty acid esters.

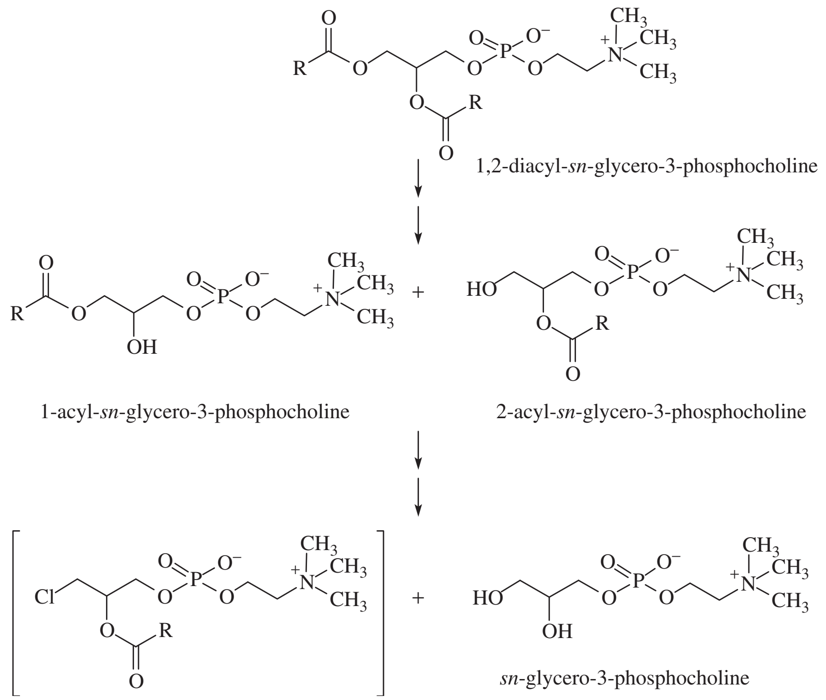

Figure 12.12 Formation of CPD from phospholipids.

corresponding oxopropyl esters at approximately 10% of glycidol esters levels (Figure 12.11).

12.2.4.3.2 Formation from phospholipids

Phospholipids are hydrolysed to deacylated products. For example, 1,2-diacyl-*sn*-glycero-3-phosphatidylcholine yields 1-acyl-*sn*-glycero-3-phosphatidylcholine, 2-acyl-*sn*-glycero-3-phosphatidylcholine and *sn*-glycero-3-phosphocholine. By seemingly analogous mechanisms to CPD esters formation (Figure 12.10), partial esters yield chloroester derivatives (such as 1-chloroester), which appears to hydrolyse to CPD esters and free CPD. CPD also arises from *sn*-glycero-3-phosphocholine (Figure 12.12). The ratio of 3-CPD and 2-CPD formed from phospholipids is about 4 : 1.

12.2.4.3.3 Formation from glycerol

Acid protein hydrolysates and many foods contain glycerol produced by hydrolysis of glycerolipids. Under acidic conditions, hydroxyl groups of glycerol can be protonated with the formation of alkyloxonium ions. In the case of the primary hydroxyl group, the next step is elimination of water, which is substituted by a chloride anion. This step is stereospecific and proceeds with inversion of the configuration at the carbon bearing the leaving group, which leads to a racemic mixture of 3-CPD. The alkyloxonium cation formed from the secondary hydroxyl group dissociates to a carbocation and water and the reaction of the carbocation with chloride ion yields 2-CPD (Figure 12.13). The ratio of 3-CPD and 2-CPD formed from glycerol is about 2 : 1. Elimination of water from glycerol simultaneously gives rise to hydroxyacetone and isomeric 2-deoxyglyceraldehyde.

Another possibility, which is envisaged in foods with low water contents during heat treatment at higher temperatures, is dehydration of the carbocation to a cation of glycidol, from which arises 3-CPD and 2-CPD by the opening of the oxirane ring by chloride ions. In this case the 3-CPD and 2-CPD ratio is about 3 : 1 (Figure 12.14).

12.2.4.3.4 Formation from allyl alcohol

In garlic and garlic-containing foods, 3-CPD and 2-CPD can result by the addition of hypochlorous acid (occurring, for example, in

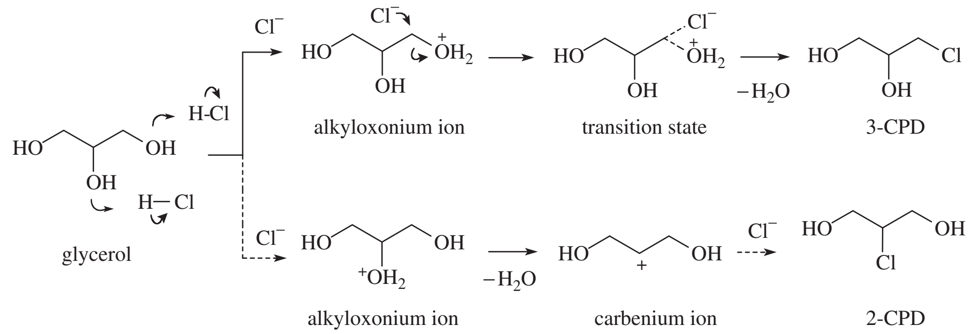

Figure 12.13 Formation of CPD from glycerol.

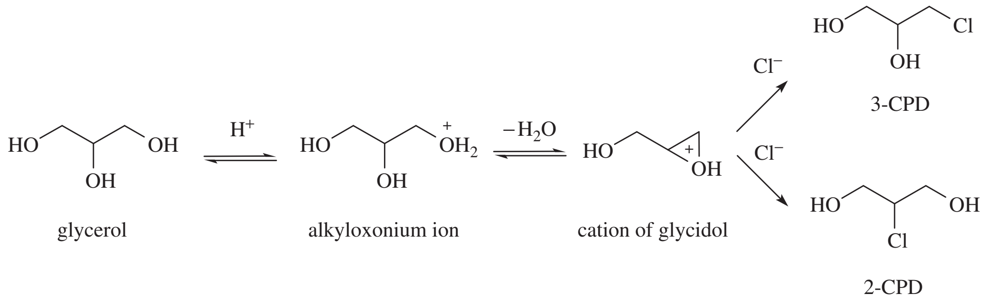

Figure 12.14 Formation of CPD from glycerol via glycidol.

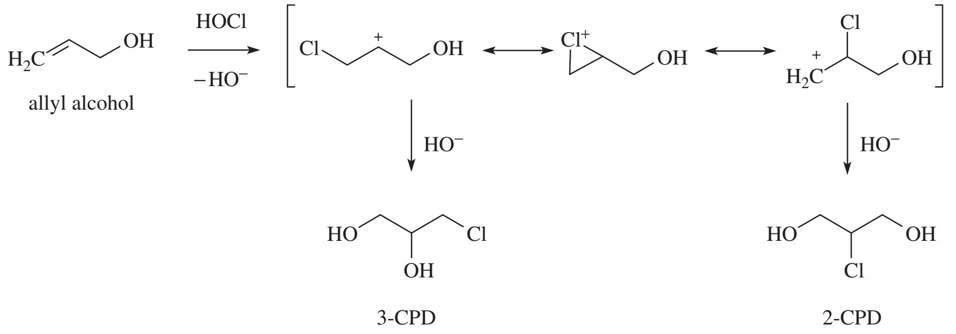

Figure 12.15 Formation of CPD from alliin.

chlorinated water) to allyl alcohol (Figure 12.15), which is one of decomposition products of alliin (Figure 8.7).

12.2.4.4 Health and toxicological assessment

Chloropropanols show various toxic effects. 3-CPD causes infertility in rats and suppression of the immune function and was shown to be genotoxic in several *in vitro* assays, but is not genotoxic and mutagenic *in vivo*. It was classified by the IARC as a chemical of the 2B group, and probably carcinogenic to humans.[3] In 2001, the Scientific Committee on Food (SCF) established a tolerable daily intake (TDI) for 3-CPD at 2 μg/kg body weight, and in 2002 the Joint FAO/WHO Expert Committee on Food Additives (JECFA) established a provisional maximal tolerable daily intake for 3-CPD, similarly at 2 μg/kg body weight. In the EU, maximum levels of 0.02 mg/kg for free 3-CPD in hydrolysed vegetable proteins and soy sauces were established in 2001. The maximum levels have been applied since April 2002 and are integrated into the Commission Regulation (EC) No. 1881/2006. These limits were not designed to account for 3-CPD esters. Data for 2-CPD and its esters are lacking and no toxicological data on esters of glycidol exist, but the degradation product glycidol and a metabolite 3-chlorolactic acid are genotoxic and carcinogenic compounds. In the human body the glycidyl esters are metabolised into free glycidol, a compound that is classified as possibly carcinogenic to humans (Group 2A compound) by IARC, as well as epichlorohydrin. 3-Chlorolactic acid, the main metabolite of 3-CPD in rats, was shown to be devoid of DNA-damaging effects *in vitro* in mammalian cells. 2-CPD is also a potential carcinogen.

The daily intake of 3-CPD by the adult population in the United Kingdom, for example, with an average consumption of foods with higher content of 3-CPD, is estimated at 0.10 μg/kg body weight, in the population aged 4–18 years at 0.18 μg/kg body weight and in children of up to 4 years at 0.28 μg/kg body weight. In populations consuming higher amounts of hydrolysates these estimates are higher (0.21, 0.38 and 0.58 μg.kg body weight, respectively). These values, of course, do not take into account the recent findings of high amounts of bound forms of 3-CPD (esters) in refined fats.

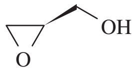
Genotoxic 1,3-DCP (a group 2B carcinogen)[3] also has other toxic effects (hepatotoxicity, nephrotoxicity and thyreotoxicity), which appear to be linked to its toxic metabolites and degradation products (epichlorohydrin and 1,3-dichloroacetone). Its positional isomer 2,3-DCP is also potentially genotoxic and carcinogenic. The concentration of 0.005 mg/kg 1,3-DCP in hydrolysates and soy sauces was recommended with respect to the current limit of quantification. The daily intake of 1,3-DCP by the adult population in the United Kingdom was estimated to be 0.051 μg/kg body weight and in children at 0.136 μg/kg body weight.

12.2.4.5 Mitigation

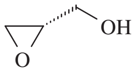
At the beginning of the 1980s, manufacturers of acidic protein hydrolysates started to implement practices that led to the reduction in the amount of chloropropanols. The stripping of crude hydrolysate with steam led to the removal of volatile chloropropanols, including 1,3-DCP and 2,3-DCP. Shortly after identification of non-volatile chloropropanediols, 3-CPD and 2-CPD, this procedure had to be replaced by decontamination of crude hydrolysate in a slightly alkaline medium. Other decontamination methods were also considered, such as degradation of CPD by microorganisms and enzymes, CPD extraction with ethyl acetate, butan-1-ol, butan-2-ol or isobutanol and removal of residual solvent by steam stripping. Some manufacturers have stopped production of traditional acidic protein hydrolysates and replaced them with aromatised enzymatic hydrolysates.

Table 12.10 shows some examples of the detoxified hydrolysates. Today, decontamination is performed on the crude hydrolysate cooled to a temperature of 90–100 °C, which is alkalinised to pH 8–9 with sodium hydroxide, potassium, ammonium or sodium carbonates, and dehydrohalogenation is allowed to proceed for 1.5–3 h. After decontamination, the hydrolysate is acidified with hydrochloric acid to have the same pH as the hydrolysate produced by traditional technology. Table 12.10 correspondingly illustrates one of the problems that emerged in this context. 2-CPD is much more stable than 3-CPD, is dehydrohalogenated more slowly than 3-CPD and accumulates in detoxified hydrolysates. For its removal, decontamination must be carried out at higher pH, higher temperature or for longer. The organoleptic properties of decontaminated hydrolysate are also somewhat different from the traditional hydrolysate.

The mechanism of dehydrohalogenation of vicinal chlorohydrins (α-chloroalcohols) is shown in Figure 12.16. Reaction in alkaline solutions is very rapid and the corresponding alkoxide (alcoholate) forms as the primary product. Important reaction intermediates are oxiranes (1,2-epoxides). By opening of the oxirane ring, the corresponding vicinal diols appear as the final reaction products. In the case of 3-CPD and 2-CPD, the dehydrohalogenation intermediate is glycidol and the final product is glycerol. Enantiomers of 3-CPD are decomposed at the same rate, and (*R*)-CPD gives rise to (+)-(*R*)-glycidol (**12-38**), and (*S*)-CPD yields (−)-(*S*)-glycidol (**12-39**) by inversion of configuration, known as Walden inversion.



12-38, (*R*)-glycidol



12-39, (*S*)-glycidol

Another problem is that glycidol, which is classified as a Group 2B carcinogen, accumulates under certain conditions in hydrolysates, because the rate of decomposition of CPD isomers is higher than the rate of decomposition of glycidol. For example, the maximum concentration of glycidol (after 5 min of decontamination at 65 °C at pH 9) reaches about a third of the initial CPD concentration. Glycidol is a very reactive compound which reacts not only with water, but also with many other nucleophilic reagents (alcohols, thiols, amines and acids). Its reaction with

Table 12.10 Concentrations of 3-CPD and 2-CPD in decontaminated hydrolysates.

Starting concentrations of 3-CPD and 2-CPD (mg/kg)	Conditions			Final concentrations (mg/kg)	
	Temperature (°C)	pH	Time (h)	3-MCPD	2-MCPD
95.7/15.1	100	8.5	3	<0.01	0.025

glycerol yields polyglycols and the main product with ammonia is 3-aminopropane-1,2-diol (**12-40**). Both enantiomers occur in acidic protein hydrolysates at a level of about 30 mg/kg. Another product is the tertiary amine tris(2,3-dihydroxypropyl) amine (2–4 mg/kg, **12-41**). With ammonia, 2-CPD yields 2-aminopropane-1,3-diol (serinol, **12-42**) as the main product. The reaction with the amino group of amino acids produces *N*-(2,3-dihydroxypropyl)amino acids (**12-43**). These reactions paradoxically contribute to the hydrolysate decontamination. Under alkaline conditions, L-amino acids isomerise to D-amino acids to some extent.

12.2.5 Polycyclic aromatic hydrocarbons

12.2.5.1 Structure and nomenclature

Polycyclic aromatic hydrocarbons (PAHs) and their derivatives represent an important group of virtually ubiquitous environmental contaminants, some members of which are characterised by their genotoxic and carcinogenic potential. Contamination of agricultural crops and food raw materials by exogenous PAHs is mainly due to polluted agricultural land or to air (atmospheric) pollution of the given locality. PAHs present in foods may also be endogenous contaminants, because considerable contamination of food can be caused by PAHs arising from natural precursors during some culinary or technological operations. For this reason, PAHs are classified as technological contaminants.

PAHs found in many foods, at least in trace amounts, contain 2–6 fused aromatic rings. In total more than 100 compounds have been identified. Compounds represented by formulae **12-46** to **12-71** are currently the most common PAHs, both in terms of their occurrence in the environmental components and in the context of health dietary risks for consumers. The symbol '*' indicates 15 priority PAHs according to the U.S. Environmental Protection Agency (EPA) and by the symbol '+' indictes 16 priority PAHs according to the European Scientific Committee on Food.[4]

Polycyclic systems, in which the adjacent rings have common atoms, may be *ortho*- or *ortho*-*peri*- or *peri*-condensed. If none of the common atoms are part of more than two rings, the system is *ortho*-condensed and can be either linear (such as in anthracene) or angular (e.g. in phenanthrene). The number of common atoms in this system is equal to twice the number of the common sides. The *peri*-condensed system exists if at least one of the common atoms belongs to three rings. The aggregate number of common atoms

[4] In recent years, the evaluation of PAHs was carried out as part of the International Programme on Chemical Safety (IPCS), as well as by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and also by the EU Scientific Committee for Food (SCF). SCF was appointed by the European Commission in 1997 and in 2003 transferred to the European Food Safety Authority (EFSA). On the basis of available studies, the authority identified in 2002 a group of 15 priority PAHs, which can be regarded as potentially genotoxic and carcinogenic to humans. The basis for the recommendations were evidences of mutagenicity and genotoxicity for animal somatic cells *in vivo* obtained in different types of biological tests on experimental animals and conclusive evidence of carcinogenicity, except benzo[*ghi*]perylene, where data are insufficient. In 2005, JECFA confirmed the correctness of SFC recommendations and suggested to extend the priority list of PAHs by benzo[*c*]fluorene. When assessing the health risks in 2008, the EFSA Scientific Committee (CONTAM Panel) focused on food contaminants and also dealt with the question of the relevance of Toxicity Equivalency Factors (TEFs) for risk characterisation of PAH mixtures. This approach is commonly applied in assessing the contributions of individual components of mixtures of polychlorinated dibenzodioxins and dibenzofurans. Owing to the lack of data on the carcinogenic effects of individual priority PAHs in the case of oral exposure and taking into account the different mechanisms of their action, the formerly used TEF concept was rejected as scientifically unsupported (the prediction of carcinogenic effects of PAH mixtures based on TEF was not experimentally confirmed) and SCF suggested a system, which is based on knowledge of the effects of a marker of carcinogenic PAHs, benzo[*a*]pyrene and the data on the profiles of PAHs in foods evaluated on the basis of carcinogenicity studies of two characterised mixtures of coal tar in mice.

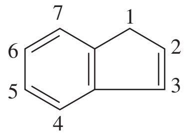
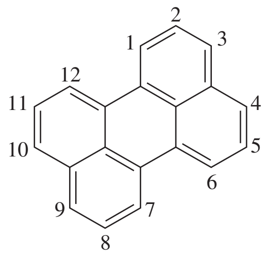
of several rings (at least three) is lower than twice the number of common sides. An example of such a hydrocarbon is pyrene.

For selected hydrocarbons, trivial names are used. Names of *ortho*- and *peri*-condensed polycyclic hydrocarbons that have no trivial names are formed from the name of a hydrocarbon, for which there is an appropriate trivial name, and a prefix indicating the nature and location of other rings, for example benzo[*a*]pyrene. The individual isomers are distinguished by letters *a*, *b*, *c*, etc., by which all peripheral sides of the basic hydrocarbon are identified, progressively from side *a* between C-1 and C-2. Examples of such isomers are benzo[*a*]pyrene and benzo[*e*]pyrene. The orientation of a formula should be such that the maximum benzene rings lie in a horizontal position, and also such that as many benzene rings as possible are lying at the top right of this horizontal axis of the molecule. The numbering of atoms is done in a clockwise direction, starting from the carbon atom of the ring of the far right and the furthest from the horizontal axis (carbons that cannot carry a substituent are not numbered). Besides the already mentioned hydrocarbons, the names of other contaminants are derived from indene (**12-72**) and perylene (**12-73**).



12-72, indene



12-73, perylene

Physico-chemical properties of PAHs, and correspondingly their fate in the environment and living organisms, are conditioned by the presence of conjugated double bond systems and the differences between individual hydrocarbons are determined by the number and relative position of condensed rings. PAHs are generally substances of low reactivity and the stability of linear condensed hydrocarbons generally decreases with the number of *ortho*-condensed rings. Angular and *peri*-condensed hydrocarbons are more stable. Melting points, boiling points, lipophilicity (measured by K_{OW}) and adsorption to soil or sediment particles (measured by K_{OC}) increase with an increase in the relative molecular weight of PAHs, but their vapour pressure (related to the value of Henry's law constant k_H) and water solubility decrease. The most important properties of selected PAHs are summarised in Table 12.11.

12.2.5.2 Occurrence and main sources

12.2.5.2.1 Main sources and penetration to environment

PAHs and their mixtures have been part of the human environment since time immemorial. They enter the ecosystem and the human food chain from anthropogenic sources (sources related directly or indirectly to human activities) and non-anthropogenic sources (natural, especially geochemical). However, the biosynthesis of these substances by some organisms has been demonstrated (Table 12.12).

Results of studies investigating the levels of PAHs in sediments or deeper layers of the polar icecaps show that, until approximately the end of the last century, a certain balance existed in the environment between production and degradation of these compounds. In other words, PAHs released by volcanic activity, fires and the existing human activities or biosynthesis, were eliminated from the environment by different degradation mechanisms to roughly the same extent, especially through photodegradation and microbial degradation. Current estimates of global annual emissions, however, refer to between tens of thousands and hundreds of thousands of tons of PAHs, which can contribute to a gradual increase in pollution of the atmosphere, terrestrial environment and hydrosphere. Up to 90% of this increase in PAH concentrations in environmental components is due to the burning of fossil fuels.

Transport in the environment occurs mainly through airflow and, in an aqueous environment, by re-suspension of contaminated sediments. These processes are associated with the solubility of PAHs in water (partition coefficient K_{OW}), their vapour pressure (Henry's law constant k_H), adsorption coefficient normalised to the organic carbon content of the soil or sediment (K_{OC}) and, last but not least, their chemical and biological stability. Some of these characteristics, especially k_H, K_{OW} and K_{OC}, correlate with relative molecular weights (M_r) of PAHs, and therefore PAHs are often divided into three groups:

- low molecular weight PAHs (referred to as light, $M_r = 152–178$ Da): acenaphthene, acenaphthylene, anthracene, phenanthrene and fluorine;
- medium molecular weight PAHs ($M_r = 202$ Da): fluoranthene and pyrene;
- high molecular weight PAHs (referred to as heavy, $M_r = 228–278$ Da): benzo[*a*]anthracene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene, benzo[*ghi*]perylene, chrysene, dibenzo[*ah*]anthracene, indeno[1,2,3-*cd*]pyrene, dibenzo[*ah*]pyrene and dibenzo[*ai*]pyrene.

12.2.5.2.2 Transport in the environment

A significant transport medium of a number of pollutants is air. PAHs are found there in the form of vapour or sorbed on solid aerosol particles. To date, almost 500 PAHs and their derivatives have been found in the atmosphere. It is reported that up to 75% of PAHs (especially the higher molecular weight compounds) in

the atmosphere are bound to the surface of the respirable fraction of particles (particles with a diameter lower than 1 μm). More volatile PAHs (except fluoranthene) are associated primarily with larger particles (airborne dust, soot and others). The concentration of PAHs generally increases with a decrease in the atmospheric temperature. The total concentration of PAHs in air can be in the range of several orders. The background concentrations are in the range of 0.1–1 ng/m^3. In heavily polluted localities, the concentrations of PAHs may reach hundreds of ng/m^3 (expressed as the sum of 16 priority PAHs according to the U.S. Environmental Protection Agency, EPA). Mean concentrations in the air in urban and industrial areas are between 0.3 and 6 ng/m^3.

In air, PAHs are found sorbed to solid particles and as gases (aerosols). The dwell period of PAHs in the air is associated with a variety of processes, many of which also determine the extent of contamination of terrestrial vegetation, including crops. The level of dry and wet atmospheric depositions is significant. Particle-bound PAHs can be transported over long distances and are removed from the atmosphere through precipitation and dry deposition. PAHs are transported from surface waters by volatilisation and sorption to settling particles (sediments). Typically about 45% of the total PAH amount emitted is captured by vegetation, 10% is deposited in the soil, 5% in water areas and the remaining 40% is either chemically transformed or transported by air flow to more remote areas. In surface waters, PAHs are transformed by photooxidation, chemical oxidation and microbial metabolism. In soil and sediments, microbial metabolism is the major process for degradation of PAHs.

Data from southern England document the rising burden for soil by PAHs, arguably due to anthropogenic activities. The PAHs content in the surface soil layer (30 mm) has increased over the past 140 years from 18 to 130 μg/kg. The estimated half-life of soil retention is considerable, for example 371–387 days for chrysene, 229–309 days for benzo[*a*]pyrene and 361–420 days for dibenzo[*a,h*]anthracene. PAHs containing two or three benzene rings are volatilised more rapidly.

12.2.5.2.3 Occurrence in food raw materials and foods

The main source of contamination of fresh agricultural products and many other food raw materials is deposition of PAHs from air (vapours and dust particles), and to a lesser extent sorption from soil and water.

Contamination of vegetation

Knowledge on the mechanisms of exogenous contamination of terrestrial vegetation by PAHs is important both for assessing bioaccumulation, transformation and phytotoxicity (ecotoxicological aspects) and in terms of load monitoring of the human food chain (especially of agricultural crops) and then for the adoption of measures aimed at protecting human health. Plants receive PAHs by:

- absorption from water
- absorption through the root surface
- absorption through leaves from the vapour phase of air
- absorption through leaves from deposited particles.

The transmission of PAHs from soil to the plant root system is not very significant due to their high hydrophobicity. Its extent, however, depends on the water regime and the lipids content in the root cortex. For example, in carrots grown in soil with added sludge rich in PAHs (total content as the sum of 15 PAHs was 500 μg/kg), elevated levels were found, with 75% of the total content accumulated in the epidermal layer rich in lipids (200 μg/kg dry matter), while the content of PAHs in the edible part of the carrot was lower and was represented mainly by low molecular weight, more water-soluble PAHs (including fluorene, acenaphthene and phenanthrene). The intake of PAHs by leaves proceeds by direct intake through pores in the case of more volatile fractions, as well as through the cuticle from deposited dust particles containing sorbed contaminants. An important factor is the length of the growing season and characteristics of these aerial parts, which is why evergreen conifers are suitable indicators of environmental contamination. Results for PAHs in plants range from hundredths to tens of μg/kg. For example, the amounts of PAHs in different plant species were 22–88 g/kg in the leaves of trees, 48–66 g/kg in cereals, 0.05–50 g/kg in the above-ground parts of the vegetables, 0.01–6 g/kg in vegetable roots and 0.02–0.04 g/kg in fruits. In the vicinity of massive sources of contamination, however, the levels of PAHs in vegetation can reach 25 mg/kg. Knowledge of the rate of intake of PAHs by plants and their occurrence can be summarised as follows:

- low molecular weight PAHs are sorbed by plants more easily than hydrocarbons of higher molecular weights;
- one factor limiting intake of PAHs from contaminated soil is its composition, especially the concentration of carbon in organic compounds (with a higher content, PAHs are immobilised for potential transmission, due to strong sorption);
- PAH concentration in the above-ground parts of plants is higher than in roots;
- elevated PAH concentrations can be expected especially in plants with a high content of cuticular waxes and species with high leaf area and rough surface;
- PAH concentration is higher on the surface of plants than in the inner parts;
- vegetation and soil in the vicinity of emission sources are more contaminated than in more distant areas.

Contamination of animals

The source of PAHs to farm animals is mainly contaminated feed or water supply, but many animals are able to metabolise and eliminate these compounds, therefore their bioaccumulation is not as extensive as with persistent organochlorine compounds, such

as DDT and PCBs. For example, the value of the bioaccumulation factor (BAF) for benzo[*a*]pyrene in beef is about 0.003 mg/day.

Food chain uptake does not appear to be a major source of exposure to PAHs for aquatic organisms. The main source of PAHs is environmental contamination by oil products (indicators of oil substances in the aquatic ecosystem is fish). For example, areas with oil leakages (such as tanker accidents) may temporarily cause a significant increase in the levels of PAHs in fish muscle and especially in the gonads rich in fat, and the levels of PAHs in edible parts can be up to 500 times higher than the typical values. Normally, PAHs occurring in fish are gradually degraded and excreted, so the values of the bioconcentration factor are relatively low, but in crustaceans and other invertebrates, PAHs may significantly concentrate in tissues. Bioconcentration factors for fish are frequently in the 10–10 000 range, higher for compounds with higher relative molecular weight and lower for low molecular weight PAHs.

Occurrence in foods

A summary diagram of sources of PAHs in foods is shown in Figure 12.17. It is obvious that many food commodities can be contaminated from several sources. Data on the concentrations of PAHs in food have been obtained in a number of developed countries since the 1990s. Their comparison and generalisation, however, was quite difficult, not only due to differences in the spectrum of monitored compounds (the extent of contamination was often expressed as the sum of PAHs based on the priority list of EPA compounds), but also because different analytical methods were used and there was considerable uncertainty over the data obtained. Evaluation of the data available in 13 EU member states in 2004, however, documented the existence of increased contamination of certain food groups. Systematic monitoring implemented in EU Member States for the purposes of risk assessment was initiated by EFSA in 2005. It was recommended that 15 PAHs identified from a toxicological point of view were followed as a priority. The aggregated data are illustrated in Figure 12.18. Based on their evaluation, it was stated that benzo[*a*]pyrene, regarded for many years as a marker of food contamination by carcinogenic PAHs, does not fulfil this function optimally. Benzo[*a*]pyrene was found in at least 50% of the samples of a given commodity; however, in 30% of samples its concentration did not exceed the limit of detection, although the samples contained high concentrations of other PAHs with similar toxic potential. The facts illustrated by Figure 12.18 led scientists to consider the advisability of increasing the number of markers of contamination by carcinogenic PAH. With regard to typical levels of PAHs, three groups of PAHs were designed, representing 34%, 60% and 80% of the total amount of PAHs:

- PAH2: benzo[*a*]pyrene and chrysene
- PAH4: PAH2, benzo[*a*]anthracene and benzo[*b*]fluoranthene
- PAH8: PAH4, benzo[*k*]fluoranthene, benzo[*ghi*]perylene, dibenzo[*ah*]anthracene and indeno[1,2,3-*cd*]pyrene.

The available data show that for an objective assessment of food contamination at least the PAH4 group (benzo[*a*]anthracene and benzo[*b*]fluoranthene) should be monitored, since 26% of samples contained at least one other carcinogenic PAH (very often chrysene). Figure 12.19 illustrates the average findings of the sum of eight PAHs in 33 food items, nine of which exceeded or closely approached 10 μg/kg. The highest amounts of PAHs found in tea (20% of samples actually exceeded the level of 100 μg/kg) cannot be directly associated with a significant exposure for consumers, because the infusion is very diluted.

Technological and culinary processes

Smoking Smoking is an age-old process of cooking and flavouring meat and fish over a low smoky fire, increasing their shelf life by partial dehydration and through the antibacterial properties of the absorbed smoke. Among the more than 300 products of

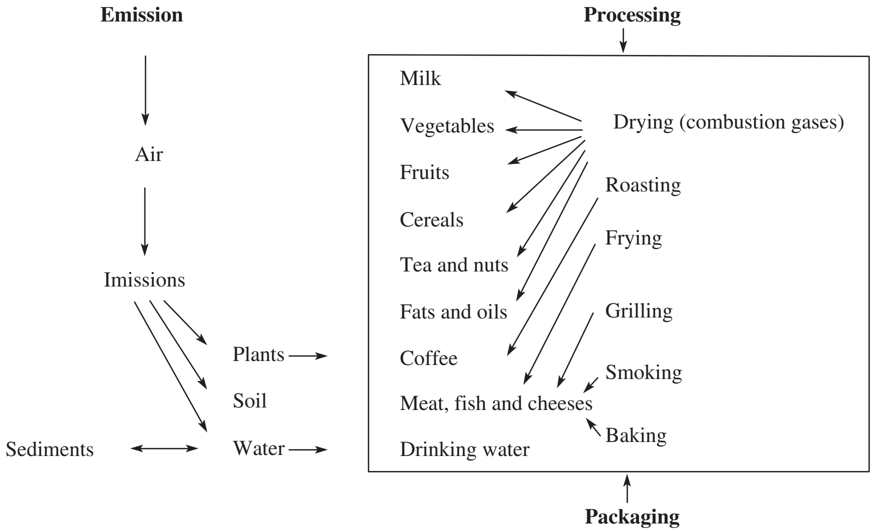

Figure 12.17 Possibilities of food contamination by PAH (emissions are measured directly at source, for example chimney, while imissions in the surrounding area).

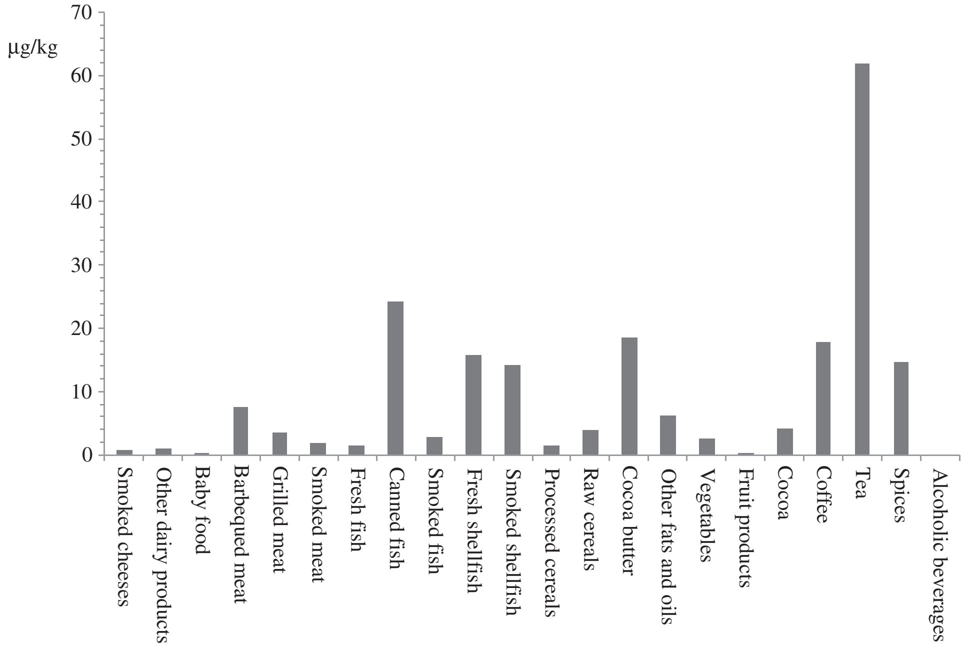

Figure 12.19 Mean values of PAH8 representing 33 food categories (agregated data for 4065 samples). According to Scientific Opinion of the Panel on Contaminants in the Food Chain on request from the European Commission on Polycyclic Aromatic Hydrocarbons in Food. The EFSA Journal 724, 1-114 (2008).

the pyrolysis of lignin, hemicelluloses, cellulose and other natural components of burnt wood or sawdust, about 70 PAHs have also been identified. Since carbon black dispersed in the released smoke contains the greatest proportion of PAHs (almost 90%), the major source of contamination is the surface of smoked foods. The resulting PAH content in the smoked product, however, depends on a number of factors. The critical factors are the fuel moisture, oxygen supply, technology of smoke formation, type of smoking

process (according to the temperature in the smoking room, it is classified as 'hot' or 'cold') and time of smoking. In practice hard wood is preferred (such as beech and oak wood), since it burns at lower temperatures and produces less carbon black compared with soft woods that contain a higher proportion of lignin, which is a major precursor of PAHs. Under normal conditions of smoke development at combustion temperatures in the range of 500–700 °C, smoke contains significant amounts of naphthalene, and the carcinogenic fraction of PAHs contributes to the total content of pollutants by about 5% wt. An illustration of the impact of smoking techniques on the content of benzo[*a*]pyrene in smoked products is shown in Table 12.13. In general, large differences are found between the products smoked in the home and in industrial smoke houses. Benzo[*a*]pyrene and benzo[*a*]anthracene concentrations in meat directly smoked over a fire can exceed tens of μg/kg, while concentrations of these substances in similar commercial products normally do not exceed 1 μg/kg. In modern food processing, the smoke evolution is automatically controlled and most PAHs (up to 90%) are removed from the smoke by filtration, washing and cooling.

A significant role in terms of content and distribution of PAHs is played by the type of smoked products, namely the size of surface exposed to smoke, and the products' fat content. The highest amount of PAHs is on the surface and their diffusion into deeper layers is not significant. For example, amounts of PAHs in the skin of smoked fish are between 4 and 24 times higher than in subsurface layers. A barrier against penetration of PAHs into the edible part may be formed by synthetic hydrophilic polymers, such as cellophane (regenerated cellulose). Currently, for flavouring meat, fish and other products such as cheese, smoking substances called liquid smoke are often used that have a controlled content of benzo[*a*]pyrene and other PAHs, which are below the acceptable limits.

Grilling Grilling or roasting on the grill (barbeque) is another form of heat treatment, temperatures of which vary over a wide range of from 150 to 400 °C. Grilling may, under certain circumstances, lead to very significant increases in both endogenous and exogenous PAHs in the product. Sources of contamination of its surface can be as follows:

- pyrolysis products of fat falling in drops onto the hot heater or into burning fuel;
- pyrolysis products of fuel used;
- pyrolysis products of grilled food generated endogenously in contact with the flame from food components.

A major impact of the grilling process on concentrations of benzo[*a*]pyrene in barbequed frankfurters is shown in Table 12.14. It is evident that from the hygienic–toxicological point of view it is especially risky to grill fatty materials in a direct flame, when the levels of contaminants may be up to several orders of magnitude higher than those of conventionally heat treated products.

Table 12.13 Influence of smoking conditions on benzo[*a*]pyrene concentration in smoked meat products of comparable parameters (surface, fat content and packaging).

Technology of smoke development (smoking technique)	Content of benzo[*a*]pyrene (μg/kg)
Smoldering smoke	<0.1–36
Moist smoke	0.1–0.8
Smoke from friction generator	0.1–4.6
Hot smoking (bright)	<0.1–2.1
Hot smoking (dark)	0.2–36
Cold smoking (light)	0.1–3.2
Cold smoking (dark)	0.1–56

Table 12.14 Content of benzo[*a*]pyrene in grilled frankfurters under various conditions.[a].

Heat source	Mean content (μg/kg)	Range of values (μg/kg)
Frying pan	0.1	Not detected–0.2
Electric oven	0.2	0.1–0.3
Charcoal	0.3	Not detected–1.0
Pine cones	18	2–31
Logs	54	6–212
Embers	8	<1–25

[a]Original content of 0.2 μg/kg.

Drying and roasting The amounts of benzo[*a*]pyrene in products dried by indirect heating are generally low, often below 0.1 μg/kg. Higher amounts, however, can be expected in the event of contact with combustion gases. A possible source of PAHs in the production of beer and whiskey is malt, which is also sometimes dried by direct heating. Considerable attention is paid to roasted coffee. Formation of phenanthrene, anthracene and benzo[*a*]anthracene in coffee beans was observed at temperatures above 220 °C, whereas formation of pyrene and chrysene required 260 °C. Low levels of benzo[*g*,*h*,*i*]perylene were also noted for dark roasting below 260 °C, with simultaneous partial degradation of three-ring PAHs, suggesting that transformation of low molecular PAHs to high molecular PAHs occurs as the degree of roasting is increased. The PAH transfer to the infusion was fairly moderate (<35%).

12.2.5.2.4 Exposure sources

Quite the most important source of human exposure to PAHs (typically >95%) is food (oral intake). Pollutants also penetrate the body by inhalation of contaminated atmospheric particles, which are the dominant source in smokers. Dermal exposure is generally

regarded as a rarity, with the exception of professionally exposed persons.

The first comprehensive studies focusing on the estimation of dietary exposure to individual PAHs were published in the 1990s; however, the comparability of these results was limited not only by differences in analytical methods and analytes (often it was the EPA priority list including the volatile fraction of PAHs), but also by differences in the food basket composition and calculation methodology. Table 12.15 summarises estimates of dietary exposure of EU consumers to benzo[*a*]pyrene and to PAH2, PAH4 and PAH8 groups of PAHs defined above in recent years. The EU database for average consumption of individual food categories was used for the calculation. Generally, the most important dietary sources of PAHs to the European population are cereals, cereal products and seafood. These categories were also used to calculate exposure to PAHs of extreme drinkers (Table 12.16). As a biomarker to assess exposures to PAHs of workers (e.g. in the petrochemical industry and in aluminium production plants) and also that of ichthyofauna and ruminants exposure, the major pyrene metabolite 1-hydroxypyrene, which is excreted into the bile, urine and milk, was employed.

Information on the occurrence of derivatives of PAHs in food is very limited, but their concentrations are lower than those of the parent PAHs. In recent years, considerable attention has been devoted to nitro derivatives of PAHs in view of their toxic potential. High amounts of 1-nitronaphthalene, 2-nitrofluorene and 1-nitropyrene were found in home-smoked meat, where their concentration reached tens of μg/kg. Surprisingly high contamination by nitro derivatives of PAHs has been demonstrated in some types of spices and tea. Typical concentrations generally do not exceed units of μg/kg.

12.2.5.3 Formation

Information on the mechanisms of formation of PAHs and derived substances are significant not only in terms of taking measures that minimise possibilities of their penetration into the food chain, but also to reduce endogenous contamination of food in some culinary or technological processes.

12.2.5.3.1 Formation of hydrocarbons

One of the most important routes of PAHs formation are combustion processes (pyrolysis) of organic matter with limited availability of oxygen at temperatures of 500–900 °C, and especially above 700 °C. The mechanism of PAHs formation is **pyrosynthesis**

Table 12.15 Exposure of consumers to benzo[*a*]pyrene, PAH2, PAH4 and PAH8 through selected foods.

Foods	Daily consumption (g)	Exposure (ng/day)			
		benzo[*a*]pyrene	PAH2	PAH4	PAH8
Cereals and cereal products	257	67	129	257	393

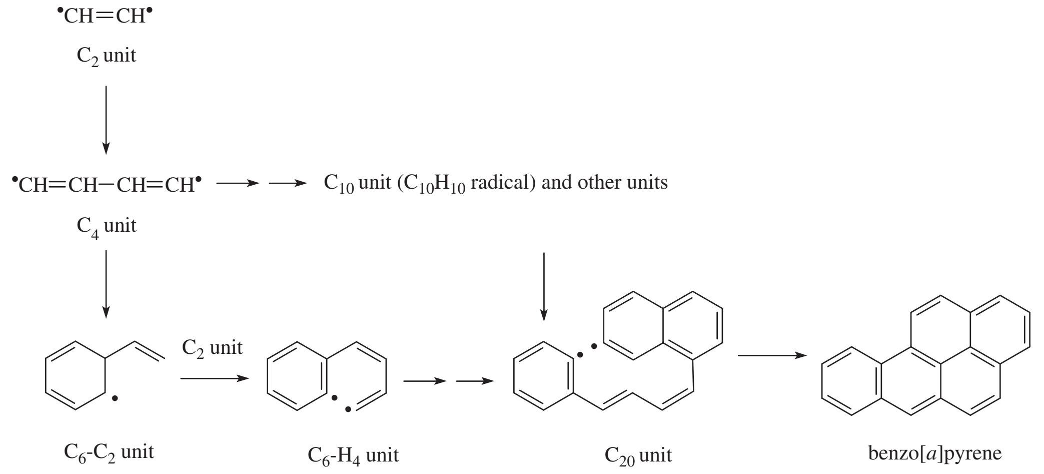

Figure 12.20 Formation of benzo[*a*]pyrene by pyrolysis of organic matter.

from low molecular weight unsaturated aliphatic hydrocarbons. Figure 12.20 illustrates the formation of benzo[*a*]pyrene by recombination of free hydrocarbon radicals. This pathway, for example, produces PAHs during combustion of fossil fuels. Flame temperature and oxygen availability determine their composition. Many fuels already contain some PAHs that can get into emissions directly. A range of natural compounds may be PAH precursors, such as plant steroids and other terpenoids. Figure 12.21 illustrates the main decomposition products of stigmasterol.

Another important pathway leading to PAHs is the thermal elimination reaction of benzene derivatives (Figure 12.22). For example, the elimination of water from phenolic compounds (X = OH) yields, via 1,2-didehydrobenzene (often incorrectly called benzyn), another reactive intermediate benzobicyclo[2,2,2]triene and naphthalene as a final product. The contribution of endogenously generated compounds to the total dietary intake of PAHs is not too significant as the contamination of food is largely exogenous.

12.2.5.3.2 Formation of hydrocarbon derivatives

In the evaluation of reactivity of PAHs, reactions that occur in the atmosphere are of particular interest, because the resulting products can contaminate crops. The extent and nature of these reactions depends on temperature, intensity of solar radiation and the concentration of substances, which are capable of electrophilic substitution on the aromatic nucleus. Reactions of PAHs with ozone, singlet oxygen, nitrogen or sulfur have been described, and particular attention was focused on reactions leading to PAH nitro derivatives, because of their high toxicity. Certain amounts of these contaminants are emitted directly into the atmosphere from sources formed during organic matter combustion, but they may also arise by radical reactions in the gas phase. PAHs (or amino-PAHs) generally react with free hydroxyl radicals ($HO^•$) to form reactive hydroxyl radicals of PAHs, which react with $^•NO_2$ radicals in the gas phase forming hydroxynitro derivatives of PAHs. Hydroxynitro derivatives eliminate water to form PAH nitro derivatives. This

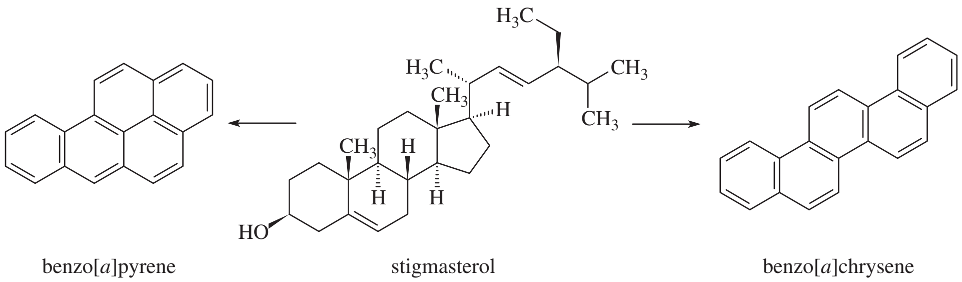

Figure 12.21 Formation of benzo[*a*]pyrene and benzo[*a*]chrysene by thermal decomposition of stigmasterol.

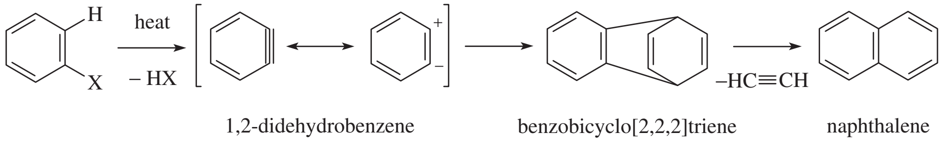

Figure 12.22 Formation of naphthalene from benzene derivatives.

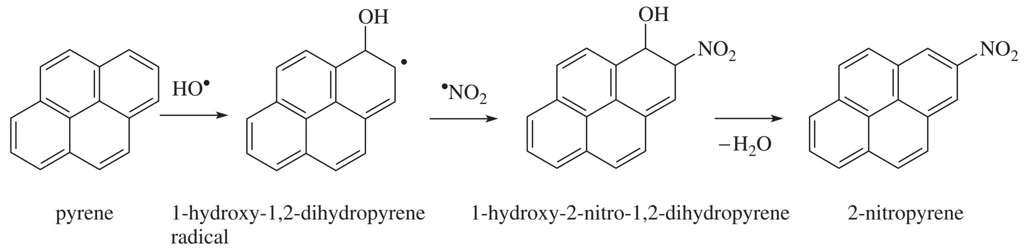

Figure 12.23 Formation of 2-nitropyrene in the atmosphere.

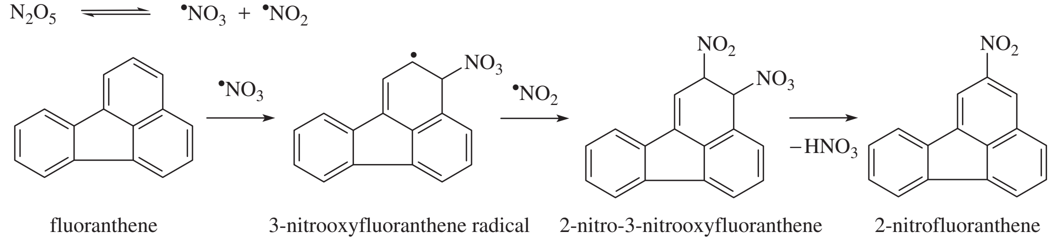

Figure 12.24 Formation of 2-nitrofluoranthene in the atmosphere.

reaction takes place in daylight. Another nitrating substance is nitric oxide (N_2O_5), which is cleaved to $^{\bullet}NO_3$ and $^{\bullet}NO_2$ radicals. The resulting radicals react with PAHs with elimination of nitric acid (HNO_2) yielding nitro-PAHs. Nitration of PAHs by nitric oxide radicals proceeds especially in the dark. Two different mechanisms of nitro-PAH formation can therefore be distinguished. Reactions of the first type that produce 2-nitropyrene in daylight are illustrated in Figure 12.23. The formation of 2-nitrofluoranthene in the absence of sunlight is illustrated in Figure 12.24. The amount of this compound produced is about the same as that generated during daylight.

12.2.5.4 Health and toxicological assessment

In the last decade a rigorous evaluation of the toxicity and health risks of PAHs associated with their long-term dietary intake has taken place. The acute toxicity of PAHs is relatively low; for mice and rats the LD_{50} of benzo[*a*]pyrene is >1600 mg/kg body weight. As indicated in Table 12.15, foods are clearly the most important source of PAHs (for non-smokers). To date, in terms of regulating polycyclic aromatic hydrocarbons (PAHs) in food, the EU has only established limits for benzo[*a*]pyrene, through European Commission regulation (EC) No. 1881/2006, which has hitherto been regarded as an indicator of the overall burden by PAHs. Maximum limits apply to baby foods and foods that contain mostly fats and oils, and for foods where smoking or drying processes might cause high levels of PAH contamination. For example, the maximum levels of benzo[*a*]pyrene in infant formulae and follow-on formulae, cereal-based and baby foods for infants and young children and dietary foods for special medical purposes for infants are 1 μg/kg, and for oils and fats (excluding cocoa butter), and the meat of fish other than smoked fish, the maximum levels were set at 2 μg/kg and to 5 μg/kg wet weight in smoked meats and smoked meat products. Maximum levels have likewise been set for fish and fishery products, where high levels of contamination may be caused by pollution of the environment (5 μg/kg for smoked fish, smoked fishery products, crustaceans and cephalopods and 10 μg/kg for bivalve molluscs). The EFSA recommendation to follow a sum of four PAHs, benzo[*a*]pyrene, chrysene, benzo[*a*]anthracene and benzo[*b*]fluoranthene has still not been incorporated into the legislation.

PAHs absorption in the gastrointestinal tract is generally easy; however its extent depends on food composition and varies over a range of about 12–99%. Low molecular weight PAHs are absorbed better. Absorption of PAHs increases with higher fat content, but some food components (such as flavonoids and other polyphenols) reduce the intake of PAHs. The bioavailability of PAHs from burnt food is surprisingly low, even though their content is relatively high, which is due to the absorption of PAHs by charred particles. Absorption of PAHs is followed by a rapid distribution in the body, since they can easily penetrate the lipoprotein membranes. With the exception of benzo[*a*]pyrene, the toxicokinetics of the priority PAHs are little documented. In general, however, thanks to extensive biotransformation, accumulation of PAHs in the human body (and correspondingly in other mammals) does not occur. Biotransformation of the individual PAHs is quite similar, but the quantity and rate of metabolite formation depend on the parent compound structure. In the initial stage of biotransformation, PAHs are oxidised by oxidoreductases of the cytochrome P450 complex, which are located in endoplasmic reticulum or microsomes of cells in various tissues (especially the liver) and are induced by PAHs or other inducers. So far, most attention in this respect has been devoted to benzo[*a*]pyrene, although some related compounds (nitro-PAHs or acridine derivatives) exhibit

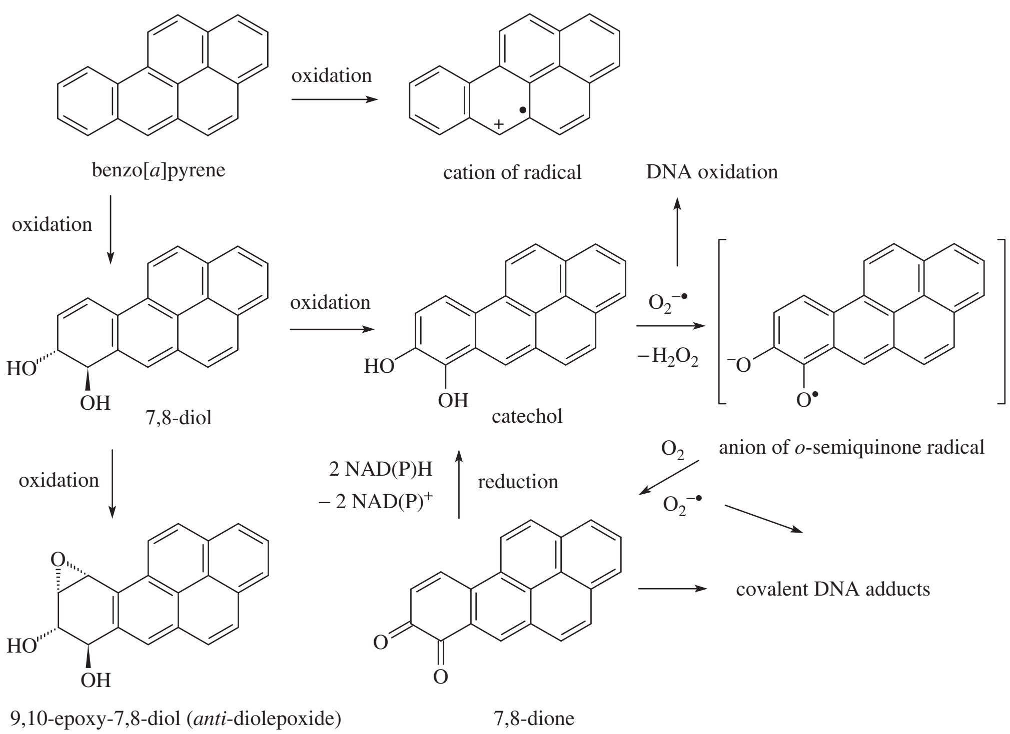

Figure 12.25 Metabolism of benzo[*a*]pyrene.

even greater carcinogenic effects. These effects are related to the metabolic transformation of PAHs to reactive metabolites, such as benzo[*a*]pyrene-7,8-diol and benzo[*a*]pyrene-7,8-dione, which can yield covalent compounds, for example with DNA (Figure 12.25). Pyrene is analogously transformed into 1-hydroxypyrene, which is the main biotransformation product. Oxidative DNA damage may similarly occur by reaction with superoxide radicals.

The metabolism of nitro derivatives of PAHs is different from metabolism of the parent PAHs. Orally administrated compounds are mainly reduced to amino derivatives by intestinal microflora. Their elimination from the body occurs after oxidation to hydroxy derivatives and acetylation of amino group in the liver. Hydroxynitro derivatives of PAHs are the major products that are resorbed unchanged from the gastrointestinal tract. Estimation of risks from dietary intake of nitro-PAH derivatives has not been worked out in detail, with respect to the limited data on their occurrence in foods. Generally, these direct carcinogens require metabolic activation. Particularly intense mutagenic effects have been demonstrated in nitro derivatives of pyrene.

12.2.5.5 Mitigation

Possibilities to limit the occurrence of exogenous PAHs are mainly connected with minimisation of anthropogenic and some non-anthropogenic sources and prevention of their dissemination into the food chain. Limitation of the formation of endogenous PAHs can often be achieved by modifying the process conditions or choosing less risky cooking processes, as discussed in the earlier section on the occurrence of PAHs in food and on the impact of technological and culinary processes on their formation.

12.2.6 Monocyclic aromatic hydrocarbons

Foods contain a variety of hydrocarbons, which arise in natural processes in the plant or animal organisms. The main hazardous substances of particular importance are, however, polycyclic aromatic hydrocarbons (PAHs). Some monocyclic aromatic hydrocarbons (MAHs) are also undesirable contaminants, particularly benzene, toluene, ethylbenzene and xylenes. Compared with PAHs, monocyclic aromatic hydrocarbons are less hydrophobic (K_{OW} values are lower) and therefore somewhat more soluble in water.

The main sources of contamination of the food chain with monocyclic aromatic hydrocarbons are oil spills, but also include a variety of coatings and plastics. Monocyclic aromatic hydrocarbons may also arise as products of the combustion of various materials. Food contamination occurs primarily by absorption from the air and water, and in animals from the surrounding environment. Another type of food contamination is migration from packaging materials. In recent years, much attention has been paid to contamination of yoghurt and biscuits by styrene (vinylbenzene) released from the polystyrene used to manufacture various packagings.

Examples of findings of monocyclic aromatic hydrocarbons in certain foods from the UK market (Table 12.17) illustrate the inputs of these substances from the external environment, because the food surface layers were generally more contaminated than inner layers. In addition to foods, the monocyclic aromatic hydrocarbons

Table 12.17 Concentrations of monocyclic aromatic hydrocarbons in selected foods.

		Content (μg/kg)		
Foods	**Sampling site**	**Benzene**	**Toluene**	**Other hydrocarbons**

	Inner part	<10	<10–56	<10–20

content is monitored in drinking water. From a toxicological point of view, findings of benzene or styrene are particularly serious because of their carcinogenic potential.

Some MAHs may also occur in foods as technological contaminants. The study carried out in 2006–2007 in the United States, Canada and Great Britain reported on the findings of benzene in some soft drinks. The benzene concentrations in some samples exceeded 10 μg/kg (the highest amount was 90 mg/kg), which caught the attention of food safety experts. In a follow-up study conducted in the Czech Republic, 30% of samples of soft drinks exceeded the maximum limit for drinking water (1 μg/l). Benzene concentrations in these samples ranged from 1.1 to 3.2 μg/kg. In packed fermented vegetables (green olives, cucumbers and caper berries) stored under different conditions (glass or plastic containers, ambient or refrigerated storage), benzene levels higher than 10 μg/l were found in cucumbers and caper berries containing benzoic and ascorbic acids, but only when packed in plastic pouches and after prolonged storage at room temperature when ascorbic acid was partially or totally degraded during storage.

The formation of MAHs in soft drinks and some foods can be explained by decarboxylation of aromatic acids, whether natural or used as additives. The second case corresponds to the formation of benzene in soft drinks and fermented vegetables preserved with benzoic acid, which in the presence of ascorbic acid can yield benzene by decarboxylation. The reaction is catalysed by traces of transition metals. Traces of benzene found in cranberry and mango products that were not preserved with benzoic acid were due to a higher content of naturally present benzoic acid.

In comparison with other possible sources of exposure (emissions from motor vehicles, evaporation losses during handling, storage and distribution of gasoline) the benzene intake via soft drinks is negligible. Nevertheless, in order to reduce benzene intake by the body, soft drink recipes should be formulated to avoid benzene formation, which means that the simultaneous presence of benzoic acid (or its salts) and ascorbic acid should be avoided or limited.

Decarboxylation of cinnamic acid analogously yields styrene. Cinnamic acid is present as a minor constituent in cinnamon, where it arises by autoxidation of cinnamaldehyde, especially at higher temperatures. The concentration of styrene in cinnamon may even reach 40 mg/kg.

12.2.7 Nitroso compounds

12.2.7.1 Structure and nomenclature

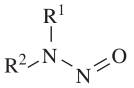
Since 1956, when the carcinogenicity of *N*-nitrosamines was proved, this group of contaminants has been given special attention. Nitroso compounds are formed from various organic compounds by the action of nitrosation reagents. The nitrosation agents may enter into food:

- during technological processing as food additives (such as nitrites or nitrates)
- as contaminants (e.g. nitrates from fertilisers)
- during drying of food by direct heating using combustion gases, which contain nitrogen oxides.

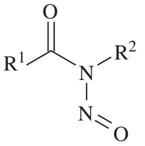
Nitroso compounds in foods may also occur as exogenous contaminants migrating from different sources, such as certain types of elastomers or latex toys, teats and soothers. Another source of nitrosamines is tobacco smoke.

All nitroso compounds contain a nitroso group (N=O) in the molecule. The most common nitroso compounds are *N*-nitroso compounds, which include *N*-nitrosamines (**12-74**) derived from secondary amines and *N*-nitrosamides (**12-75**) derived from

N-substituted amides of carboxylic acids. O-, S- and C-Nitroso compounds are also known.



12-74, N-nitrosamines



12-75, N-nitrosamides

12.2.7.2 Occurrence, main sources and dietary intake

N-Nitrosamines have been found in a number of foods. The greatest attention was paid to their occurrence in smoked meats, cheeses (especially in smoked chesses), skimmed milk, fish, beer and spirits, especially in whisky. The content of volatile and non-volatile N-nitrosamines in selected foods is given in Table 12.18 and Table 12.19, respectively.

The possibility of the formation of nitrosamines and their concentrations in foods depend on many factors, such as the presence and quantity of amines and their precursors, type and quantity of nitrosation agents, pH, temperature, reaction time, composition of food (such as fat content), method of heat treatment, presence of substances that catalyse nitrosation reaction (e.g. rhodanides and to a lesser extent chlorides), and the presence of inhibitors (e.g. ascorbic acid, its esters and salts, sulfur dioxide, phenolic antioxidants, such as gallates and melanoidins).

Table 12.18 Content of volatile nitrosamines in selected foods.

Food	Nitrosamine[a]	Content (μg/kg)	Food	Nitrosamine[a]	Content (μg/kg)
Pickled meat	NDMA, NDEA, NPYR, NPIP	traces-55	Non-fat milk powder	NDMA	0.1-3.7

12.2.7.3 Formation

12.2.7.3.1 N-Nitrosamines

Nitrosamines are formed by nitrosation of secondary amines and as volatile intermediates arise by nitrosation of primary and tertiary amines and quaternary ammonium salts in acidic media. Numerous precursors of nitrosamines, such as amino compounds containing a secondary amino group, are natural components of food (amines, amino acids, amino sugars, some vitamins, lipids, aromatic substances and other compounds). For example, the amino acids proline, histidine, tryptophan and sarcosine contain a secondary amino group in the molecule. Other secondary amines are formed from amino acids by decarboxylation catalysed by enzymes, in other enzymatic reactions and by thermal decomposition at temperature about 180 °C and higher. For example, histamine, tryptamine, putrescine and agmatine arise by decarboxylation of the parent amino acids, spermidine and spermine are produced from putrescine and tryptamine yields the hormone serotonine (see Figure 10.18). Various products of the Maillard reaction also include secondary amines, such as carbinolamines, glycosylamines, aminodeoxysugars (Amadori compounds), heterocyclic compounds such as pyrroles, imidazoles, oxazolines and others. Choline bound in phospholipids yields dimethylamine by degradation (see Section 3.8.3). Other secondary amines may get into food as contaminants.

Secondary amines

The general mechanism of nitrosation of secondary amines is shown in Figure 12.26. Nitrosation reagents are formed in acidic solutions from nitrous acid and nitrites, respectively, by a sequence of reactions indicated in Figure 12.27. Nitrites are present in foods as additives or contaminants. In foods and beverages obtained by fermentation, nitrites may arise by reduction of nitrates by microbial reductases. In beer, for example, wild yeasts partly assimilate nitrates to give ammonia, and the activity of nitrate reductase

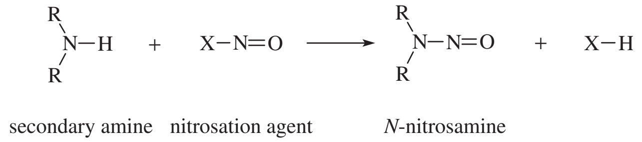

Figure 12.26 General mechanism of secondary amine nitrosation.

yields nitrites that are further reduced to ammonia by the action of ammonia nitrite reductase. Nitrates are also reduced to nitrites by some contaminating denitrifying bacteria. Nitrites are reduced to nitrous oxide (dinitrogen monoxide, N_2O) and nitric oxide (nitrogen monoxide, NO) by cytochrome cd_1-nitrite reductase, nitric oxide is reduced to nitrous oxide, from which elemental nitrogen arises by reduction, catalysed by reductases.

Effective nitrosation agents are the nitrosyl cation (NO^+), nitrogen oxides (dinitrogen trioxide, N_2O_3, and nitrogen dioxide, NO_2) or nitrosyl halogenides that are formed in the presence of hydrohalogen acids. The relative ratio or nitrosation agent depends on pH. In media with pH < 2, the predominant nitrosation agent is the nitrous acid cation ($H_2NO_2^+$) and nitrosyl cation (NO^+), respectively. At pH > 3, the main nitrosation agent is dinitrogen trioxide (N_2O_3). Both reagents are present in media with pH ranging from 2 to 5. Dinitrogen trioxide (N_2O_3) readily decomposes to dinitrogen monoxide (N_2O) and nitrogen monoxide (NO) and its dimer (N_2O_2), respectively. For example, at 25 °C and under atmospheric pressure, solutions contain equal amounts of both oxides and about 10% undissociated dinitrogen trioxide (N_2O_3). Nitrogen monoxide (NO) is also produced, together with nitrates, by disproportionation of nitrous acid:

$$3HNO_2 \rightarrow 2NO + H^+ + NO_3^- + H_2O$$

Dinitrogen monoxide (N_2O), formed by disproportionation of dinitrogen trioxide (N_2O_3), is easily oxidised by oxygen to nitrogen

dioxide (NO_2):

$$2NO + O_2 \rightarrow 2NO_2$$

Nitrosation reactions may be catalysed by and also inhibited in the presence of other substances (Figure 12.28, Y–N=O is a stronger nitrosation agent than X–N=O). Catalytic effects are exhibited, for example, by thiocyanate (SCN^-) and halide (iodides, bromides and chlorides) anions. The inhibitory effects have been reported for some inorganic and organic compounds that preferentially react with nitrosation agents and reduce them. In this way ascorbic acid inhibits nitrosamine formation (at concentrations of 500–1000 mg/kg) and tocopherols (at concentrations of 100–500 mg/kg). These vitamins, if used in combination, show a higher inhibitory effect than when applied individually. Inhibitory effects are also exhibited by other substances, such as sulfur dioxide, cysteine and glutathione.

For practical reasons, *N*-nitrosamines are divided into:

- volatile nitrosamines
- non-volatile nitrosamines.

Volatile nitrosamines are a group of relatively non-polar low molecular weight compounds, while non-volatile nitrosamines are polar compounds. The most common and also the most toxic volatile nitrosamine is *N*-nitrosodimethylamine, which is produced from dimethylamine, and via dimethylamine, from other amino compounds, such as sarcosine, creatine, trimethylamine and choline (Figure 12.29). In malt, the main precursors of dimethylamine are alkaloids hordenine and gramine, occurring, for example, in germinating barley. The concentration of dimethylnitrosamine in malt and beer depends on the conditions during barley germination and malt storage. Concentrations found in malt and beers in the past have been drastically reduced by introducing indirect heating during malt kilning.

Precursors of non-volatile, but also of certain volatile nitrosamines, are often amino acids and amino acid derived amines. It is estimated that *N*-nitrosoamino acids constitute about 1% of the total *N*-nitroso-compounds present in foodstuffs. For example, *N*-nitrososarcosine arises from sarcosine and also from creatine (Figure 12.29), proline yields *N*-nitrosoproline, and its decarboxylation gives *N*-nitrosopyrrolidine. *N*-Nitrosoproline also arises from ornithine. Similarly, *N*-nitrosopyrrolidine is produced from putrescine, spermidine and also from pyrrolidine, which is the product of proline decarboxylation (Figure 12.30). By the same sequence of reactions, *N*-nitroso-4-hydroxyproline arises from 4-hydroxyproline. Lysine and biogenic amine cadaverine give rise

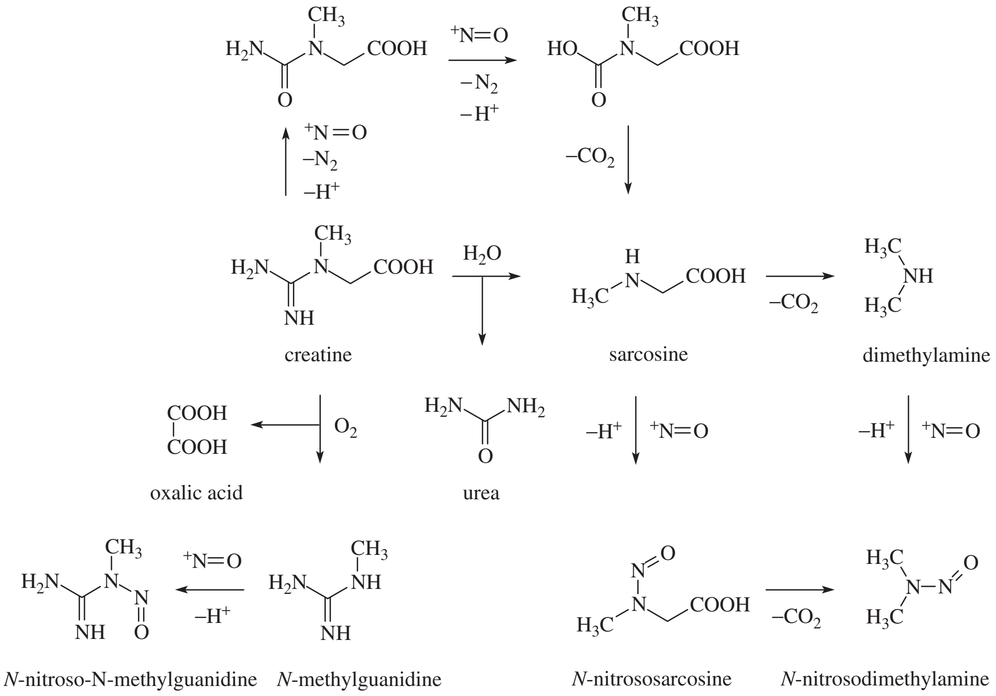

Figure 12.29 Formation of *N*-dimethylnitrosamine and other *N*-nitroso compounds from creatine and sarcosine.

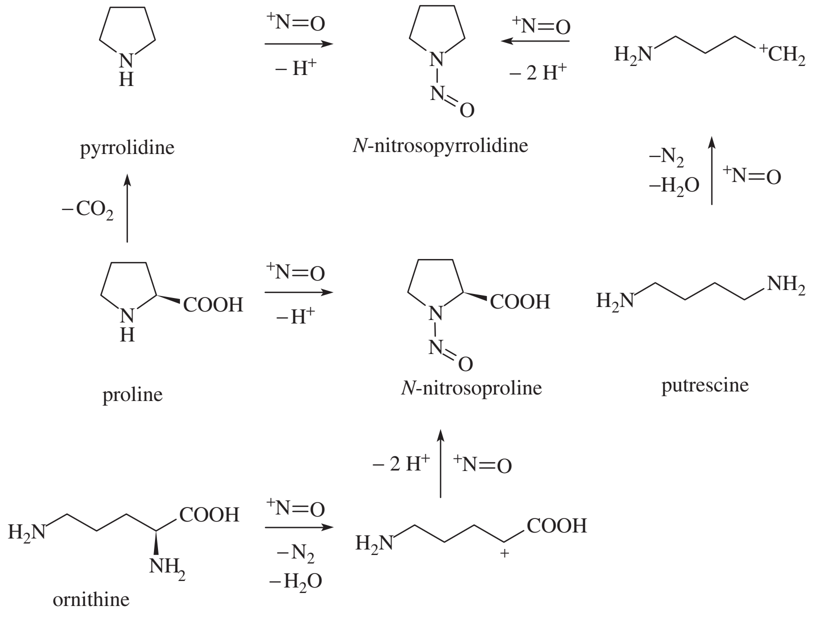

Figure 12.30 Formation of *N*-nitrosoproline and *N*-nitrosopyrrolidine.

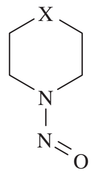
to *N*-nitrosopiperidine. *N*-Nitrosomorpholine (**12-76**) is formed from ethanolamine, which is a component of some phospholipids. Under certain conditions, nitrosation of diethanolamine, which is used in the manufacture of personal care products, yields *N*-nitrosodiethanolamine.



12-76, *N*-nitrosopiperidine, X = CH_2
N-nitrosomorpholine, X = O

Precursors of some non-volatile nitrosamines are formed in the Maillard reaction. For example, 4-thiazolidine carboxylic acid arises from cysteine and formaldehyde (Figure 12.31), which is a component of combustion gases and liquid smoke preparations, and is also produced by the Strecker degradation of glycine and by retroaldolisation of sugars (see Section 4.7.1.2.3). Nitrosation of 4-thiazolidine carboxylic acid then yields *N*-nitroso-4-thiazolidine carboxylic acid. 4-Thiazolidine carboxylic acids substituted at C-2 arise in reactions of cysteine, with higher aldehydes resulting from the Strecker degradation of certain amino acids or in degradation of sugars. Reaction with acetaldehyde, for example, yields 2-methyl-4-thiazolidine carboxylic acid and 2-hydroxymethyl-4-thiazolidine carboxylic acid is produced in a reaction with glycolaldehyde.

Non-volatile nitrosamines are likewise produced by nitrosation of *N*-alkylsubstituted guanidines and *N*-alkylsubstituted ureas. *N*-Methylguanidine, for example, occurs in fresh meat at concentrations of up to 10 mg/kg and also arises together with *N*-nitrosoguanidine by decomposition of creatine in the presence

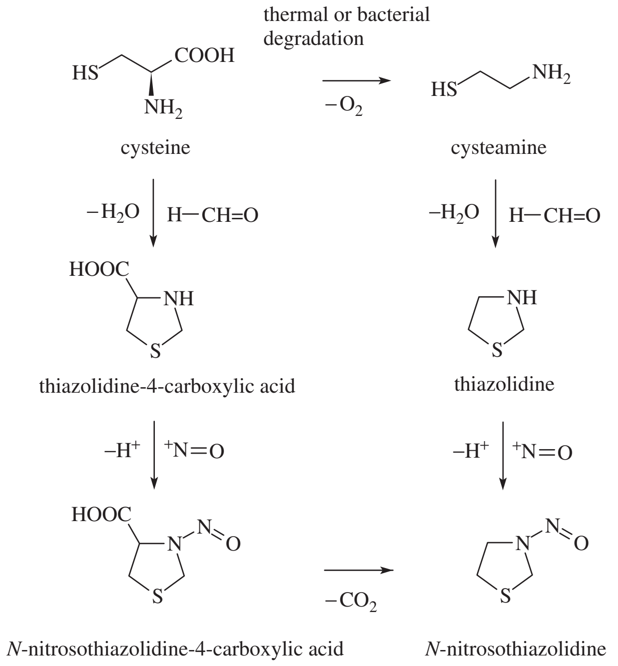


Figure 12.31 Formation of nitrosamines from cysteine.

of nitrites (Figure 12.29). Another example of *N*-substituted nitrosoguanidines is *N*-nitrosoagmatine (**12-77**) formed by nitrosation of agmatine, which is a product of arginine decarboxylation. In the meat of certain shellfish, agmatine occurs in concentrations of up to 200 mg/kg. Methyl-, propyl- and but-3-en-1-ylureas and the corresponding *N*-nitroso-*N*-alk(en)ylureas were found, for example, in fish and shellfish and ham. The key *N*-methylurea precursor is creatinine, which is present in fairly high

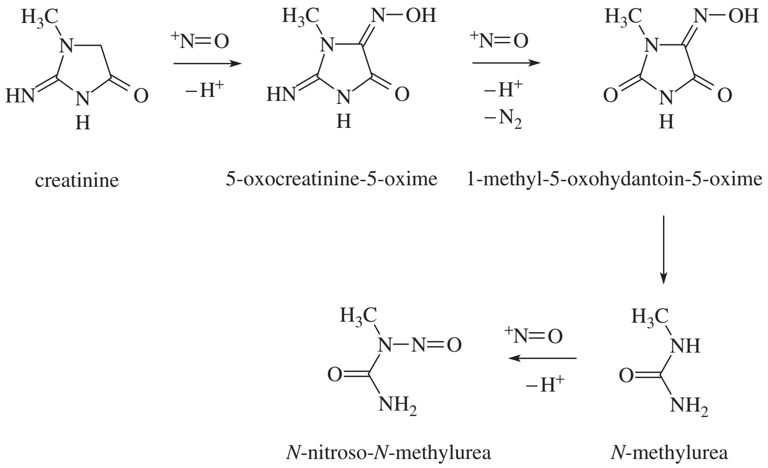

Figure 12.32 Nitrosation of creatinine.

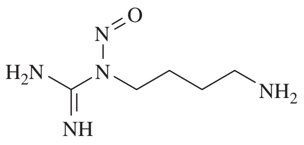
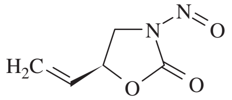
concentrations in meat, fish and seafoods and can be nitrosated to form traces of *N*-nitroso-*N*-methylurea (Figure 12.32) via 1-methyl-5-oxohydantoin-5-oxime. The optimum pH for *N*-nitroso-*N*-methylurea formation from creatinine ranges between pH 1 and pH 3. The step from 1-methyl-5-oxohydantoin-5-oxime to *N*-nitroso-*N*-methylurea is, however, not clear; 1-methyl-5-oxohydantoin-5-oxime might be nitrosated directly to *N*-nitroso-*N*-methylurea or indirectly via the intermediate formation of methylurea. *N*-Nitroso-*N*-methylurea is a potent carcinogen that has been shown to induce cancer of various organs, mainly of the forestomach, brain and the nervous system, in a wide variety of animal species. At gastric pH, small amounts of *N*-nitroso-*N*-methylurea (0–2.6 μg/kg) were formed from various cured meats and this amount increased with additional nitrite up to 17.6 μg/kg of meat. At gastric pH, *N*-nitroso-*N*-methylurea can also be produced in other foods, such as fish sauce, herring, shrimp, sardines, oysters, mussels and pickled vegetables.



12-77, *N*-nitrosoagmatine

Some nitrosamines are formed only in certain commodities. For example, goitrin present in cruciferous vegetables and rapeseeds results from the glucosinolate progoitrin by the action of myrosinase, and its nitrosation yields *N*-nitroso-5-vinyloxazolidin-2-one (**12-78**). During the burning of tobacco there similarly arise, in addition to common volatile nitrosamines (*N*-nitrosodimethylamine and its higher homologues), non-volatile nitrosamines, such as *N*-nitrosodiethanolamine and nitrosamines derived from nicotine and some other tobacco alkaloids. Examples of these nitrosamines are *N*-nitrosonornicotine (**12-79**), *N*-nitrosoanatabine (**12-80**), *N*-nitrosoanabasine (**12-81**) and 4-(methylnitrosamino)-1-(3-pyridyl)butan-1-one (**12-82**).



12-78, *N*-nitroso-5-vinyloxazolidin-2-one

Primary amines

Nitrous acid reacts with primary aliphatic amines in the presence of mineral acids with the formation of volatile nitrosamines, which isomerise to stable diazohydroxides. Diazohydroxides are split into nitrogen and a primary alkyl cation, which may partly isomerise to a secondary cation and both cations are eliminated, which yields the corresponding alkene. Substitution reactions then yield primary and secondary alcohols and symmetrical and unsymmetrical secondary amines. In the presence of hydrohalogen acids, both alkyl

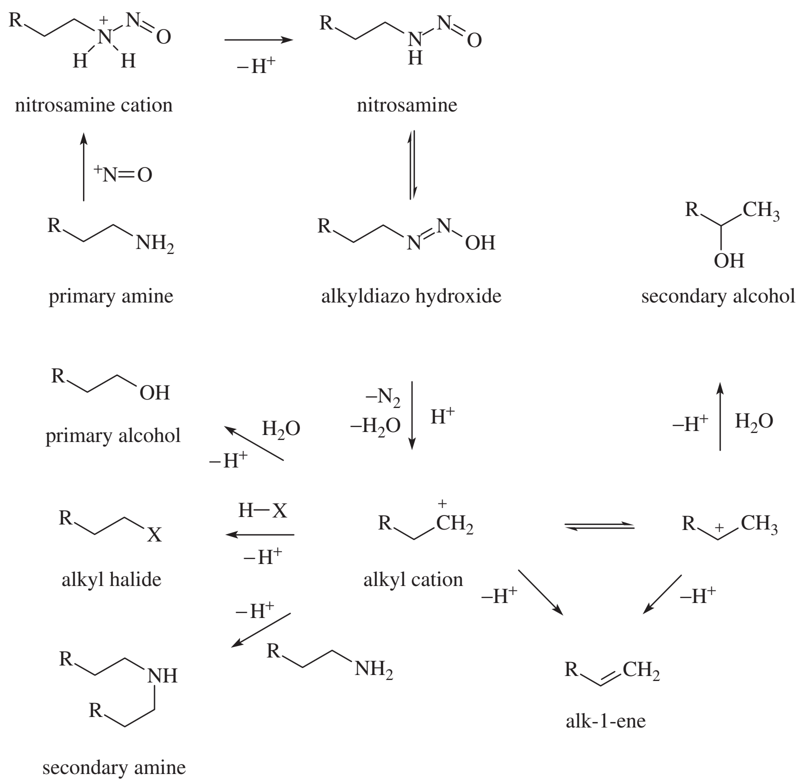

Figure 12.33 Reaction of primary amines with nitrous acid in acidic solutions.

halides are produced (Figure 12.33). Aromatic primary amines, which should however not be natural food components, yield by nitrosation diazonium salts $(Ar–N{=}N)^+ X^-$. In the absence of mineral acids, nitrous acid reacts with primary, secondary and tertiary aliphatic amines with the formation of nitrites. Secondary amines, for example, yield salts, the structure of which is $(R^1R^2NH_2)^+NO_2^-$.

Tertiary amines

Tertiary amines react with nitrous acid in the presence of mineral acids to form nitrosamine cations, which may be cleaved analogously as nitrosamines derived from primary amines to alkyl cations and the corresponding nitrosamines. Splitting of hyponitrous acid ($H_2N_2O_2$) yields the corresponding imine cation, which decomposes to an aldehyde and a secondary amine (Figure 12.34).

12.2.7.3.2 N-Nitrosamides

N-Substituted amides are produced in small amounts by heating carboxylic acids with amines. They are formed relatively easily from fatty acids or their esters (such as triacylglycerols) and amines. The reactivity of esters of fatty acids is greater than the reactivity of free fatty acids. At temperatures above 150 °C, amino acids also

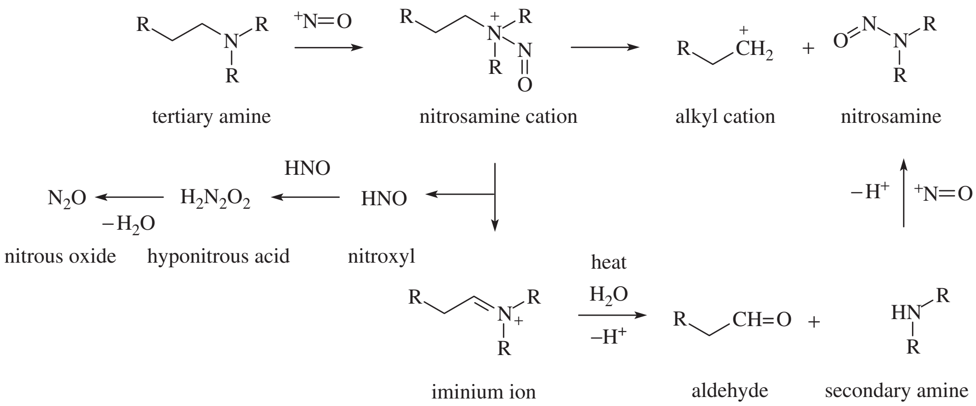

Figure 12.34 Reaction of tertiary amines with nitrous acid in acidic solutions.

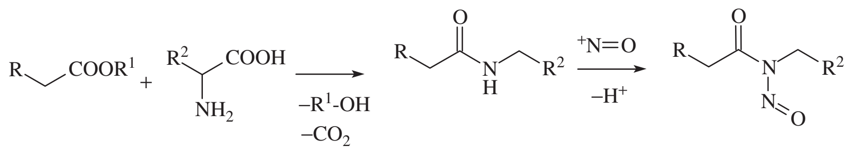

Figure 12.35 Formation of nitrosamides from amino acids and lipids.

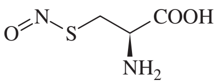
react to form amides. Nitrosamides are formed by nitrosation of *N*-substituted amides by the same mechanisms as *N*-nitrosamines from secondary amines (Figure 12.35).

12.2.7.3.3 S-, O- and C-Nitroso compounds

In addition to *N*-nitroso compounds, *S*-nitroso compounds are also formed in foods. The reaction of nitrite with the sulfhydryl group of free cysteine or protein-bound cysteine leads to the formation of mutagenic *S*-nitrosocysteine (**12-83**), which was found in meat and meat products containing nitrites. Nitrosothiols in meat, including *S*-nitrosocysteine, consume 3–12% of added nitrite. They show antimicrobial activity, participate in the development of the characteristic aroma of smoked meat and in transnitrosation reactions. For example, they react with myoglobin and yield nitroxymyoglobin (see Section 9.2.1.5.3).



12-83, *S*-nitrosocysteine

Less information is available on the occurrence of *C*-nitroso-compounds in foods. Stable compounds are derivatives in which the nitroso groups are bound to the tertiary carbon. Such a compound is, for example, the nitrosation product 3-deoxy-D-*erythro*-hexosulose, which is one of the major degradation products of glucose and other sugars (Figure 12.36).

Compounds with a nitroso group on the primary or secondary carbon irreversibly isomerise to isonitroso compounds that are oximes of aldehydes or ketones:

$$R–CH_2–N{=}O \rightarrow R–CH{=}N–OH$$
$$R^1R^2CH–N{=}O \rightarrow R^1R^2C{=}N–OH$$

Examples of such compounds are products of nitrosation of ketones arising from autoxidation of lipids. Their oximes and oxime decomposition products are flavour-active components of smoked meat. The reaction begins at the methylene group adjacent to the carbonyl group. The elimination of a proton provides a ketone anion that reacts with a nitrosyl cation to yield a *C*-nitroso compound that isomerises to oxime (Figure 12.37).

Another example is the nitrosation of creatinine in meat, by which 5-oxocreatinine-5-oxime and 1-methyl-5-oxohydantoin-5-oxime can arise (Figure 12.32). Some phenols also react with nitrosation reagents yielding nitroso compounds and oximes. In addition to nitroso compounds and oximes, in reactions with nitrosation agents there also arise nitro, oxynitro and nitronitroso compounds, as in the case of polycyclic aromatic hydrocarbons (PAHs). The mechanisms of their formation and other aspects of their presence in food are not yet sufficiently known. An example is the nitrosation of *p*-coumaric acid, which is dependent on pH. Acidic pH results in 4-hydroxybenzaldehyde (16%), 1′,4-dihydroxybenzeneacetaldehyde oxime (59%), 4-hydroxy-1′-oxobenzeneacetaldehyde oxime (26%) and 7-hydroxy-1,2(4*H*)-benzoxazin-4-one (6%), whereas 4-(2-oxido-1,2,5-oxadiazol-3-yl)phenol was formed at acidic (6%) and neutral and alkaline pH (both 1%) (Figure 12.38).

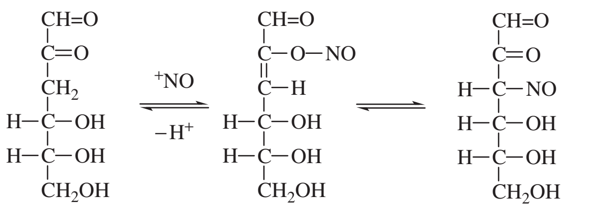


Figure 12.36 Nitrosation of 3-deoxy-D-*erythro*-hexosulose.

12.2.7.4 Health and toxicological assessment

Although food and tobacco products are important sources of external exposure to *N*-nitrosamines, exposure also occurs from nitrosamines produced internally in the digestive tract. About 5% of ingested nitrates are reduced to nitrites in saliva. These nitrites can subsequently react with secondary and tertiary amines, as well as *N*-substituted amides, carbamates and other related compounds, to form *N*-nitroso compounds within the gastrointestinal tract. This internal formation is a major source of human exposure to *N*-nitrosamines.

N-Nitrosamines exhibit mutagenic, teratogenic and mainly carcinogenic effects. Carcinogenicity has been demonstrated in various organs of a number of animals. Many nitrosamines were classified by the IARC as Groups 2A or 2B carcinogens. The synergistic effect of *N*-nitrosamines taken in with other carcinogenic compounds has also been demonstrated. EFSA are discussing the benefits of eating vegetables, especially leafy vegetables with a higher content of nitrates, and the risk of nitrosamine formation *in vivo*. In a similar context, the antimicrobial protection against bacteria *Clostridium botulinum* in certain meat products by added nitrites is being evaluated. In general, reducing the levels of nitrites to the minimum necessary amount seems to be an appropriate strategy for limiting the exposure of consumers to nitrosamines. In terms of chemical safety, it is also necessary to monitor and possibly eliminate the

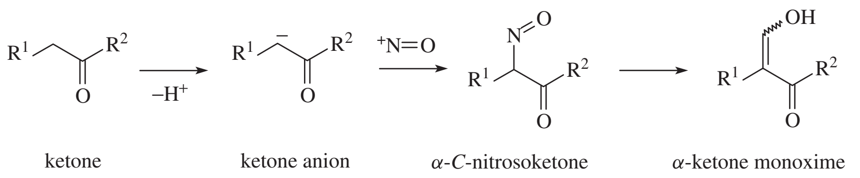

Figure 12.37 Formation of oximes from ketones.

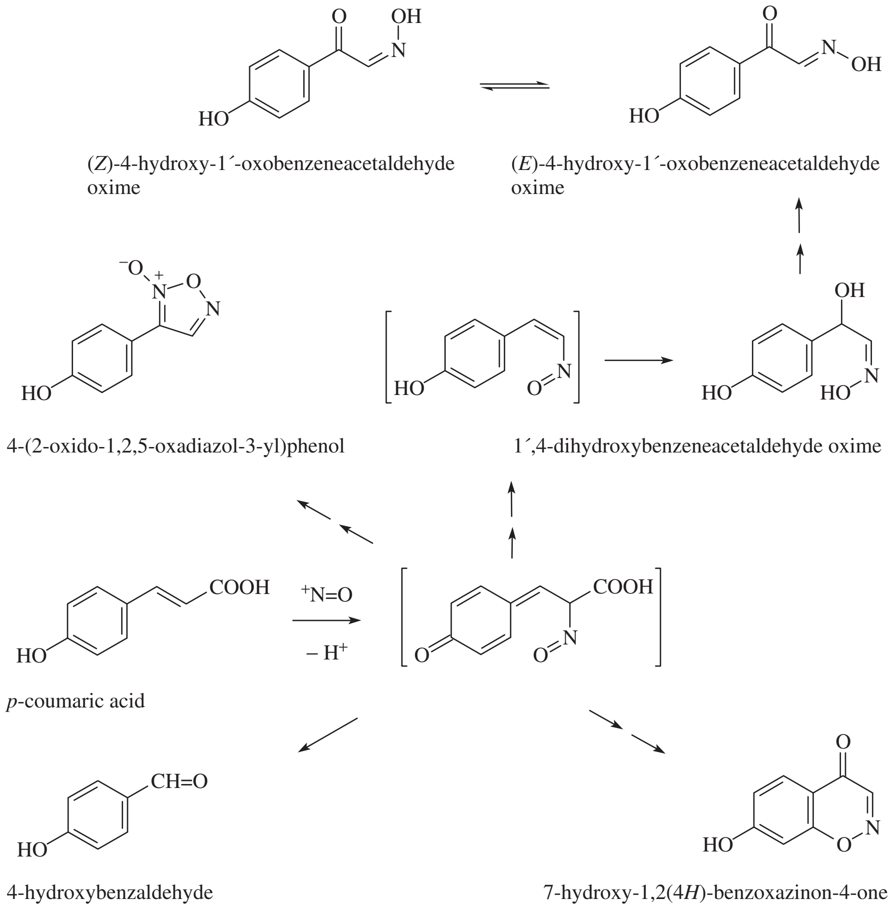

Figure 12.38 Nitrosation of *p*-coumaric acid.

migration of nitrosamines from food packaging and other contact materials.

At present, maximum levels of nitrosamines in foods are set only for beer in some EU member states, which stipulate that beer may contain up to 0.5 μg/l of *N*-nitrosodimethylamine and the sum of nitrosamines including *N*-nitrosodimethylamine, *N*-nitrosodiethylamine, *N*-nitrosodibutylamine, *N*-nitrosopyrrolidine, *N*-nitrosopiperidine and *N*-nitrosomorpholine must not exceed 0.0015 mg/l. Action levels for *N*-nitrosodimethylamine in barley malt and malt beverages range from 5 to 10 μg/l. In other foods, nitrosamines have not been limited since 2004. Within the EU, legislation also exists for infants' teats and soothers (Commission Directive 93/11/EEC), which limits total *N*-nitrosamines to 10 μg/kg and nitrosatable materials to 200 μg/kg. Annexes II and III of the European Cosmetic Directive 76/768/EEC specify that nitrosamine contamination or *N*-nitrosodiethanolamine contamination must not be present in health and beauty care products or cosmetics in amounts exceeding 10 μg/kg.

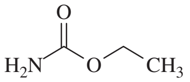
12.2.7.5 Mitigation

The formation of nitroso compounds in foods can be successfully controlled by reducing the concentration of added nitrite, drying foods by indirect heating, using substances that inhibit nitrosation (such as ascorbic acid and tocopherols) and by suitable changes to the technological processes (lowering the temperature during processing). For example, the technological modification of drying malt indirectly instead of directly by combustion gases, leads to a significant reduction in the content of volatile nitrosamines in beer.

12.2.8 Ethyl carbamate

12.2.8.1 Structure and nomenclature

The presence of toxic carbamic acid ethyl ester (ethyl carbamate, also called urethane, **12-84**) in fermented food products was first observed in 1976. The Canadian authorities first drew attention to this fact in 1985, when they carried out an extensive inspection of spirits imported from Europe. The ethyl carbamate level was restricted to 30 μg/kg in table wines, 100 μg/kg in fortified wines, 150 μg/kg in distilled spirits and 400 μg/kg in fruit brandies and liqueurs. These guidelines have been used as a reference in other countries, which do not have a specific legislation on this issue.



12-84, ethyl carbamate

12.2.8.2 Occurrence, main sources and dietary intake

Concentrations of ethyl carbamate in bread, yoghurt, soy sauce, beer or wine generally reach tens of μg/kg. Substantially higher amounts of ethyl carbamate can be encountered in alcoholic beverages, especially in spirits made from stone fruits, which in rare cases can contain thousands of μg/l of ethyl carbamate. The output from the latest EU study is presented in Table 12.20.

12.2.8.3 Formation

High amounts of ethyl carbamate in some beverages were first explained by the use of diethyl dicarbonate, which was permitted as a preservative at that time (see Section 11.2.1.2.6). Findings of ethyl carbamate in products that were not stabilised with diethyl dicarbonate highlighted a number of other mechanisms of its formation. Research in the follow-up period showed that the main

[a] nd = not determined (under the limit of detection).

precursors of ethyl carbamate in fermented foods were cyanides, urea, citrulline and carbamoyl phosphate.

12.2.8.3.1 Formation from cyanides

In distilled spirits, especially stone fruit spirits, ethyl carbamate is formed via reaction of ethanol with cyanides, and correspondingly isocyanate ions that are byproducts from the degradation of cyanogenic glycosides. Cyanide ions released from cyanogenic glycosides, either enzymatically or thermally, are undoubtedly the most important dietary precursors of ethyl carbamate in distillates. Cyanogenic glycosides are substances present in many food products. Examples of cyanogenic glycosides (see **10-73**) are amygdalin and prunasin occurring in stone fruits (cherries, apricots and plums) and epiheterodendrin, which is found in barley. Cyanogenic glycosides also occur in sugar cane, but their structure has not yet been precisely described. Although it can be assumed that ethyl carbamate may be formed during the fermentation of stone fruits, the transition of ethyl carbamate to the distillate is not very significant due to its low volatility (relatively high boiling point of 185 °C). A substantial proportion of ethyl carbamate in distillates arises by photochemical reactions. The most efficient light is that with wavelengths of 350–425 nm. In addition to the amount of precursors present, light exposure, temperature, pH and the presence of certain other compounds are the main factors influencing the formation of ethyl carbamate in distilled spirits during storage and transport.

It is supposed that the main reaction is the oxidation of cyanides, released from cyanogenic glycosides, to cyanates that may isomerise to isocyanates:

$$2N{\equiv}C^- + O_2 \rightarrow 2\ N{\equiv}C{-}O^- \leftrightarrow 2\ O{=}C{=}N^-$$

The reaction is effectively catalysed by divalent copper ions, which are often released from the distillation apparatus. By another reaction copper cyanate is produced, and nucleophilic addition of water gives rise to copper carbamate, which provides ethyl carbamate by alcoholysis or decomposes to copper hydroxide, carbon dioxide and ammonia.

$$\begin{aligned}
2C{\equiv}N^- + 4HO^- + 4Cu^{2+} &\rightarrow 2N{\equiv}C{-}O^- + 4Cu^+ \\
&\quad + 2H_2O \\
Cu^{2+} + 2N{\equiv}C{-}O^- &\rightarrow Cu(O{=}C{=}N)_2 \\
Cu(O{=}C{=}N)_2 + 2H_2O &\rightarrow Cu[O(O{=}C)NH_2]_2 \\
Cu[O(O{=}C)NH_2]_2 + 2CH_3CH_2OH &\rightarrow 2CH_3CH_2OC({=}O)NH_2 \\
&\quad + Cu(OH)_2 \\
Cu[O(O{=}C)NH_2]_2 + 2H_2O &\rightarrow Cu(OH)_2 + 2CO_2 \\
&\quad + NH_3
\end{aligned}$$

Ethyl carbamate can also be produced in small quantities by other reactions, for example from vicinal dicarbonyl compounds, such as methylglyoxal, biacetyl and pentane-2,3-dione, which are byproducts of fermentation (see Section 8.2.2.1.3). Some dicarbonyl compounds may arise by fragmentation of sugars.

12.2.8.3.2 Formation from N-carbamoyl compounds

Ethyl carbamate precursors in wine, beer, yoghurt and some other fermentation products are mainly *N*-carbamoyl compounds, such as urea (carbamide) and citrulline, which are the result of catabolic processes in yeasts and bacteria from arginine, an amino acid abundantly represented in grapes. As a result of the cleavage of urea from arginine through the action of arginase in yeasts and bacteria, ornithine and urea are produced, and the product of catabolism of arginine (by arginine deiminase) in lactic acid bacteria is citrulline.

Ethyl carbamate in wine is formed (mostly at the end of fermentation) from urea. The intermediates of its degradation are probably cyanates and cyanic acid (HO–C≡N), also known as hydrogen cyanate, which may isomerise to isocyanic acid (H–N=C=O). Isocyanic acid can also arise by protonation of the cyanate anion and nucleophilic addition of ethanol to isocyanic acid yields ethyl carbamate. Isocyanic acid also reacts with other nucleophilic reagents, such as water (with formation of ammonia and carbon dioxide), thiols and amino groups of proteins. By catalysis with ornithinecarbamoyl transferase, citrulline is transformed into ornithine and carbamoyl phosphate, the ethanolysis of which yields ethyl carbamate (Figure 12.39).

Azodicarbonamide, used as a blowing agent in beer bottle cap liners and as a bread improver, has also been suggested as an ethyl carbamate precursor.

12.2.8.4 Health and toxicological assessment

Ethyl carbamate is characterised by a broad spectrum of biological effects. Even in the 1940s, ethyl carbamate was used as an anaesthetic substance, which was particularly suitable for children, as it acts on the central nervous system and has sedative effects similar to those of barbiturates. At the beginning of the 1940s, however, reports also appeared of ethyl carbamate's carcinogenicity. In 2007, the International Agency for research on Cancer (IARC) reassessed ethyl carbamate and up-graded its classification from Group 2B to group 2A.[3] The current tolerable daily intake (TDI) is 20 ng/kg body weight, which corresponds (in the case of a person weighing 70 kg) to an annual intake of 520 μg. This value could easily be exceeded in some population groups (consumers of higher amounts of alcohol).

At present, there is no international standard for the maximum allowable level of ethyl carbamate in foods. However, some countries, such as Canada, Korea and some member states of the EU (such as France, Germany and Czech Republic) have established maximum levels of ethyl carbamate in alcoholic beverages. In the Czech Republic, for example, the limit for the content of ethyl carbamate in fruit spirits is 0.4 mg/l) and for other spirits and wines the maximum level of ethyl carbamate is lower by one order of magnitude.

Toxicological studies have shown that nearly 90% of orally received ethyl carbamate is excreted as carbon dioxide by the action of cytochrome P450 oxidase complex. In the minor pathway, illustrated in Figure 12.40, however, ethyl *N*-hydroxycarbamate, vinyl carbamate and oxiran-2-yl carbamate arise as minor products,

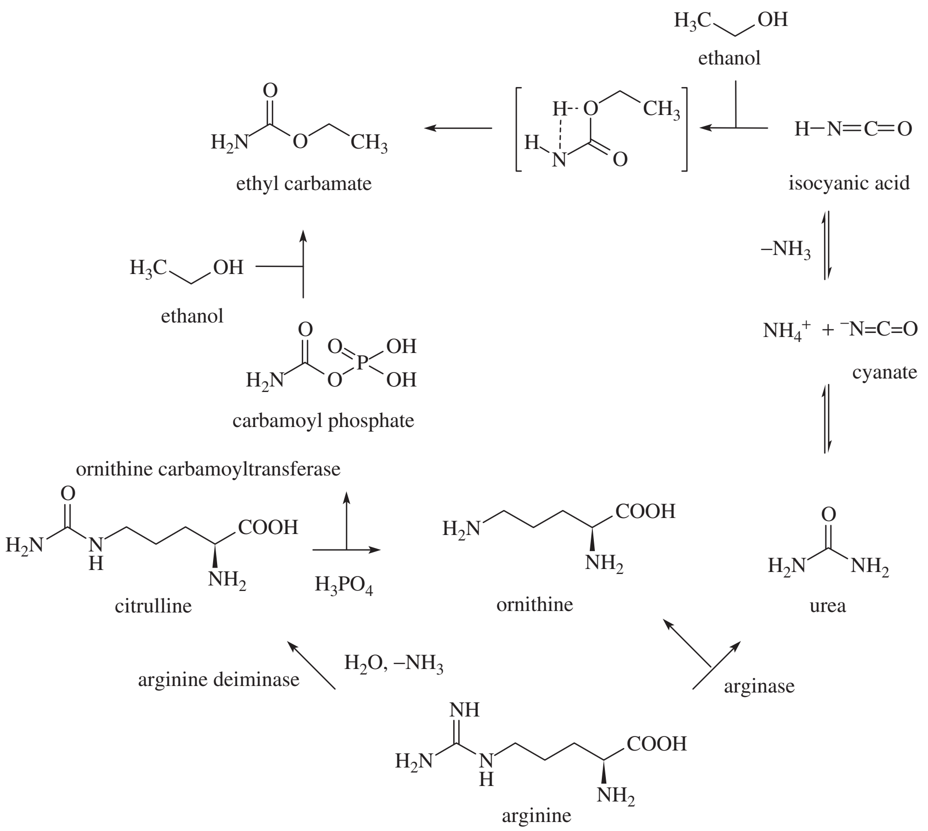

Figure 12.39 Formation of ethyl carbamate from *N*-carbamoyl compounds.

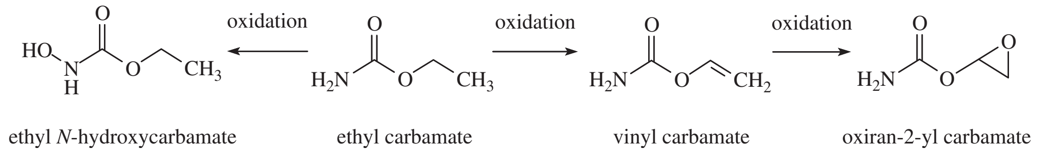

Figure 12.40 Metabolic activation of ethyl carbamate.

which are responsible for the genotoxic and carcinogenic effects of ethyl carbamate.

12.2.8.5 Mitigation

The joint FAO/WHO Expert Committee on Food Additives (JECFA) evaluated ethyl carbamate in 2005 and concluded that its intake from foods, including alcoholic beverages, would be of little concern. However, dietary exposure of ethyl carbamate from both food and alcoholic beverages was of concern, and measures to reduce its concentrations in some alcoholic beverages were recommended. Preventive measures in the production of distilled spirits (such as whisky and stone fruit spirits) are based on the reduction of the amount of cyanogenic glycosides. It is therefore recommended to use low cyanogen barley varieties, fruit which has had the stones removed, or to minimise the mechanical damage to the stones and seeds. Even for small distilleries, simple options like fruit destoning exist to minimise the ethyl carbamate content. It is also recommended that the first fraction of distillate containing greater amounts of isocyanic acid is not used. After exposure of spirits in clear glass bottles to solar radiation, maximum concentrations of urethane are reached in about 2 days, therefore measures should be taken to prevent products from light exposure, for example, by using proper containers and covering boxes. Other possibilities of reducing the levels of ethyl carbamate include special copper catalysts added to the mash or in front of the dephlegmators in conventional distillation equipment.

One possibility for the production of wines is the use of genetically modified *Saccharomyces cerevisiae* yeast with low arginase activity, which are able to metabolise urea or to use the enzyme urease that catalyses the hydrolysis of urea into carbon dioxide and ammonia. Urea cannot be used as a nitrogen source. In the case of malolactic fermentation, the use of pure *Oenococcus oeni* yeast cultures is recommended. Generally, it is recommended to keep the temperature in the range of 18–25 °C during fermentation, or to use a lower pH value, which increases during fermentation due to generated ammonia. Special care should be taken to minimise heat

exposure by maintaining the correct cold temperature, preferably at or below 20 °C, and critically not above 38 °C, along the chain from production through shipment to storage and retail.

12.3 Microbial toxins

Over the last 20 years, at least in the industrialised world, food-borne diseases caused by fungi, bacteria, parasites, viruses and prions have generated substantial media attention (such as Bovine Spongiform Encephalopathy, BSE, in cattle caused by a specific type of misfolded proteins called prions, which is a neurological disease commonly known as 'mad cow disease').

Microorganisms invading food raw materials and foods and occurring under adverse circumstances in ready-to-eat meals can cause various health problems. According to the nature of the agent and mechanism of its action, food borne diseases are divided into infections (toxo infections) and poisoning (intoxications). Studies of intestinal infectious diseases indicate that between 50 and 60% of all causative agents are unidentified. The following sections deal only with toxic metabolites of microscopic filamentous fungi known as **mycotoxins** and with bacterial toxins called **bacteriotoxins**. The inherent vegetative forms of microorganisms or their spores do not constitute a health hazard.

12.3.1 Mycotoxins

Mycotoxins are toxic secondary metabolites produced by toxinogennic fungal species (microscopic filamentous fungi, also known as moulds), multicellular, eukaryotic, heterotrophic, saprophytic or parasitic microorganisms, which, together with yeasts (estimated to be 1% of all fungal species) are a group of microscopic fungi. Microscopic fungi belong to 6000 genera with 64 000 species out of about 100 000 fungi. In medical and veterinary mycology about 150 species of microscopic pathogenic fungi are known, and in foods 114 fungal and 12 yeast species have been characterised. Of the total number of 114 species that are of importance in foods, 65 species are toxinogenic. Mycotoxins are produced by vegetative parts of fungi known as mycelia and secreted into the substrate, but can also occur in the reproductive structure – spores that contaminate the human environment. Poisoning associated with exposure to mycotoxins in food and feed is demonstrated by various symptoms, known collectively as **mycotoxicoses**. The symptoms of a mycotoxicosis depend on the type of mycotoxins, its concentration and length of exposure, as well as age, health and sex of the exposed individual. Mycotoxicoses can be categorised as acute or chronic. Acute toxicity generally has a rapid onset and an obvious toxic response. Chronic toxicity is characterised by low-dose exposure over a long time period, resulting in cancers and other generally irreversible effects. Mycotoxins, in view of their ubiquity, can occur at virtually all levels of the food chain of humans and livestock.

Of nearly 1000 known mycotoxins, more than 300 have been at least partially characterised, and approximately 20 of them can occur in food or feed in toxicologically relevant concentrations. To ensure the protection of consumer and livestock health, the maximum concentrations for these mycotoxins were set (or a determination based on available data is considered) in selected food commodities. According to FAO estimates, contamination by mycotoxins in up to 25% of food consumed can be demonstrated, and more severe levels of contamination can be found particularly in developing countries. It should be noted that the negative health effects resulting from dietary intake of mouldy food has occurred for as long as the human race has existed, especially since humans left the nomadic way of life and began to grow different crops and store surpluses. The oldest described mycotoxicosis is ergotism, induced by metabolites (alkaloids) of ascomycetes known as ergot fungi, the prominent member of which is the fungus *Claviceps purpurea* that grows on rye and related plants. Another mycotoxicosis is alimentary toxic alexia (ATA), which is induced by T-2 toxin, and related trichothecenes, produced by fungi of the genus *Fusarium* and by certain other fungi. Consumption of these mycotoxins can result in alimentary haemorrhage and vomiting, and direct contact causes dermatitis. The so-called yellow rice disease is caused by fungi of the genus *Penicillium* (e.g. *P. citreonigrum*), which produces the causative agent yellow mycotoxin citreoviridin and another mycotoxin called citrinin. The symptoms in the latter stages of this disease are characterised by hypothermia, flaccid paralysis and cardiovascular disturbances. A systematic study of mycotoxins was initiated by increased signs of dangerous mouldy food and feed in the 1960s. The major impetus for the research focused on mycotoxins was an event that took place in 1960 in Great Britain, where there was a series of mass deaths of about 120 000 turkeys and other poultry. Investigations demonstrated a correlation with the birds having been fed mouldy feed (peanut meal). The causative agents of the intoxication were identified as then-unknown fungal toxins that were called aflatoxins (from the Latin name of the fungus, *Aspergillus flavus*).

Despite intensive worldwide research on mycotoxins, many questions still remain open. Finding an effective long-term strategy to prevent or at least minimise the formation of these toxic contaminants in the process of growing and storing agricultural crops (food raw materials) is one of the key objectives of the ongoing studies. Reduction of risks to the consumer (and livestock) of dietary exposure to mycotoxins, as in the case of other pollutants, begins on the farm. Evaluation of the bioavailability and overall toxicological significance of mycotoxins and their conjugated forms can significantly contribute not only to a comprehensive assessment of health risks to humans, but also to a deeper understanding of mycotoxicoses in farm animals.

12.3.1.1 Classification

Mycotoxins are an extremely diverse group of compounds. Their relative molecular weight usually does not exceed 1000 Da. Just as is the case for other secondary metabolites, mycotoxins cannot be simply classified into groups of compounds on the basis of their chemical structure, without consideration of their occurrence, producers or the nature and intensity of the induced toxic effects. Production of mycotoxins by toxinogenic fungi is subject to a number of factors. Under certain conditions, mycotoxins may

not be produced at all, as not all strains of potentially toxic fungi are toxinogenic. A specific mycotoxin can also be produced by representatives of several genera of fungi, and two or more mycotoxins can be produced by one fungal species.

The natural criterion for classification of mycotoxins is the mechanism for the biosynthesis of their basic skeleton from primary metabolites, which are their precursors. A number of important mycotoxins are biosynthesised by the so-called polyketide pathway, specifically patulin, penicillic acid (tetraketides), ochratoxin A and citrinin (pentaketides), zearalenone (nonaketide) or sterigmatocystin and aflatoxins (decaketides). The intermediate directly involved in the biosynthesis of the polyketide is acetyl coenzyme A, which acts in the metabolism of fatty acids and other compounds. The second major pathway of biosynthesis of mycotoxins starts with mevalonic acid. From this intermediate are formed trichothecene mycotoxins containing sesquiterpenic skeletons in their molecules. For completeness, other metabolic pathways should be mentioned, which play a role in the biosynthesis of some of the less common fungal metabolites. Amino acids are biochemical precursors of cyclic polypeptides such as ergot alkaloids and others. So-called tremorgenic mycotoxins, a typical example of which is roquefortine C, are formed by the reaction of amino acids with mevalonate. Reactions similar to reactions of the Krebs cycle yield the so-called nonadrides, examples of which are rubratoxins.

The most important producers of toxicologically relevant mycotoxins are microscopic filamentous fungi of the genera *Aspergillus*, *Penicillium* and *Fusarium*. Examples are shown in Table 12.21. Some currently monitored mycotoxins are also produced by representatives of the genera *Claviceps*, *Alternaria*, *Chaetomium* and *Sordaria*.

Table 12.21 Examples of most important mycotoxins produced by fungi of genera *Aspergillus*, *Penicillium* and *Fusarium*.

Fungus	Dominant toxic secondary metabolites
Aspergillus spp.	
A. carneus	Citrinin
A. clavanus	Patulin
A. flavus	Aflatoxins B_1 a B_2, cyclopiazonic acid
A. ochraceus	Ochratoxins, penicillic acid
A. oryzae	Cyclopiazonic acid
A. parasiticus	Aflatoxins B_1, B_2, G_1,G_2
A. tereus	Citreoviridin, citrinin, patulin
A. tamarii	Cyclopiazonic acid
A. versicolor	Sterigmatocystin, cyclopiazonic acid
Penicillium spp.	
P. aurantiogriseum	Cyclopiazonic acid, penicillic acid
P. camemberti	Cyclopiazonic acid
P. chrysogenum	Cyclopiazonic acid
P. citreonigrum	Citreoviridin

F. anthopilum	Moniliformin
F. avenaceum	Moniliformin
F. chlamydosporium	Moniliformin
F. crookwellense	Deoxynivalenol, nivalenol, zearalenone
F. culmorum	Fusarin C, deoxynivalenol, nivalenol, zearalenone
F. graminearum	Deoxynivalenol, diacetoxyscirpenol, zearalenone
F. verticillioides	Fumonisins, fusarin C, moniliformin

12.3.1.2 Occurrence

Contamination of foods can occur at all stages of its production. Figure 12.41 shows the dissemination of mycotoxins in human and animal food chains and possibilities of their further fate. Contamination of food can occur especially in cases of non-compliance of requirements for safety control of fungal cultures specifically used in various food and biotechnological processes. A comprehensive list of dietary exposure sources is as follows:

- foods of plant origin in the case of preharvest primary infection and preharvest contamination of crops and products (especially cereals, oilseeds, fruits and vegetables, often dried products and nuts), contamination of final products (secondary infection);
- food of animal origin where the animals are fed contaminated feed (milk and dairy products, meat and meat products);
- food where cultural microscopic filamentous fungi (blue cheese, fermented meat products, fermented oriental soy and other plant products) are used in the manufacture;
- biotechnology products consumed as food additives, aids or supplements (microbial proteins, technical enzymes, amino acids concentrates, vitamins and other substances).

Table 12.21 (*continued*)

Fungus	Dominant toxic secondary metabolites
F. oxysporum	Moniliformin, T-2 toxin
F. poae	Fusarin C, diacetoxyscirpenol, monoacetoxyscirpenol, HT-2 toxin, T-2 toxin, zearalenone
F. sambucinum	Fusarin C, diacetoxyscirpenol, monoacetoxyscirpenol, HT-2 toxin, T-2 toxin
F. semitectum	Moniliformin, zearalenon, fusarenone-X
F. sporotrichioides	Diacetoxyscirpenol, HT-2 toxin, T-2 toxin, zearalenone
F. tricinctum	Fusarin C

Factors affecting the extent of potential (primary) mycotoxin contamination of agricultural crops under field conditions in the preharvest period are summarised as follows:

- cultivar resistance to attack by fungi;
- degree of physiological stress to which the plants are exposed (lack of minerals, small or excessive amounts of water, soil salinity, pollution, mechanical damage caused by the attack of insects or other pests);
- virulence of pathogenic fungi;
- type of mycotoxin produced (mechanism of its biosynthesis);
- phase of plant growth cycle, in which the plant was infected by fungi and the interval between the onset of a period of mycotoxin production and harvest;
- ability of plants (enzyme systems) to transform mycotoxins into non-toxic products.

An important role in terms of the intensity of mycotoxin formation is also played by climatic conditions in the preharvest period. The production of mycotoxins is promoted especially by precipitation (high relative humidity) in the later stages of crop ripening. Increased incidence of the occurrence of toxic secondary metabolites in harvested crops can be expected, especially when several factors favourable to the growth of fungi occur at the same time. In addition to fungi of genera *Fusarium* and *Claviceps* requiring relatively high humidity, cultured plants can also be infected in the period before the harvest by toxinogenic representatives of the genera *Aspergillus* and *Alternaria* and possibly likewise by fungi of genera *Chaetomium* and *Sordaria*. Even in the preharvest period, during transport, processing or storage, contamination of plant products is also possible. Producers of mycotoxin in this case can be, in particular, fungi of genera *Aspergillus* and *Penicillium*, which can grow with lower water activity in the environment. The following aspects are crucial:

- **biological properties** of the given organism, presence of competitive microflora and inoculum size;
- **chemical properties** of the substrate, its composition, presence of substances with fungicidal activity;
- **physical properties**, temperature, water activity, atmospheric composition, adequate access of light.

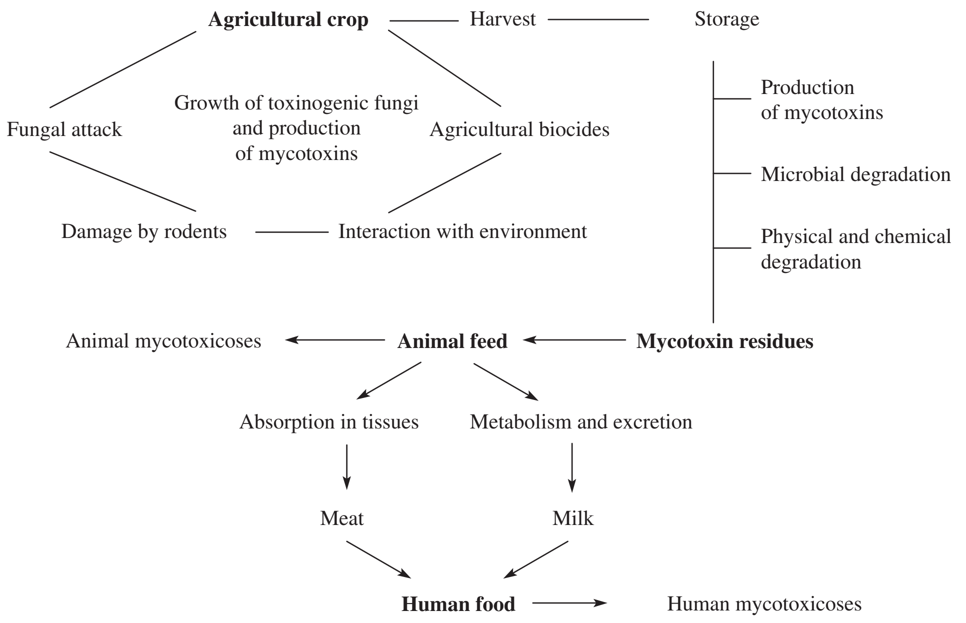

Figure 12.41 Factors influencing occurrence of mycotoxins in foods and feeds.

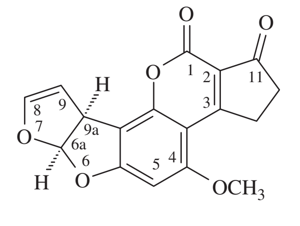
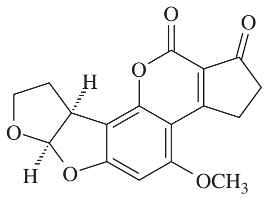
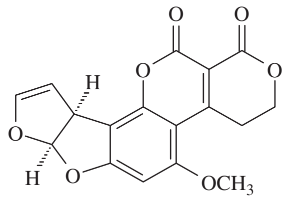
A critical factor limiting the growth of fungi during storage of agricultural crops is the content of available water. The outer layers of grains are a natural barrier to fungi. If the layers are damaged during harvest, transport or processing, mould spores can easily access the necessary nutrients for their growth, which are contained in the inner parts of the grains. Generally, smaller cereal grains (such as wheat, barley or rice) are less often attacked by fungi than larger grains, such as maize.



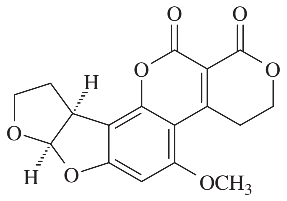
12-85, aflatoxin B_1



12-86, aflatoxin B_2



12-87, aflatoxin G_1



12-88, aflatoxin G_2

12.3.1.2.1 Major mycotoxin groups

Mycotoxins in the following sections are not sorted by their producers, but according to their structures related to toxic effects. It is obvious that some toxic secondary metabolites are produced by several types of filamentous fungi (Table 12.21).

Aflatoxins

Aflatoxins belong to the most often monitored mycotoxins, because of their high toxicity. The most important producers of aflatoxins are two closely related fungi of the genus *Aspergillus*, *A. flavus* and *A. parasiticus*. A rarer producer of aflatoxin is *A. nomius*. Their mycelia grow, under favourable conditions (temperatures between 13 and 37 °C and water activity <0.82) on virtually any substrate; however the highest amounts of aflatoxins (in some cases hundreds of thousands of mg/kg) were observed in maize, peanuts, pistachios, Brazil nuts, cottonseed and copra. Lower levels of aflatoxins are found in almonds, pecans, walnuts, raisins, figs and various spices. As evidenced by the Rapid Alert System for Food and Feed (RASFF), aflatoxins represent the contaminants most often found in the control of food imported into the EU (most often nuts and nut products). In 2007, of 754 notifications of aflatoxins in RASFF, 556 were related to nuts and nut products. In 2008 there was a further increase to 910 notifications, of which 710 were related to nuts. Also of concern is the increasing proportion of contaminated cereals, which are key items in the food basket in Europe and many other areas. This negative trend may, *inter alia*, indicate the impact of climate change (global warming) and the related development of pathogenic fungi, which require higher temperatures for their growth.

Currently 16 natural aflatoxins are known. Formulae **12-85** to **12-88** show the four major naturally occurring representatives of the B and G groups of aflatoxins, which are known as aflatoxins B_1, B_2, G_1 and G_2. The designation B (blue) or G (green) is associated with fluorescence of aflatoxins under UV light. While *Aspergillus flavus* produces mainly aflatoxins B_1 and B_2, contamination by *A. parasiticus* leads to aflatoxins G_1 and G_2 in the contaminated substrate. The basis of skeletons of all aflatoxins is coumarin condensed with bisdihydrofurofuran (dihydrobisfuran) and cyclopentanone in the first two aflatoxins, while the other two substances contain 5,6-dihydropyran-2-one instead of cyclopentanone.

Aflatoxin B_1, the chemical name for which is (6a*R*,9a*S*)-2,3,6a,9a-tetrahydro-4-methoxy-cyclopenta[*c*]furo[3′,2′:4,5]furo[2,3-*h*]-benzopyran-1,11-dione (**12-85**), is the main representative of this group of mycotoxins in contaminated food. Their total content (the sum of the four major aflatoxins) is on average higher by 24%, but the variability for different categories of foods is large (2–70%). Pistachios and Brazil nuts have a distinctly different spectrum of aflatoxins, with significantly higher average findings. Distribution of aflatoxins in contaminated commodities is very uneven, with the highest concentration often found in foci of high humidity, or in areas of mechanical damage to the plant material. Discoveries of aflatoxins have a distinct log-normal distribution, with a large number of positive findings in the area of low concentration and a small proportion of extremely contaminated samples.

Similarly to other xenobiotics, in animal organisms biotransformation of aflatoxins proceeds in three main stages (mainly in the liver): bioactivation, conjugation and deconjugation. Phase I of the biotransformation leads, apart from the formation of relatively non-toxic products, to toxic intermediates. The toxic intermediate of aflatoxin B_1 is *exo*-8,9-epoxide. Phase II represents detoxification, such as hydroxylation of aflatoxin B_1 to aflatoxins B_{2a}, M_1 and Q_1 and demethylation to aflatoxin P_1, which is accompanied by significantly reduced toxicity. These and other aflatoxins were identified as metabolites of aflatoxins of the B and G groups in the body of humans and animals and in tissue cultures. Also important is a product of oxidation called aflatoxicol. Phase III proceeds under the activity of intestinal microflora and may lead to the re-absorption of the released aflatoxin. The scope of these changes and the related toxic effects differ considerably between individual species (Figure 12.42). *Exo*-8,9-epoxide of aflatoxin B_1 reacts with DNA to form a covalent product with N^7-guanine (**12-89**) and forms an adduct with glutathione, which are excreted in the urine, and reacts with amino acids in proteins with the formation of imines and is hydrolysed by water to 8,9-dihydroxyaflatoxin, essentially 8,9-dihydroxyaflatoxin B_2, which forms adducts with proteins (as well as aflatoxicol) and is partly excreted in the urine.

When feed contaminated with aflatoxins B_1 and B_2 is given to cows, aflatoxins M_1 and M_2 resulting from hydroxylation of the parent compounds may be found in milk in roughly 12 h. The transition factor, which is the ratio between the amount of ingested precursor (aflatoxin B_1) and excreted aflatoxin M_1, is in the range of 100 : 1 to 300 : 1. The major part of this metabolite is excreted in the urine. Trace amounts of aflatoxin M_1 also appear in milk after

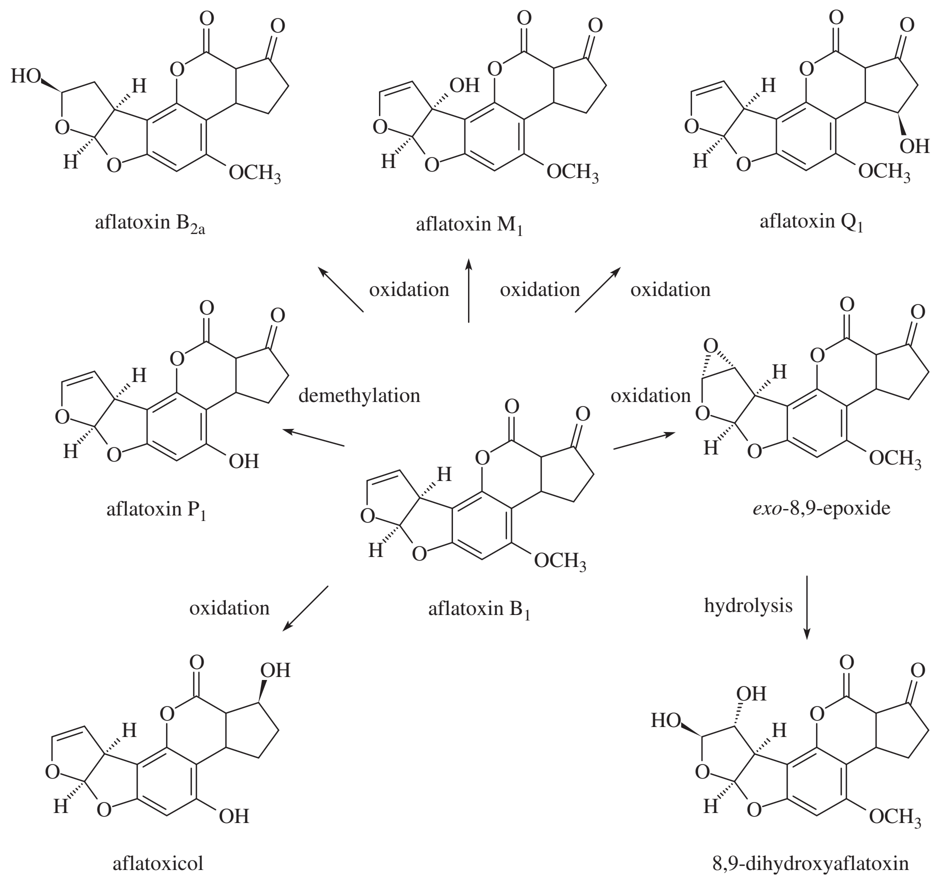


Figure 12.42 Aflatoxin B_1 metabolites.

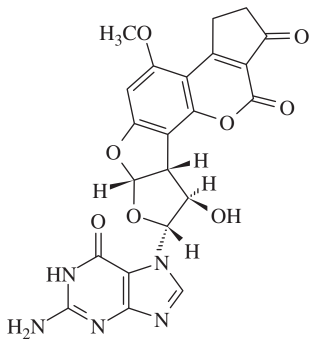


12-89, adduct of aflatoxin B_1 with guanine

a single intake of contaminated feed, even after 2–3 days. Transient factors of aflatoxins to muscles are low in cattle and for aflatoxin B_1 are in the range of 1000–14 000. Somewhat lower values (higher risk of the occurrence of residues) were found in the livers of pigs and poultry, but foods of animal origin (except milk and milk products) do not generally represent a significant dietary source of aflatoxins.

During milling of wheat grains, aflatoxins, found mostly in the outer layer (aleurone layer) of the grain and in the germ, are redistributed among individual fractions obtained depending on degree of milling, known as the flour extraction rate. The decrease of contamination in the 85% straight run wheat flour (see Section 5.6.7.3), by about 15% of the original amount, is accompanied by higher aflatoxin concentrations in the bran. Aflatoxins are relatively hydrophilic compounds and in the production of vegetable oils they are concentrated in oilseed meals that may become a source of contamination of the food chain when used for livestock feeding. Similarly, separation of fat during milk processing, increases the content of aflatoxin M_1 in some products, such as low-fat milk, cottage cheese, whey, buttermilk and other products. Fermentation processes lead to a small decrease in the amount of aflatoxins, but, for example, on average 20–25% of aflatoxins contained in barley are transferred to beer. The highest losses occur in the final stage of the brewing process when, after boiling with hops, proteins, any remaining hops and other insoluble particles are separated by filtration. The decrease of aflatoxin concentration may be related to reactions of toxins with organic molecules, particularly with the formation of complexes with proteins, which are removed. In the production of spirits, aflatoxins from contaminated material do not pass to the distillate. Aflatoxins are relatively stable compounds therefore thermal processes do not lead to their complete elimination in materials with low moisture content. The extent of their degradation depends on the amounts of water, fat and other components. Coffee roasting at 180 °C for 10 min results in only 50% decrease of aflatoxin B_1 concentration. Other examples are shown in Table 12.22.

Table 12.22 Changes in aflatoxin B_1 and M_1 levels during processing of contaminated materials.

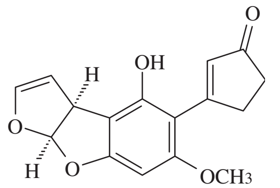
Product	Processing conditions	Losses (%)	Product	Processing conditions	Losses (%)
Peanuts	Roasting, 150 °C, 30 min	20	Rice	Steaming	0
	Dry roasting	31		Boiling under pressure, 120 °C	27
	Roasting in oil	35		Regular cooking	51
Peanut products	Roasting, 204 °C	50–60	Milk	Pasteuristion, 72 °C, 45 s	35
Peanut oil (unrefined)	Heating, 120 °C, 10 min	0		Sterilisation, 115 °C	19

Exposure of humans and animals (depending on dose) to aflatoxins may cause a variety of acute and chronic diseases. Aflatoxin B_1 is considered the most potent known natural hepatocarcinogen. One of the most tragic cases of acute human aflatoxin poisoning was reported in India in 1974, when the consumption of mouldy maize afflicted about 1000 people, about 100 of whom died. Based on the evaluation of aflatoxin concentrations and estimates of aflatoxin exposure dose, it was considered that the LD_{50} value for humans is somewhat higher than for the most sensitive animal species, such as dogs, where the LD_{50} value for aflatoxin B_1 is in the range of from 0.35 to 0.50 mg/kg body weight. Experts mention the synergies of aflatoxins and hepatitis B viruses. Numerous independent epidemiological studies have pointed to the high incidence of liver cancer in the populations in some regions of Eastern Asia and Africa, which correlates with a high dietary intake of aflatoxins. The most obvious correlation was found in areas with a frequent occurrence of chronic hepatitis B. Mutagenicity and carcinogenicity of aflatoxins generally follow the order $B_1 > G_1 > B_2 > G_2$ and are related to the interaction of reactive metabolites with DNA and inhibition of its replication and transcription, and inhibition of other processes, such as RNA and protein biosynthesis. In addition, aflatoxins induce a number of other adverse biological responses in humans, such as the so-called Reye's syndrome (a potentially fatal disease that causes detrimental effects to many organs), respiratory diseases, chronic gastritis, mental disability of children and immunosuppression. According to the IARC, aflatoxins are classified as Group 1 carcinogens to humans.[3]

In livestock, the consumption of aflatoxins in feed leads to a number of problems, which are then reflected in negative impacts on performance. Chronic exposure to aflatoxins leads to reduced growth and greater susceptibility to infections. This condition is often referred to as total failure to thrive. An extreme consequence of giving animals contaminated feed is lethal acute poisoning.

In relation to the prevention of the occurrence of aflatoxins, inhibitors of their formation are often studied. In addition to compounds used in practice for their fungicidal effects, such as preservatives, inhibitory effects of zinc or caffeine have also been demonstrated. Aflatoxin production can be stimulated by long chain fatty acids and inhibited by oleic, linoleic and lauric acids.

Contamination of plant materials with mycotoxins can become a significant economic problem, if it concerns a large volume of biomass. Because of the high carcinogenic potential of aflatoxins, special attention is paid to the possibilities of detoxification of contaminated materials, which would at least partially facilitate their use. The most common way is washing with ammonium hydroxide, often at elevated temperature and pressure. The efficiency achieved under optimal conditions can reach as high as 99%, but the principle of such treatment has not yet been satisfactorily explained. Among the degradation products of aflatoxin B_1, in model experiments, a decarboxylation product aflatoxin D_1, (3a*S*,8a*R*)-3-[3a,8a-dihydro-4-hydroxy-6-methoxyfuro[2,3-*b*]benzofuran-5-yl]-2-cyclopenten-1-one (**12-90**) has been identified. However, decontamination may cause a number of negative changes in the composition of the treated material, which results in a decrease of its nutritional or sensory quality. The use of decontaminated products for human nutrition is prohibited. Alternatively, the contaminated feedstock may be used for the production of ethanol or other fermentation products.



12-90, aflatoxin D_1

Owing to the high toxicity of aflatoxins, maximum amounts (at a strict level for what is reasonably achievable by following good agricultural and manufacturing practices) have been set for aflatoxin B_1 and for the sum of aflatoxins B_1, B_2, G_1 and G_2 as well as for aflatoxin M_1 in milk and certain milk products. The situation is quite complicated, because the limits in Europen Commission Regulation (EC) No. 1881/2006 have been subjected to rapid change, as seen for example in Commission Regulation (EC) No. 1126/2007, since for many countries strict limits can bring about serious economic difficulties. This concerns aflatoxins and *Fusarium* mycotoxins (the problematic crop is maize). To illustrate the maximum amounts set for mycotoxins, Table 12.23 summarises typical values of different EC documents. In the regulation of mycotoxins in foods, further development can be expected based on the results of toxicological evaluation and monitoring of real levels of mycotoxins in foods, depending on the geographical origin and climatic conditions. Last but not least, influences of

Table 12.23 Examples of typical limits for mycotoxins in food.

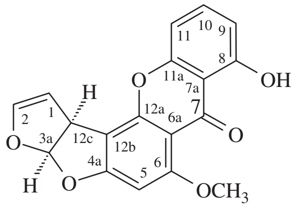
Mycotoxins	Product	Maximum levels (μg/kg)[a]
Sum of aflatoxins B_1, B_2, G_1 and G_2	Nuts, dried fruits, cereals, spices	4.0–15.0
Aflatoxin B_1	Nuts, dried fruits, cereals, spices, foods for infants and young children, dietary foods for special medical purposes	0.1–8.0
Aflatoxin M_1	Infant formulae and follow-on formulae, dietary foods for special medical purposes	0.025–0.05
Ochratoxin A	Cereals, dried vine fruit (currants, raisins and sultanas), coffee, wine, foods for infants and young children, beer, cacao, meat products, spices	0.5–10
Patulin	Apple juice and drinks from apples, cider, compotes, purees, baby food	10.0–50.0
Deoxynivalenol	Cereals, flour, pastries, biscuits, cereal snacks and breakfast cereals	200–1750
Zearalenone	Cereals, flour, pastries, biscuits, cereal snacks, breakfast cereals, baby food	20–350
Fumonisins	Maize and maize products	200–4000
T-2 toxin and HT-2 toxin	Not yet defined	–

[a]Maximum level can vary in the given range depending on the exact specification of food and depending on whether it is consumed directly or further processed. For example, the EU limit for patulin is set to 50 μg/kg in both apple juices and ciders, to 25 μg/kg in solid apple products and to 10 μg/kg in products for infants and young children.

processing technologies and transformation products of mycotoxins will be also taken into consideration, such as their conjugates with saccharides.

Sterigmatocystin

Sterigmatocystin (**12-91**) is a toxic secondary metabolite of microscopic filamentous fungi, especially fungi of the genus *Aspergillus*. One of its more prominent producers is fungus *A. versicolor*, but sterigmatocystin is also produced by fungi *A. flavus* and *A. parasiticus*. The presence of sterigmatocystin (along with aflatoxins) has



12-91, sterigmatocystin

been demonstrated in mouldy cereals, coffee beans, some animal products, such as ham, sausages and hard cheeses, where it was located mainly on the surface.

Sterigmatocystin containing the bisdihydrofurofuran skeleton is related to aflatoxins and is even regarded as their precursor. It is a xanthen-7-one derivative, with the systematic name (3a*R*,12c*S*)-8-hydroxy-6-methoxy-3a,12c-dihydro-7*H*-furo[3’,2’:4,5]furo[2,3-c]xanthen-7-one.

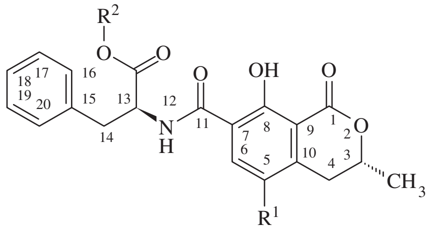
Sterigmatocystin is very acutely toxic to humans and animals and like aflatoxins acts as a hepatocarcinogen. According to the IARC, it is classified as a Group 2B carcinogen to humans.[3] As one of the priorities in the dietary risk assessment, the European Food Safety Authority (EFSA) identified the need to gather a more complete set of data on the occurrence of this mycotoxin in foods. Maximum levels in foods are not currently set due to a lack of data from which to assess the associated health risks.

Ochratoxins

Ochratoxins are a group of mycotoxins discovered in South Africa in 1965 during investigations on toxic filamentous fungi isolated from agricultural crops. The most important producers of these mycotoxins are filamentous fungi of the genus *Aspergillus*, in particular *A. ochraceus*, but some industrial strains of *A. niger* also produce these mycotoxins. In the colder climates of Europe (especially in Scandinavia), important producers of ochratoxins are fungi of the genus *Penicillium*, mainly *P. verrucosum*, *P. nordicum* and *P. carbonarius*.

From a toxicological point of view, the most important representative of this group of mycotoxins is ochratoxin A, (3*R*)-*N*-[(5-chloro-3,4-dihydro-8-hydroxy-3-methyl-1-oxo-1*H*-2-benzopyran-7-yl)carbonyl]-L-phenylalanine (**12-92**), the molecule of which phenylalanine *N*-substituted with a derivative of (3*R*)-3,4-dihydro-3-methylisocoumarine that contains at C-5 a chlorine atom to which are attributed the toxic effects of ochratoxin A. The incorporation of the chlorine atom into the skeleton of ochratoxin A is done by the action of chloroperoxidase; the chlorine donor is inorganic chloride. Ochratoxin B (**12-92**) differs from ochratoxin A only in the absence of the chlorine atom, while ochratoxin C (**12-92**) is an ethyl ester of ochratoxin A. Ochratoxins α, β and γ resulting from from parent compounds by the loss of phenylalanine caused by peptide bond hydrolysis, are virtually non-toxic, in addition to ochratoxin B, and are not routinely monitored.

Concentrations of ochratoxin A in cereals rarely exceed 50 μg/kg, but improper storage may cause a massive increase in contamination. In addition to cereals and cereal products, ochratoxin A



12-92, ochratoxin A, $R^1 = Cl$, $R^2 = H$
ochratoxin B, $R^1 = H$, $R^2 = H$
ochratoxin C, $R^1 = Cl$, $R^2 = CH_2CH_3$

has also been identified in some legumes, coffee, cocoa, grapefruit juices, raisins, nuts, spices and wine, especially red wine, which acquires ochratoxin A from the grape skins. During coffee roasting, ochratoxin A is isomerised and degraded by up to 90% to (3*R*)-isomer and 14-decarboxyochratoxin A, respectively. The occurrence and concentration of ochratoxin A in wines is likely to increase in the southern wine regions of Europe, which is connected with the infection of grapes by toxinogenic filamentous fungi *Aspergillus carbonarius* and other species (*A. niger*), which are almost absent in the northern wine regions. Attention must also be paid to the strains of *A. niger*, which are commonly used in biotechnology for the production of a variety of hydrolytic enzymes and organic acids, particularly citric acid. Their ability to produce ochratoxin A was discovered in the 1990s. Conjugated forms were found in cell cultures of wheat and maize: methyl ester of ochratoxin A and methylester and glucoside of hydroxyochratoxin A. Ochratoxin A is a relatively stable compound (Table 12.24) and losses under normal processing conditions are not significant.

Ochratoxin A is probably the only mycotoxin whose dietary intake is mainly associated with foods of animal origin. If contaminated feed is fed to animals, ochratoxin A is correspondingly found in the bodies of farm animals; it accumulates mainly in the kidney. In pigs, concentrations of ochratoxin A in the kidney may reach hundreds of mg/kg. The transient factor is in the range of 20–60 in the kidney and between 400 and 660 in the liver. Trace concentrations of ochratoxin A were also detected in the flesh, and occasionally in cheeses with moulds on the surface and in cured salami with casings treated with edible mould cultures.

The most serious biological effects of ochratoxin A to exposed animals is nephrotoxicity, but its hepatotoxicity, genotoxicity and immunotoxicity have also been demonstrated, and its carcinogenic potential is under discussion. When contaminated feed is fed to livestock, their growth is slow and relates, *inter alia*, to lower utilisation of nutrients. In humans, exposure to ochratoxin A is associated with Balkan endemic nephropathy (BEN), also known as Danubian endemic familial nephropathy, which is a chronic kidney disease that affects the kidney and leads to fibrosis and decreased kidney function. It also is characterised by a high frequency of urothelial cancer (cancer of the urinary tract).

During research focused on ochratoxin A, the frequent occurrence of this mycotoxin was found in blood plasma of people from different parts of Europe, which emphasised the need for systematic monitoring in the human food chain (after entering the human body ochratoxin A is very persistent). The highest levels of ochratoxin A in Europe were found in the population of Denmark. Recent evaluation of dietary exposure to ochratoxin A conducted by EFSA indicates that the intake of an adult European consumer is in the range of 15–60 ng/kg body weight per week, which does not exceed the Tolerable Weekly Intake (TWI), which is, according to expert estimates, 120 ng/kg body weight. Hygienic limits for ochratoxin A residues exist in many countries, examples of which are given in Table 12.23. Maximum levels are exceeded only in exceptional cases.

Patulin

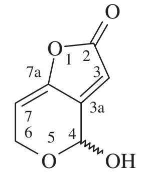
Initially patulin was evaluated as a pharmacological agent due to its antimicrobial properties. However, the gastrointestinal and dermal irritation observed in human trials prevented its use as a pharmacological agent. The most important producers of patulin are microscopic fungi of the genus *Penicillium*, especially *P. patulinum* and *P. expansum*, which are common pathogens of many fruits and vegetables. The production of this mycotoxin was also detected in some fungi of the genera *Aspergillus* and *Byssochlamys*. Within the food industry, patulin contamination is considered of greatest concern in apples and apple products, which are the main sources of human patulin intake. Nevertheless, this mycotoxin has also been found at significant concentrations in other fruits, such as pears, peaches, strawberries, blueberries, cherries, apricots, grapes and in cheeses and animal feed, especially in silages. Patulin is a relatively common contaminant of fruit concentrates and juices, especially when overripe or damaged fruit has been used. Its concentrations do not normally exceed 0.1 mg/kg, but can reach about 2500 μg/kg if the juice is obtained from rotten apples, which may contain up to about 45 000 μg/kg of patulin.

Patulin, 4-hydroxy-4*H*-furo(3,2-*c*)pyran-2(6*H*)-one (**12-93**) is a furopyrone mycotoxin, which occurs in nature as a racemate.

Patulin is highly soluble in water and is relatively stable in acidic media (pH range from 3.0 to 6.5); therefore special attention is devoted to reduction of its content in foods. The assimilated

Table 12.24 Changes in the content of ochratoxin A during processing of contaminated crops.

Products	Processing conditions	Losses (%)	Products	Processing conditions	Losses (%)
Coffee beans	Roasting, unspecified	10–20	Brewing mash	Cooking	27–28
Coffee beans	Roasting, 200 °C, 5 min	0	Cereal products	Autoclaving, 120 °C, 3 h	30



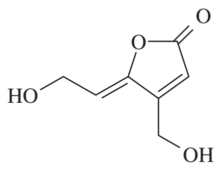
12-93, patulin

information and recommendations can be summarised in the following points:

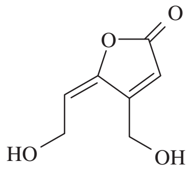
- removing mycelium from the product, even with the adjacent biomass, is not sufficient for decontamination, because patulin easily diffuses into the whole material;
- cold juice pressing does not have a significant impact on the content of patulin in the final product;
- patulin present in apple pomace, a byproduct of juice production, may pose a risk to livestock if used as feed;
- storage of products containing patulin (especially at higher temperatures) leads to a gradual decrease of its content;
- thickening of juices by vacuum distillation reduces patulin content by an average of 25%;
- pasteurisation at 80 °C leads to a negligible reduction in the concentration of patulin, but sterilisation may reduce levels of patulin in apple juice by about 20% or more;
- decrease of patulin content in foods (to about 40–95% of the original concentration) probably occurs during microwave heating.

Patulin is virtually absent from wines, because fermentation of contaminated juices by commercial yeast *Saccharomyces cerevisiae* (also by other microorganisms, such as *Gluconobacter oxydans*) leads to relatively rapid transformation of patulin into ascladiols, 5-(2-hydroxyethylidene)-4-hydroxymethyl-5*H*-furan-2-ones (**12-94** and **12-95**), but practically no information exists about the toxicity of these diols. Sulfites and compounds containing sulfhydryl functional groups (cysteine and glutathione) can contribute to a significant acceleration of patulin degradation. Owing to the electrofilicity of patulin, reactions with other nucleophilic substances such as amino acids (especially lysine and histidine) or proteins can be expected. Increased patulin degradation induced by hydroxyl and other free radicals was observed in fruit juices fortified with ascorbic acid to the level of 500 mg/l.

In addition to the antibiotic effects of patulin against Gram-negative and Gram-positive bacteria, its antifungal and antiviral properties (inhibition of replication of mycoviruses) have also been reported. Its carcinogenic and mutagenic effects have subsequently been proven, associated with inhibition of RNA transcription and selective DNA damage. Also demonstrated were negative effects on the gastrointestinal tract and neurotoxic and immunotoxic effects,



12-94, (*Z*)-ascladiol

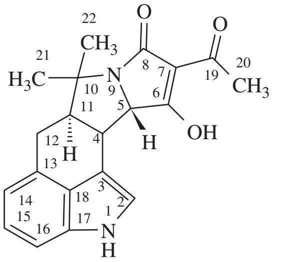


12-95, (*E*)-ascladiol

therefore the content of patulin, a Group 3 carcinogen (a compound for which there are not enough data to allow its classification)[3] in food should be reduced to a minimum technically achievable level. The limits set in the EU for apples and apple products are summarised in Table 12.23.

Cyclopiazonic acid

Cyclopiazonic acid or α-cyclopiazonic acid, by its chemical name (6a*R*,11a*S*,11b*R*)-*rel*-10-acetyl-2,6,6a,7,11a,11b-hexahydro-7,7-dimethyl-9*H*-pyrrolo[1’,2’:2,3]isoindolo[4,5,6-*cd*]indol-9-one (**12-96**), is a toxic metabolite which occasionally accompanies aflatoxins in contaminated materials. Its major producers are some strains of *Aspergillus flavus* and *A. versicolor*, but it is also produced by some other fungi, especially *Penicillium commune*, *P. griseofulvum* and occasionally *P. camembertii*. The presence of this mycotoxin has been demonstrated, for example, in maize (highest levels found were close to 10 mg/kg), sunflower seeds, peanuts, but also in meat products with edible moulds on casings and cheeses that have moulds on the rind or throughout, which may indicate that the strict criteria for selecting non-toxinogenic strains of moulds were not met. Some papers in the literature document frequent occurrence of cyclopiazonic acid in animal feed (hay and silage), but information about the deposition of this mycotoxin in animal tissues is not available. Generally, the data on the occurrence of cyclopiazonic acid are very limited, as well as information about its stability in the contaminated materials. Japanese studies have reported a significant decrease of the level of this mycotoxin in the production of soy sauce.

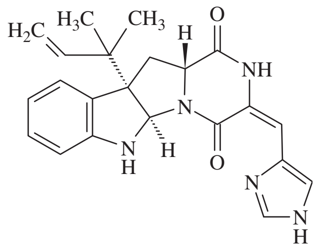


12-96, cyclopiazonic acid

The adverse health effects of cyclopiazonic acid manifest at higher concentrations. It is a specific inhibitor of calcium-ATPase, which transfers calcium after a muscle has contracted. In animals it causes necrosis of the liver and necrotic changes in the gastrointestinal tract and muscles. It is considered a potential carcinogen, but exposure limits are not yet defined.

Roquefortine C

Roquefortine C, or by chemical name 10b-(1,1-dimethylprop-2-en-1-yl)-6,10b,11,11a-tetrahydro-3-(1*H*-imidazol-4-ylmethylene)-2*H*-pyrazino(1’,2’:1,5)pyrrolo(2,3-*b*)indole-1,4(3*H*,5a*H*)-dione (**12-97**), is a basic compound, which can be categorised among alkaloids. The basis of its structure is a dihydroindole skeleton. Roquefortine C can produce some strains of the fungus *Penicillium roquefortii* used to make Roquefort cheeses (blue cheeses). These fungi are commonly found in nature and were discovered by cheese makers when aging cheeses in damp, cool caves. *P. roquefortii* comprises three accepted species: *P. carneum*, which is associated with meat, cheese and bread; *P. paneum*, associated primarily with bread and silage; and *P. roqueforti*, which is associated with various processed foods and silage.



12-97, roquefortine C

At the time of its discovery, concentrations of roquefortine C in cheeses reached as much as units of mg/kg, but today the cultural strains used either do not produce this mycotoxin at all or produce it only in trace amounts. The toxicity of roquefortine is generally low, but more detailed data on its effect on the human organism are not available.

Roquefortine C was often accompanied by a structurally related mycotoxin isofumigaclavine A (**12-98**). *P. roqueforti* molds may occasionally produce patulin, citrinin (**12-99**), penicillic acid (**12-100**), the so-called PR-toxin (**12-101**) and certain other toxins that have been implicated in incidents of mycotoxicoses. However, PR toxin is not stable in cheese and breaks down to the less toxic PR imine (**12-101**). Other secondary metabolites of *P. roqueforti* found in blue cheeses are andrastins A–D with skeletons of *ent*-5α,14β-androstane. In European blue cheeses, the content of andrastin A (**12-102**) ranged from 0.1 to 3.7 mg/kg and contents of andrastins B, C and D were on average five times lower. The most significant biological activity of adrastins is the ability to inhibit the enzyme farnesyltransferase, an enzyme that catalyses the transfer of farnesyl residue from farnesyl diphosphate to proteins. It is a part of the apparatus carrying post-translational modification of proteins in the cell. Attachment of farnesyl residue to a protein changes its physico-chemical and biological effects. Such modified proteins are able to cross the lipophilic membranes and many play a role as cell signalling molecules. They have also anticarcinogenic properties.

Citrinin

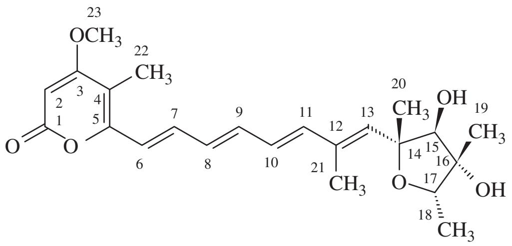
Citrinin, also known as antimycin, or by its chemical name (3*R*,4*S*)-8-hydroxy-3,4,5-trimethyl-6-oxo-4,6-dihydro-3*H*-isochromene-7-carboxylic acid (**12-99**) can exist in two tautomeric forms. The quinoid form is normally present in neutral media and the tautomeric phenol form occurs in alkaline media. Citrinin is a secondary metabolite of fungi of the genera *Aspergillus* and *Penicillium*, especially of fungi *P. citrinum* and *P. verrucosum*. Citrinin is the main contaminant of so-called yellow rice (see Section 12.3.1). In temperate climates it is found mainly in cereals, but data concerning its occurrence are limited. Citrinin has also been found in cheeses, sake and commercial red yeast rice supplements (see Section 9.7).

Shortly after its discovery in the early 1930s, citrinin was first considered to be an antibiotic, but later its strong nephrotoxicity was

demonstrated, as well as its possible teratogenicity and interference with metabolic processes leading to damage in the liver. The intoxication of livestock (especially pigs, but also other monogastric animals) is manifested by diarrhoea and reduced weight gain. Toxic effects in humans have not been clearly documented.

Citreoviridin

Citreoviridin, with the chemical name (1*E*,3*E*,5*E*,7*E*)-6-[8-(3,4-dihydroxy-2,4-dimethyloxolan-2-yl)-7-methylocta-1,3,5,7-tetraen-1-yl]-4-methoxy-5-methyl-2*H*-pyran-2-one (**12-103**) is a typical secondary metabolite of the fungus *Penicillium citreoviride*. Citreoviridin was identified in crops grown in Asia, especially in the so-called yellow rice (see Section 12.3.1); its occurrence has been reported even in pecans and maize that had not been harvested at the time of full maturity. Information on the presence of this substance in the diet of the European population is not available, nevertheless some findings, particularly in maize, have been reported.



12-103, citreoviridin

Citreoviridin is a potent inhibitor of soluble mitochondrial ATPase. In experimental animals it has caused a disease called acute cardiac beriberi, whose symptoms are similar to the symptoms of classic beriberi (convulsions and paralysis), but the disease is not curable with thiamine.

Penicillic acid

Penicillic acid, (*Z*)-3-methoxy-5-methyl-4-oxohexa-2,5-dienoic acid and the lactone of its hydrate (5-hydroxyisoprop-5-en-1-yl-4-methoxyfuran-2-one), respectively (**12-100**), is produced by a wide range of fungi. An example is the fungus *Penicillium aurantiogrisseum* found in maize. The presence of this mycotoxin has also been documented in some sausages and on the surface of hard cheeses. Occurrence of moulds in the deeper layers below the surface is limited by the availability of oxygen.

Penicillic acid is a cytotoxic agent with antibacterial and antiviral effects. During repeated administration to experimental animals its hepatotoxicity and nephrotoxicity have been demonstrated. Penicillic acid is a relatively unstable compound, which reacts readily with sulfhydryl substances under opening the lactone ring (as patulin) and a loss of toxicity.

Trichothecenes

Trichothecenes are one of the most important groups of mycotoxins. Their main producers are microscopic filamentous fungi of the genus *Fusarium* (Table 12.21). Unlike other toxinogenic fungi, in which saprophytic species prevail, *Fusarium* species are primarily parasitic fungi, plant pathogens, and some are opportunistic infectious agents of humans and animals. The production of trichothecenes has been demonstrated even in some strains of fungi of the genus *Myrothecium* (such as *M. verrucaria* and *M. roridum*), *Trichoderma*, *Cephalosporium*, *Verticimonosporium* and *Stachybotrys*. *Stachybotrys atra* moulds were known in ancient times and are now attracting attention again. Representatives of this genus grow preferentially on substrates rich in cellulose, such as wood, paper and cotton. An unusual feature, compared with other moulds, is the high content of trichothecenes, especially T-2 toxin, in their spores. Inhalation of spores can cause pulmonary haemorrhage, and some fatalities have been reported in cases involving children.

As regards their chemical structure, trichothecenes constitute a diverse group of compounds derived from tricyclic sesquiterpenes. The most important structural features causing their biological activities are six-membered rings containing a double bond between carbons C-9 and C-10, an epoxy ring between C-12 and C-13 and hydroxyl or acetyl groups at appropriate positions on the trichothecene nucleus and the structure and position of the side chain. All trichothecenes have the same stereochemistry: α at C-3, C-7 and C-8 and β at C-4 and C-5 in A and B trichothecene types. For example, the systematic chemical name of deoxynivalenol (vomitoxin) is: (3α,7α)-3,7,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one and that of T-2 toxin is: (2α,3α,4β,8α)-4,15-bis(acetyloxy)-3-hydroxy-12,13-epoxytrichothec-9-en-8-yl 3-methylbutanoate. According to the characteristic structures related to the physico-chemical and biochemical properties, trichothecenes can be divided into four types:[5]

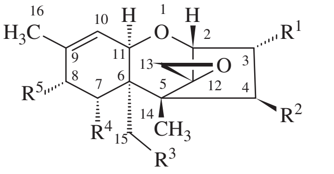
- type A trichothecenes (**12-104**) that do not have the C-8 oxo group; such as the T-2 toxin, T-2 tetraol, HT-2 toxin, diacetoxyscirpenol, neosolaniol and some other trichothecenes produced by *F. acuminatum*, *F. sporotrichiodes*, *F. sporotrichiodes* var. *tricinctum* and *F. poae*;

- type B trichothecenes (**12-105**) typically having the C-8 carbonyl group; they include, for example, nivalenol, deoxynivalenol (also called vomitoxin), 3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, trichothecin and fusarenone-X produced by *F. nivale* and *F. episphaeria*;

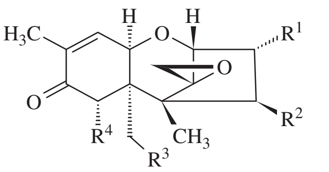
- type C trichothecenes typically have a second epoxide group at C-7/C-8 (or at C-9/C-10), such as crotocin (**12-106**), and are produced by *Cephalosporium crotocingigenum*;

- type D trichothecenes contain a macrocyclic ring between C-4 and C-15 with two ester linkages, which include, for example, verrucarin A (**12-107**).

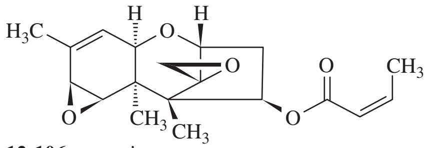
[5]Recognised may be two additional trichothecene types. The type E trichothecenes include mycotoxins with an opened macrocyclic ring and the type F trichothecenes do not have the 12,13-epoxide ring as it is replaced by a vinyl linkage with the oxygen atom in the epoxide ring removed.



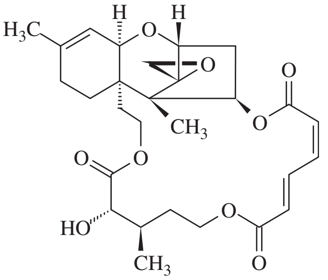
12-104, T-2 toxin, $R^1 = OH$, $R^2 = R^3 = OCOCH_3$, $R^4 = H$, $R^5 = COCH_2CH(CH_3)_2$
T-2 tetraol, $R^1 = R^2 = R^3 = R^5 = OH$, $R^4 = H$
HT-2 toxin, $R^1 = R^2 = OH$, $R^3 = OCOCH_3$, $R^4 = H$, $R^5 = COCH_2CH(CH_3)_2$
diacetoxyscirpenol, $R^1 = OH$, $R^2 = R^3 = OCOCH_3$, $R^4 = R^5 = H$
neosolaniol, $R^1 = OH$, $R^2 = R^3 = OCOCH_3$, $R^4 = H$, $R^5 = OH$



12-105, deoxynivalenol, $R^1 = R^3 = R^4 = OH$, $R^2 = H$
nivalenol, $R^1 = R^2 = R^3 = R^4 = OH$
trichothecin, $R^1 = R^3 = R^4 = H$, $R^2 = OCOCH{=}CHCH_3$
fusarenone-X, $R^1 = R^2 = R^3 = OH$, $R^4 = OCOCH_3$



12-106, crotocin



12-107, verrucarin A

Nearly 180 trichothecenes and their derivatives are currently known. While trichothecenes of types C and D do not commonly occur in crops, trichothecenes of types A and B are widespread. The presence of one and sometimes more trichothecenes has been demonstrated mainly in cereals (wheat, barley, oats and maize) grown in the temperate zones of Europe, America and Asia. Grains attacked by *Fusarium* spp. are characterised by a typical reddish colour. Findings of trichothecenes A and B have also been reported in soybeans, oil seeds, banana and mango.

One of the most trailed trichothecenes is a type B trichothecene deoxynivalenol, which is mainly produced by the fungus *Gibberella zeae*, anamorph (the asexual reproductive form in the life cycle) of *Fusarium graminearum* found mainly in warmer geographic regions (its optimum growth temperature is 25 °C). The producer is also *F. culmorum* requiring a lower temperature (its optimum is 21 °C). These microscopic fungi cause an important disease in wheat, barley, maize and other cereals called *Fusarium* head blight (FHB) that causes losses in grain yield and quality. Under conditions favourable for the growth of toxinogenic fungi, the deoxynivalenol concentration can reach up to 10 mg/kg; however, typical findings are significantly lower. The incidence of deoxynivalenol (as well as other mycotoxins) in cereals is highly variable, depending on the climatic conditions in the locality and the type of crop and, of course, the resistance of crop varieties.[6] In some years, this mycotoxin can be present in virtually 100% of examined samples.

In recent years the need for more information about the type A trichothecenes has been emphasised, not only with regard to their toxicity (this is greater than that of deoxynivalenol), but also due to the increasing trend of incidence in European cereals. Mycotoxins T-2 and HT-2 (a product of T-2 deacetylation) are found mainly in oats, where their amounts may be up to 1000 μg/kg, but the annual variability of contamination is considerable. The only way to reduce the level of type A trichothecenes in foods and feeds containing oats is the removal of bran from grains, as bran may contain 75–90% of the total amount of these mycotoxins.

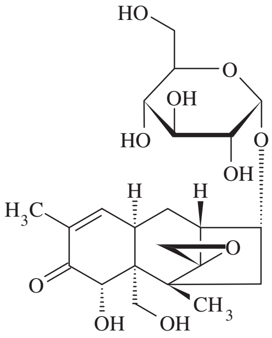
Physico-chemical properties of trichothecenes are dependent on the presence of polar substituents, therefore type B trichothecenes are generally more polar than type A trichothecenes. Under normal conditions of technological and culinary processing of cereals, trichothecenes are relatively stable toxins and pass from contaminated raw materials into the final products, such as bakery products, breakfast cereals, beer and others. During the processing of wheat in mills, a significant portion of these mycotoxins (up to 50%) is removed, but their contamination in the bran is roughly two to three times higher than the original contamination in the grain. Wholewheat flour derived by grinding the whole grain generally contains higher amounts of trichothecenes than white flour, as its content of mycotoxins depends on the degree of milling (four extraction rate) and is generally 20–70% of the original amount in the grain. For example, flour produced from wheat with a deoxynivalenol content of 0.51 mg/kg contained 0.35 mg/kg of this mycotoxin, while its concentration in the bran increased to 1.12 mg/kg.

The results of studies focused on changes in the content of trichothecenes in the production of bread and other bakery products are sometimes very different, nevertheless some decrease in contamination of flour was observed, especially in fermented products, where the losses of deoxynivalenol ranged from 15 to 56%. A decrease in concentrations of deoxynivalenol (up to 40%) and some other mycotoxins (nivalenol and acetyloxynivalenols) also occurs after the addition of sulfites to the dough, as sulfites react with trichothecene mycotoxins with the addition to the C-9/C-10 double bond yielding the corresponding hydroxysulfonates. A significant reduction in the content of trichothecenes, especially

[6]The resistance of cereals is classified into different groups: type I is resistance to primary infection, type II resistance to the spread of infection, type III is the resistance to infection of grains, type IV is tolerance against *Fusarium* head blight (FHB) and trichothecenes, type V is the resistance to the accumulation of trichothecenes: Class 1 is chemical modification (such as conjugation), Class 2 is inhibition of biosynthesis.

B group mycotoxins, is also achieved by washing the contaminated grains, as mycotoxins mainly occur on the surface of grains. Such a reduction in the mycotoxin content occurs during barley steeping, the purpose of which is to evenly hydrate the endosperm mass of barley, raising the moisture level to allow uniform growth during its germination. For example, barley with extremely high deoxynivalenol concentration of 16.1 mg/kg contained only 8% of this amount after 24 h of steeping. In aqueous solutions, deoxynivalenol is relatively stable and is not decomposed during brewing. Sometimes a slight increase in its concentration compared with the concentration in malt can even be recorded.

Studies in recent years have shown a more serious aspect of trichothecene mycotoxins, which should be considered when assessing exposure risks. In addition to their free, routinely monitored forms, plant materials contain various conjugates, which are either water soluble (so-called masked mycotoxins) or insoluble (so-called bound mycotoxins). In the former case, the conjugates with mono- or oligosaccharides arise during the detoxification process in contaminated plants as other conjugates of xenobiotics. Until recently, masked mycotoxins escaped routine analysis, due to their different physico-chemical properties (especially higher polarity). The best known conjugated trichothecene is deoxynivalenol-3-β-D-glucoside (**12-108**), which may occur, for example in wheat, in amounts corresponding to up to 30% of the molar concentration of free deoxynivalenol. Relatively high levels of deoxynivalenol-3-β-D-glucoside were recently found in malt, beer and other fermented cereal products, when the molar ratio of deoxynivalenol-3-β-D-glucoside to deoxynivalenol in some samples may be even ≥1. Increased concentrations of deoxynivalenol, deoxynivalenol-3-β-D-glucoside and other fusariotoxins during the production of malt and beer can be an order of magnitude higher, which is probably related to the activity of hydrolytic enzymes that contribute to the release of these mycotoxins from their linkages to polysaccharides such as starch. Increased levels of mycotoxins may be also due to *de novo* activity of potentially present moulds. Data on the bioavailability and toxicity of deoxynivalenol-3-β-D-glucoside are not yet available, but previous research suggests that enzymes of intestinal bacteria are able to cleave this conjugate, which may lead to additional release of deoxynivalenol in mammals. It would however mean that the currently evaluated dietary exposure to deoxynivalenol is underestimated.



12-108, deoxynivalenol-3-β-D-glucopyranoside

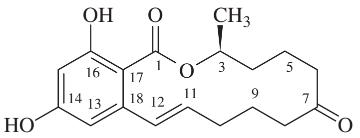
Foods of animal origin do not contribute significantly to the exposure of consumers, as the transfer of trichothecenes into meat, milk and eggs is insignificant because trichothecenes undergo rapid detoxification (epoxide ring opening and formation of glucuronides) after absorption in the digestive tract. In livestock (including cattle and pigs), acetylated trichothecenes are easily hydrolysed by enzymes of the intestinal microflora.

Trichothecenes exhibit a wide range of biological effects, such as antibacterial, antiviral, cytostatic and fungistatic; some of them are also phytotoxic. Toxicity to vertebrates varies over a considerable range. Based on experiments with animals, some of them (especially T-2 toxin as a representative of the type A trichothecenes) are mutagenic and immunotoxic (immunosuppressive) compounds that lower the body's normal immune response. In humans, exposure to T-2 toxin is associated with a disease called alimentary toxic aleukia (ATA), which is manifested by a marked reduction or the complete absence of leukocytes or platelets in blood serum. The disease has been reported in the temperate zone, which stretches from the south of Russian Siberia to the Balkans. The largest epidemic was recorded in the former Soviet Union in the 1940s, when, as a result of the war, unharvested grains (mainly millet) in fields were covered with snow and were attacked by *Fusarium* moulds. The grain harvested the following spring was extremely contaminated and caused the deaths of more than 17 000 people. To a lesser extent, alimentary toxic aleukia occurred in the 1950s and 1960s in Hungary and France. Typical symptoms of intoxication are gastrointestinal inflammation, vomiting and diarrhea, often with headaches. In later stages, the intoxication leads to a reduction in the number of platelets and white blood cells, in the third stage to various infections caused (in healthy people) by banal harmless microflora.

Another type A trichothecene, diacetoxyscirpenol, is significantly less acutely toxic in contrast to T-2 toxin, but is characterised by significant teratogenic potential. Deoxynivalenol, a representative of the type B trichothecenes, is the least toxic mycotoxin of this group, but is often the main trichothecene in contaminated foods. Signs of acute intoxication caused by deoxynivalenol are vomiting, abdominal pain, diarrhea and headaches associated with dizziness. Extremely high toxicity is shown by macrocyclic trichothecenes of type D. For example, the acute toxicity of verrucarin is still about ten times higher than that of T-2 toxin. In comparison with aflatoxins, trichothecenes exhibit direct biological effects without metabolic activation. It is expected that they react with some cellular components, such as ribosomes, which results in inhibition of protein synthesis. The IARC, however, has not included trichothecenes among human carcinogens. Currently, maximum limits are set only for deoxynivalenol (Table 12.23).

Zearalenone

Zearalenone, also known as mycotoxin F_2, or (3*S*,11*E*)-14,16-dihydroxy-3-methyl-3,4,5,6,9,10-hexahydro-1*H*-2-benzoxacyclotetradecine-1,7(8*H*)-dione (**12-109**), is another toxicologically significant secondary metabolite of filamentous fungi of the genus *Fusarium*. The major producers of zearalenone are fungi *F. culmorum*, *F. graminearum*, *F. cerealis*, *F. equiseti* and *F. semitectum*. Zearalenone is found mostly in cereals, especially in maize, but often also in wheat, barley and oats and sometimes in



12-109, zearalenone, (*E*)-isomer

spices. Producers of zearalenone are found in virtually all climatic zones, and almost without exception the positive samples (typical concentrations are in the range of tens to hundreds of μg/kg) are also contaminated by fusariotoxins (deoxynivalenol and nivalenol) and by fumonisins. Some *Fusarium* strains also produce other zearalenone derivatives, whose concentrations can be 10–20% of the free mycotoxin. For example, (*E*)-zearalenone-related metabolites from cultures of *F. graminearum* are 13-formylzearalenone, 5,6-dehydrozearalenone, two epimers of 5-hydroxyzearalenone and 10-hydroxyzearalenone, α- and β-epimers of zearalenol, α- and β-zearalanol (*Z*)-zearalenone and (*Z*)-zearalenol.

The dominant secondary metabolite found in maize, but also in wheat, is zearalenone-14-β-D-glucoside, which is accompanied by the corresponding malonate and diglycosides (diglucoside and xylosylglucoside). Fungi *Thamnidium elegans* also produce zearalenone 14,16-diglucoside. Another metabolite identified only in maize is zearalenone-14-sulfate. The formation of zearalenone conjugates was studied intensively in the model plant thale cress (*Arabidopsis thaliana*), which led to identification of glucoside, malonylglucoside, diglucoside, triglucoside, xylosylglucoside and α-zearalenol and β-zearalenol. It is assumed that these recognised metabolites may also be present in cereals (Figure 12.43).

Zearalenone is relatively thermostable and does not decompose, for example, even when heated to $120\,^{\circ}\mathrm{C}$ for 4 h; therefore the loss is mainly attributed to the formation of complexes with components of the material. Irradiation by UV light causes isomerisation of the natural (*E*)-isomer (*trans*-isomer) to (*Z*)-isomer (*cis*-isomer), (3*S*,11*Z*)-14,16-dihydroxy-3-methyl-3,4,5,6,9,10-hexahydro-1*H*-2-benzoxacyclotetradecine-1,7(8*H*)-dione (**12-110**).

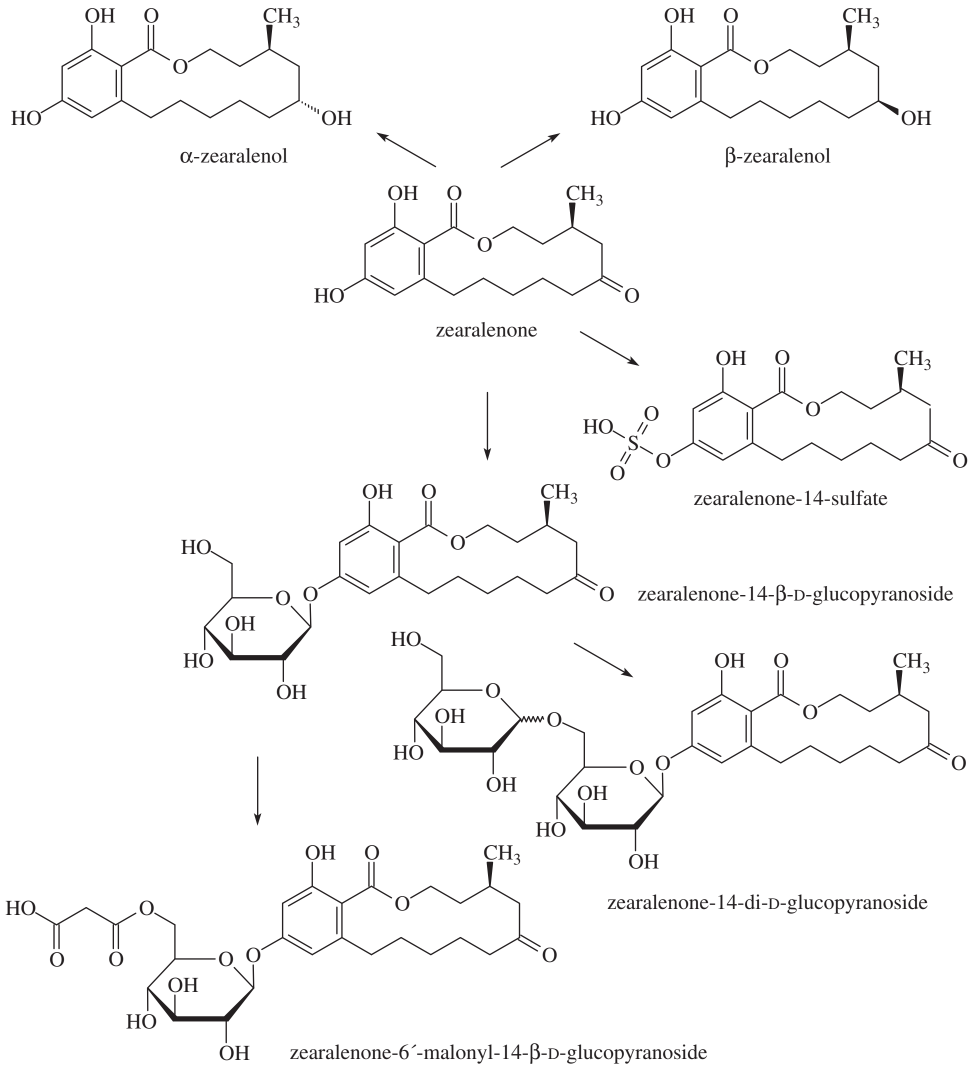


Figure 12.43 Zearalenone derivatives in plants.

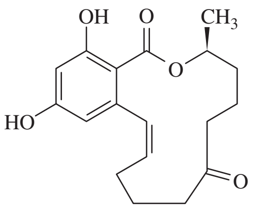


12-110, zearalenone, (*Z*)-isomer

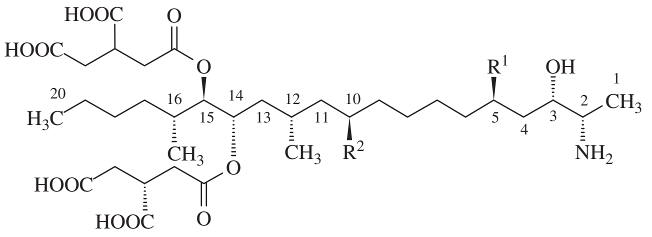
Washing of maize, which is effective for decreasing the concentration of deoxynivalenol and other trichothecenes, does not lead to a significant decrease in the amount of zearalenone, probably due to its hydrophobicity. As a relatively stable compound, zearalenone is transferred to cereal products, including bread, malt and beer. Zearalenone is relatively lipophilic, therefore is also found in vegetable oils, especially in germ oils. As in the case of other fusariotoxins, the content of zearalenone in flour is lower than that in the original grains and depends on flour extraction rate. For example, white flours made from contaminated wheat contain only 30–50% of the initial amount of zearalenone, while zearalenone concentrations in bread (compared with its content in flour) decrease by 34–40%. Other experiments have shown the residual content of zearalenone was 60% of the initial amount in bread and 80% in biscuits. In the production of pasta in the presence of 1% potassium carbonate, the loss of zearalenone was 48–62%.

Zearalenone is rapidly metabolised in the liver of humans and animals. Primarily, the C-7 oxo group is reduced to give α- and β-zearalenol and the C-11 double bond is reduced to yield the corresponding zearalanols (see Section 12.8.3.1). These products are then secreted as soluble glucuronides, but in small amounts can be found in milk and eggs, but this route of human dietary exposure is marginal. Acute toxicity of zearalenone is low; however, zearalenone and its derivatives exhibit significant oestrogenic and anabolic effects. Dietary intake may cause (thanks to the structural similarity with the steroid hormones oestrogens) hyper oestrogenic syndrome. Oestrogenic potential is approximately one tenth of the potential of 3,17β-estradiol. Generally, the binding affinity to the oestrogenic receptors decreases as follows: α-zearalanol > α-zearalenol > β-zearalanol > β-zearalenol. With regard to the oestrogenic effect, zearalenone is sometimes referred to as a mycoestrogen (see Section 10.3.3.5.1). The IARC ranks zearalenone in Category 3 (compounds unclassifiable as to carcinogenicity in humans), but maximum limits are set for selected cereal commodities (Table 12.23).

Fumonisins

This group of mycotoxins was only discovered in the late 1980s in South Africa. Twenty filamentous fungi of the genus *Fusarium* have been idenitified, which biosynthesise these secondary metabolites, however, the main producers of fumonisins are fungi *F. moniliformis* and *F. proliferatum*. Fumonisins are found in cereals, most notably in maize (where their contents can reach tens of mg/kg) and maize products, such as maize flakes, polenta and other products. The presence of fumonisins was also demonstrated in rice, millet and other cereals. Findings in animal feed, especially in silage, are also common.

Dozens of secondary metabolites from the fumonisin group are currently known, which are divided, according to their structure, into four groups (A, B, C and P) that mainly include relatively polar diesters of propane-1,2,3-tricarboxylic acid with 2-amino- or 2-acetylamino-12,16-dimethyl-3,5,10,14,15-pentahydroxyeicosane (**12-111**). In terms of toxicity or chemical food safety, monitored mycotoxins are B group fumonisins. The most common compounds occurring in the highest concentration are fumonisins B_1 and B_2, which often occur in a ratio of about 3 : 1. Fumonisin B_3 can often be found in materials with higher levels of contamination. For example, the systematic chemical name of fumonisin B_1, also known as macrofusine, is (2*S*,2′*S*)-2,2′-{[(5*S*,6*R*,7*R*,9*R*,11*S*,16*R*,18*S*,19*S*)-19-amino-11,16,18-trihydroxy-5,9-dimethylicosane-6,7-diyl]bis[oxy(2-oxoethane-2,1-diyl)]}disuccinic acid. Fumonisin B_1, the predominant metabolite, is known to cause a range of species-specific toxic responses, including leucoencephalomalacia in horses, pulmonary oedema in swine and hepatosis and nephrotoxicity in rodents. It is known to intervene in the sphingolipid metabolism by inhibition of ceramide synthase, which is believed to be the key event in the toxicogenesis of fumonisins.



12-111, fumonisin B_1, $R^1 = R^2 = OH$
fumonisin B_2, $R^1 = OH$, $R^2 = H$
fumonisin B_3, $R^1 = H$, $R^2 = OH$

Like many other mycotoxins, fumonisins are relatively stable even at higher temperatures. For example, a significant decrease in the concentration of fumonisins in maize meal occurs during heating to 200 °C for 60 min. During baking of muffins from contaminated maize flour at 220 °C, a noticeable reduction of the amount of fumunisins B_1 and B_2 occurred after about 30 min of baking. With normal thermosterilation of sweet maize, losses of fumonisins were around 15%, rarely more. Higher pH values may cause hydrolysis of one or both propane-1,2,3-tricarboxylic acids. This reaction proceeds, for example, during the production of some speciality maize products, such as authentic Mexican *tortillas* and *nachos* prepared from maize flour with the addition of lime milk (see Section 5.8.5.2), and results in a reduction of fumonisin B_1 content of up to 60% of the original amount. Hydrolysed fumonisins may occur in products at a level of up to 20% of the parent mycotoxin amount. Their toxicity has not yet been evaluated, but it is suggested that they may be more toxic than the parent compounds, because they are less polar and therefore more easily absorbed by the intestinal mucosa.

Losses of fumonisins during technological processing of contaminated materials may be due to reactions with some components of the material, which yields bound forms of mycotoxins. Reaction depends mainly on the composition of the raw materials and the conditions employed during processing. Figure 12.44 illustrates the formation of conjugates of fumonisin B_1 with starch and proteins, which takes place at higher temperature. The first reaction step is dehydration to fumonisin bisanhydride that subsequently reacts with either protein (via lysine ε-amino groups and sulfhydryl groups of bound cysteine) or starch. In the reaction of fumonisin B_1 with reducing sugars, the amino group of the side chain enters the reaction, which yields analogous products which also arise in the Maillard reaction. In model experiments and real foods, the corresponding glycosylamines, Amadori products and also other products are produced. The identified adducts from reaction of fumonisin B_1 with glucose include *N*-(1-deoxy-D-fructos-1-yl)fumonisin B_1, *N*-methylfumonisin B_1, *N*-(carboxymethyl)fumonisin B_1, *N*-(3-hydroxyacetonyl)-fumonisin B_1, *N*-(2-hydroxy-2-carboxyethyl)fumonisin B_1 and *N*-methylfumonisin B_1.

Toxicity of fumonisins is caused by inhibition of the enzyme sphingosine *N*-acetyltransferase (ceramide synthase) due to the structural similarity of fumonisins with sphingosine (see Section 3.5.1.1.3). The toxic effects are closely related to the presence of the amino group in the molecule of fumonisin; the reaction products with reducing sugars are virtually non-toxic as the amino group is blocked. Fumonisin B_2 is more cytotoxic than fumonisin B_1.

The assessment of dietary risk of exposure to fumonisins is relatively complicated with regard to a variety of individual mycotoxins. In some types of maize products, fumonisins that are not currently monitored may significantly contribute to the toxic effects. Fumonisins cause a number of livestock diseases, such as mycotoxicosis known as Equine LEucoencephaloMalasia (ELEM) in horses or Porcine Pulmonary oEdema (PPE) in pigs. Intoxication by higher doses of mycotoxins can be fatal in both cases. In connection with the possible occurrence of fumonisins in foods, their hepatotoxicity and nephrotoxicity to humans and carcinogenicity demonstrated

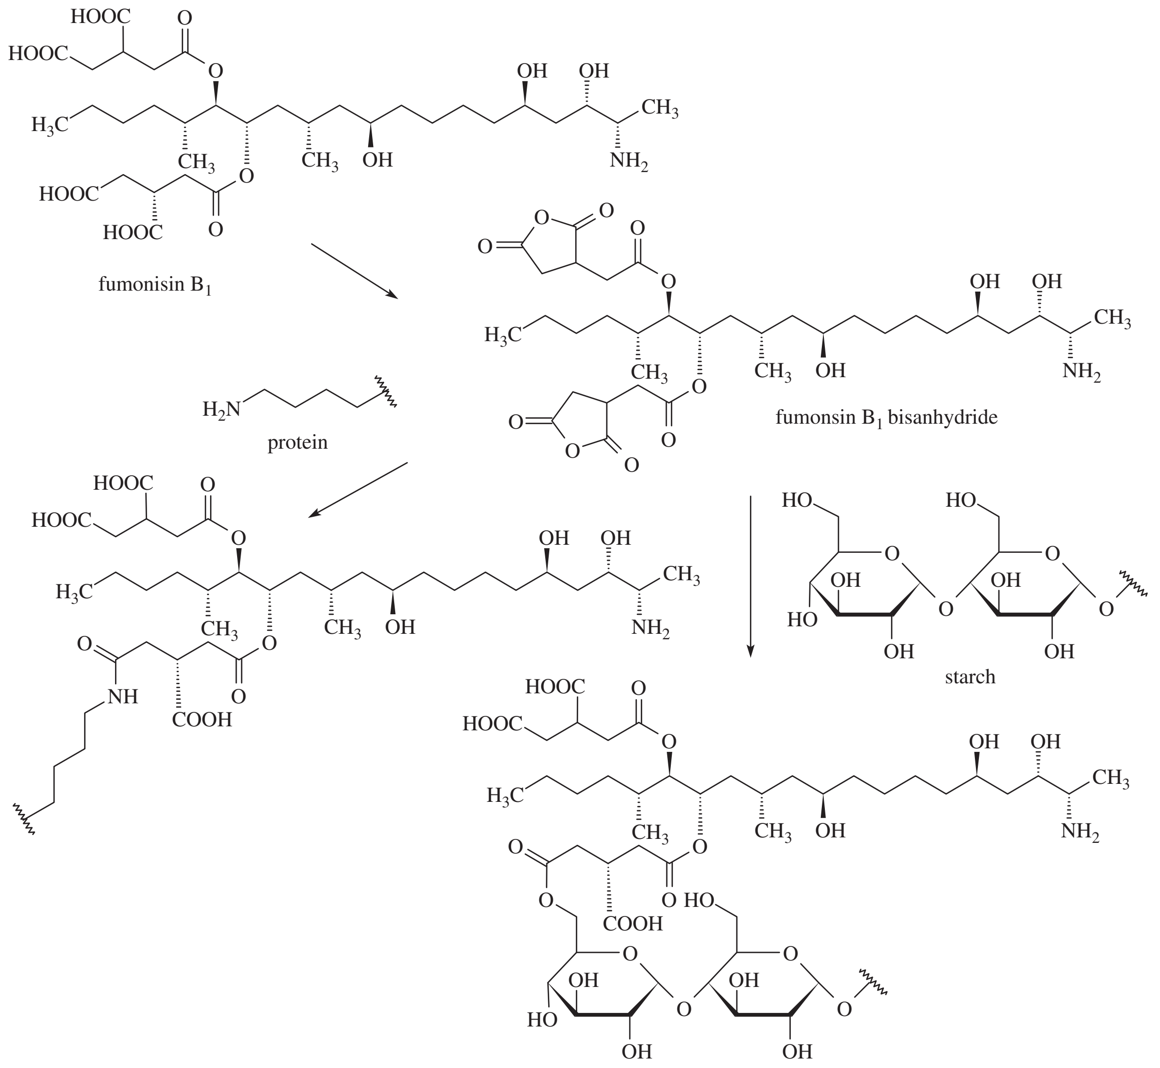


Figure 12.44 Reaction of fumonisin B_1 with proteins and starch.

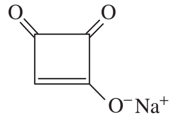
in animals are often discussed. Studies from South Africa and China document a possible contribution of high doses of fumonisins from maize in the aetiology of human oesophageal cancer. According to the IARC, fumonisins are classified as class 2B carcinogens,[3] and are characterised as promoters of carcinogenic processes. For fumonisins B_1 and B_2, maximum limits are set for the sum of two major mycotoxins (Table 12.23) in selected cereal commodities. The tolerable daily intake (TDI) for fumonisins B_1, B_2 and B_3 alone or in combination is 2 μg/kg body weight.

Moniliformin

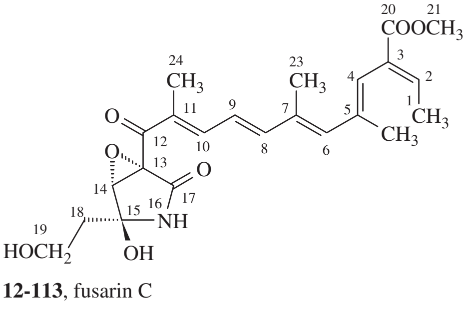
Moniliformin sodium salt (sodium 3-hydroxycyclobut-3-ene-1,2-dione, **12-112**) was originally isolated from substrates attacked by fungus *Fusarium moniliformis* (syn. *F. verticillioides*). Now five producers of this genus are known (*F. avenaceum*, *F. subglutinans*, *F. proliferatum* and others). Moniliformin is most often found in maize, but is also phytotoxic to wheat and tobacco. Poultry is very sensitive to this mycotoxin, especially chickens and ducklings. The toxicological evaluation of this toxin is not yet complete and hygienic limits have not been established.



12-112, moniliformin

Fusarin C

Fusarin C (**12-113**) is a co-metabolite of the parasitic fungus *Fusarium moniliformis* (syn. *F. verticillioides*) occurring primarily on maize, but it was also found, along with moniliformin, in other cereals. Of the nine known producers of fusarin C (*F. graminearum*, teleomorph of *G. moniliformis Gibberella fujikuroi*, *Fusarium venenatum* and others), seven have been isolated from European crops and soils. Fusarin C is a potent mutagen and a potential human carcinogen. From this perspective, its toxicity is similar to that of aflatoxin B_1 and sterigmatocystin.



12-113, fusarin C

Ergot alkaloids

Ergot fungi refer to a group of fungi of the genus *Claviceps*, which includes about 50 species occurring mostly in the tropical regions. The most prominent member of the genus *Claviceps* is the common fungus *C. purpurea*. This fungus parasitises on certain cereals, especially on rye and triticale, but also on wheat. The infested grain is transformed by the fungus into black-to-dark purple sclerotium, known as ergot. In some cereals, ergot bodies may reach up to 20 mm in length, but in forage grasses they remain small and slender. Cereal heads may contain one or several ergot bodies, which contain an interesting group of ergot alkaloids with a wide range of biological effects. Ergot alkaloids are used today in medicine, especially in neuroendocrinology and in treatment of diseases associated with impaired neural transmission in both the central and peripheral nervous systems (e.g. migraine, Parkinson's disease or senile dementia).

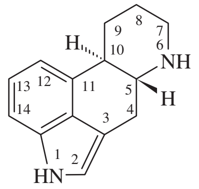
Historically, these alkaloids sometimes caused a very serious disease called ergotism, the first mycotoxicoses described in humans. Epidemics of ergotism were documented in ancient Greece and large epidemics were recorded in the Middle Ages in Europe, particularly in populations that relied on bread prepared from rye flour which was contaminated by ergot alkaloids. *Ergotism gangraenosus* was a type of poisoning that affected the circulatory system (symptoms included swelling of the limbs, their inflammation and, in the last stage, gangrene), while *ergotism convulsivus* was manifested primarily by an impaired nervous system (symptoms were hallucinations and ecstasy). The apparent randomness of these epidemics and the helplessness of people against their effects were still fertile ground for the spread of religious beliefs in the early modern period, as evidenced by the name of the diseased state: Holy Fire ('*ignis sacer*' in Latin) or St. Anthony's fire ('*ignis sancti Antonii*'). The last case of mass-poisoning in Europe was described in the French village of Pont-Saint-Esprit in 1951. Outside Europe, a milder convulsive form of ergotism with no fatalities occurred in India in 1975. The last recorded outbreak of gangrenous ergotism occurred in Ethiopia in 1977–1978, when 140 people showed signs of intoxication with high mortality (34%). In 2002, a severe outbreak of gangrenous ergotism was again reported in Ethiopia.

In the last two decades, investigations have indicated an increase in the occurrence of *Claviceps purpurea* infections. This increase seems to be associated with the more extensive use of hybrid varieties of rye and perennial rye breeds and changes of agro-technical practices, especially in years when continuous moist conditions prevail during the stages of the disease cycles. First, moisture is needed at the soil surface during spring and early summer to promote germination of ergot bodies. Second, wet, cloudy and cool weather extends the period of flowering and increases the possibility for spores to enter the florets. Favourable temperatures for their growth are in the range of 18–30 °C. Unfortunately, there is not much a farmer can do to control ergot in the field, but ergot bodies are relatively easy to clean from the seed lot, especially if a gravity separator is used.

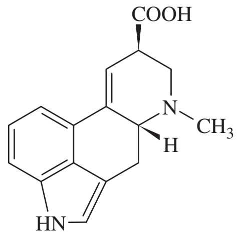
The ergot sclerotia contain from 0.15 to 0.5% alkaloids synthesised by a combination of fungal and plant metabolisms and more than 50 have been characterised. Ergot alkaloids are 3,4-disubstituted indole derivatives derived from the tetracyclic ring of ergoline, (6a*R*)-4,6,6a,7,8,9,10,10a-octahydroindolo[4,3-*fg*]quinoline (**12-114**), which has a C-9 double bond, a methyl group at N-6 and is substituted at C-8, therefore ergot alkaloids are in fact derivatives of lysergic acid, also known as (+)-D-lysergic acid

(**12-115**) and by chemical name 7-methyl-4,6,6*a*,7,8,9-hexahydroindolo[4,3-*fg*] quinoline-9-carboxylic acid, or 6-methylergol-9-ene-8-carboxylic acid, which is typically bound as an amide with an amino alcohol as in ergometrine (**12-116**) or with a small polypeptide structure as in ergotamine (**12-117**). The building blocks for lysergic acid are tryptamine and an isoprene unit. The relative representation of individual alkaloids is different in various producer strains and also differs depending on the host plant and of environmental factors. Ergot alkaloids are accompanied by simpler bases, biogenic amines (such as histamine and tyramine) and betaines (2-mercaptohistidine known as ergothioneine, **2-56**). Ergot alkaloids can be divided according to the structure into three main groups:

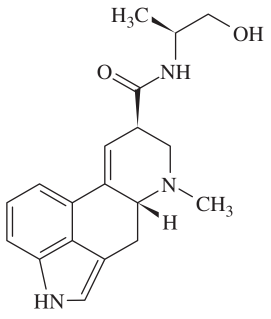
- clavines (hydroxy- or dehydroderivatives of 6,8-dimethylergoline)
- simple lysergic acid derivatives (typically amides)
- peptide ergot alkaloids known as ergopeptines (peptides derived from lysergic acid).



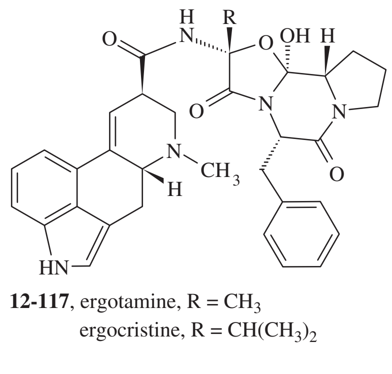
12-114, ergoline



12-115, lysergic acid

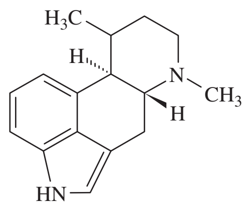


12-116, ergometrine

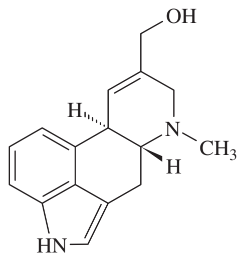


12-117, ergotamine, R = CH_3
ergocristine, R = $CH(CH_3)_2$

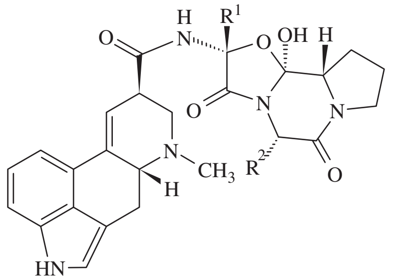
Clavines (clavine alkaloids), such as agroclavine (**12-118**) and elymoclavine (**12-119**) are considered precursors to other ergot alkaloids. At the end of the 1930s, a hallucinogenic drug – lysergic acid diethylamide (LSD) – was synthesised by modification of natural derivatives of lysergic acid. In terms of chemical food safety, the European Food Safety Authority (EFSA) has identified ergometrine (**12-116**), ergotamine, ergocristine (**12-117**), ergocornine, ergosine and ergocryptine (α-ergocryptine) (**12-120**) as the most important mycotoxins.



12-118, agroclavine



12-119, elymoclavine



12-120, ergocornine, $R^1 = R^2 = CH(CH_3)_2$
ergosine, $R^1 = CH(CH_3)CH_2CH_3$, $R^2 = CH_3$
ergocriptine, $R^1 = CH(CH_3)_2$, $R^2 = CH(CH_3)CH_2CH_3$

During processing of contaminated grains, alkaloids from the sclerotium may pass into flour and then into the final products, but concentrations of ergot alkaloids in contaminated flours rarely exceed 0.1 mg/kg. Rye flours may commonly contain higher amounts of alkaloids than wheat flours. For example, a monitoring of Swiss flours in 1985 found that the total alkaloid content in rye flours was 0.015–0.397 mg/kg and in white and brown wheat flours 0.004 and 0.103 mg/kg, respectively. Monitoring in Sweden in 1993 found the highest concentration in wheat and rye products to be 0.024 mg/kg, with ergotamine as the most frequently detected toxin, while ergocristine was the major alkaloid detected in wheat and rye flour at levels up to 0.062 mg/kg in Canada in 1980.

With the exception of ergometrine, ergot alkaloids are relatively nonpolar compounds and therefore are not very soluble in water. Lysergic acid is a chiral compound with two stereo centres. The isomer with inverted configuration at C-8 close to the carboxy group is called D-isolysergic acid. Inversion at C-5 close to the nitrogen atom leads to L-lysergic acid and L-isolysergic acid, respectively. Alkaloids with a double bond between carbons C-9 and C-10 (ergolenes) are susceptible to epimerisation, especially in non-acidic media (Figure 12.45). The laevo-rotating ergopeptins with configuration (*R*) at C-8 thus give rise to dextro-rotating (*S*)-isomers

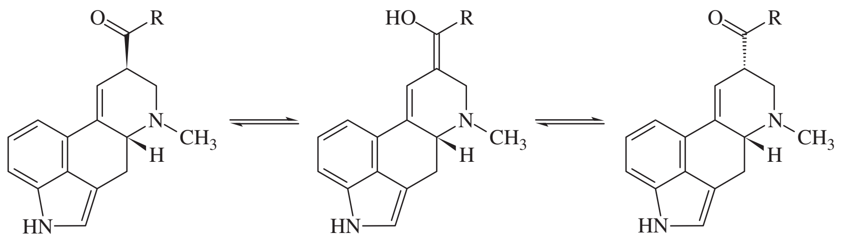


Figure 12.45 Isomerisation (epimerisation) of ergot alkaloids.

(D-isolysergic acid derivatives) that are called ergopeptinins. The individual isomers differ in both biological and physico-chemical properties. Their amount increases with unsuitable conditions of grain storage.

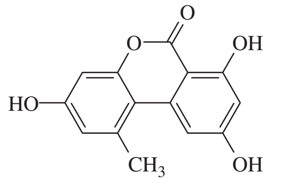
In addition to ergot, ergot alkaloids occur in some higher plants. For example, derivatives of D-lysergic and D-isolysergic acids were isolated from the seeds of beach moonflower (*Ipomoea violacea*) and the related Christmas vine *Turbina corymbosa* (Convolvulaceae). The seeds of beach moonflower were used traditionally among Mexico's Zapotec Indians for ceremonial and curative purposes.

Currently, no country regulates ergot alkaloids in food, and only in Canada and Uruguay are ergot alkaloids regulated in feeds. For example, the Canadian guideline limits for ergots in feed for swine is 6000 μg/kg, 3000 μg/kg in feed for dairy cattle, sheep and horses and 9000 μg/kg for chicks. In the EU the issue of ergot alkaloids is currently under discussion by CONTAM, an EFSA panel, and maximum limits at a level of 400–500 μg/kg in grain intended for human consumption are being discussed. For example, in India regulatory measures exist for the occurrence of ergot bodies in cereals and the designed limit is 0.01% (1 ergot body per 10 000 grains). At present, the maximum permissible level in the United States and Canada is 300 mg ergot per kg grain. Feed materials exceeding this limit are labelled 'ergoty'.

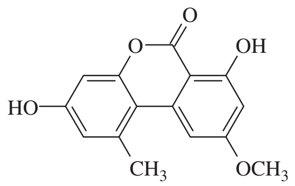
Alternaria toxins

Many species of the genus *Alternaria* can invade crops at the pre- and preharvest period and cause considerable losses due to rotting of various food crops, mainly fruits and vegetables. Owing to their ability to grow even at low temperatures, they are also responsible for spoilage of these commodities during refrigerated transport and storage. Several *Alternaria* species are known producers of toxic secondary metabolites known as *Alternaria* mycotoxins. The best-known representative of these fungi is *A. alternata* found on cereals, sunflower seeds, oilseed rape, olives, various other fruits and vegetables, especially on tomatoes.

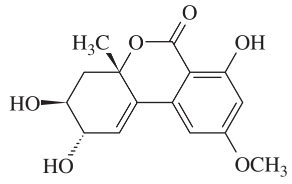
Alternaria mycotoxins can be divided into three groups based on their structure. The first group are derivatives of dibenzopyrone, which include alternariol, 3,7,9-trihydroxy-1-methyl-6*H*-dibenzo[*b*,*d*]pyran-6-one (**12-121**), isolated in 1953 as the first alternaria toxin, alternariol monomethyl ether, 3,7-dihydroxy-9-methoxy-1-methyl-6*H*-dibenzo[*b*,*d*]pyran-6-one (**12-122**) and altenuene, 2α,3α,4aβ-tetrahydro-2,3,7-trihydroxy-9-methoxy-4a-methyl-6*H*-dibenzo[*b*,*d*]pyran-6-one (**12-123**). The second group includes derivatives of perylene represented by altertoxin I, 1,2,7,8,12b-pentahydro-1,4,6b,10-tetrahydroxyperylene-3,9-dione (**12-124**) and derived epoxide altertoxin II, perylo(1,2-b)oxirene-7,11-dione (**12-125**). In the third group are tetramic acid (1,5-dihydro-4-hydroxy-2*H*-pyrrole-2-one) derivatives, which include the most studied mycotoxin of this group tenuazonic acid, (5*S*,6*S*)-3-acetyl-5-*sec*-butyl-4-hydroxy-3-pyrrolin-2-one (**12-126**).



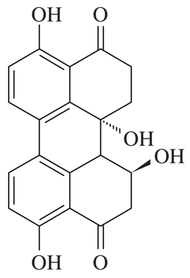
12-121, alternariol



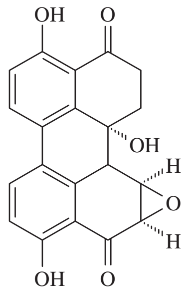
12-122, alternariol methyl ether



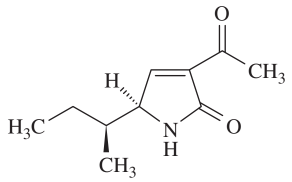
12-123, altenuene



12-124, altertoxin I



12-125, altertoxin II



12-126, tenuazonic acid

Information on the occurrence of alternaria mycotoxins in food and feed is relatively limited. For example alternariol, its methyl ether and tenuazonic acid were frequently detected in apples, apple products, apple juice concentrates, mandarins, olives, pepper, red pepper, tomatoes, tomato products, oilseed rape meal, sunflower seeds, sorghum, wheat and edible oils (olive oil, rapeseed oil, sesame oil and sunflower oil). The maximum levels reported in foods are

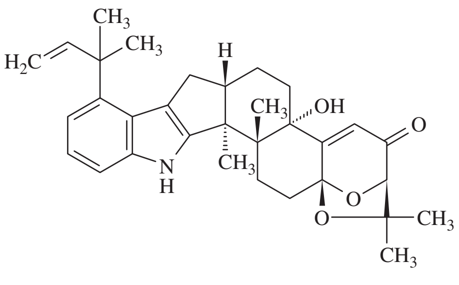
in the range of about 1–1000 μg/kg; higher levels are commonly found in visibly infected rotted products that are not suitable for consumption. Alternaria mycotoxins are relatively stable under conditions of technological and culinary food processing.

Exposure to *Alternaria* toxins has been linked to a variety of adverse health effects. They exhibit only low acute toxicity (the most toxic substance is tenuazonic acid) and their chronic toxic effects are not yet fully described. Mycotoxicoses however were described not only in animals, but have also been associated with alimentary toxic aleukia, a frequently fatal mycotoxicosis that followed the ingestion of overwintered grain or grain byproducts infested with fungi. This intoxication primarily affected poor rural families in the former USSR in the 20th century. Toxicological studies demonstrated the ability of tenuazonic acid to inhibit protein synthesis; alternariol and its methyl ether were shown to be teratogenic. Alternaria toxins are generally highly cytotoxic (for bacterial and mammalian cells) and from a toxicological point of view altertoxins are of the highest concern, probably being mutagenic, but their mutagenicity is at least one order of magnitude lower in comparison with aflatoxin B_1. Exposure limits as tolerable daily intake (TDI) or a Provisional Maximum Tolerable Daily Intake (PMTDI) for alternaria toxins have not been derived. Monitoring of foods may give impetus to further toxicological studies.

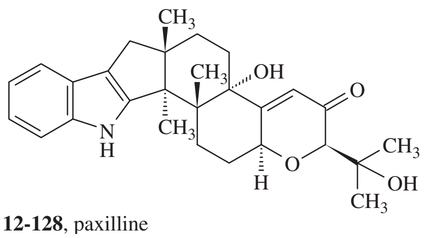
Tremorgens

Tremorgens include a rather heterogeneous group of more than 30 alkaloids (indole diterpenoids). Producers of tremorgens are fungi of the genus *Aspergillus* and also fungi of some other genera, such as *Penicillium* or *Claviceps*. The first tremorgen aflatrem, 9-(1,1-dimethylprop-2-en-1-yl)-2,3,5b,6,7,7aα,8,13,13b,13c,14,15-dodecahydro-5bβ-hydroxy-2,2,13bβ,13cα-tetramethyl-4*H*-3β,15aβ-epoxy-1-benzoxepino[6′,7′:6,7]indeno[1,2-*b*]indol-4-one (**12-127**) was isolated from the mycelium of *Aspergillus flavus* and is also produced by other *Aspergillus* species, such as *A. miniscle-rotigenes*. Another example of this group of mycotoxins is paxilline (or paxiline, **12-128**), which is produced by fungus *Penicillium paxilli*. Fungus *Claviceps paspali* produces ergot alkaloids in sclerotia and also tremorgens called paspalitrems, such as paspalitrem A (**12-129**), B and C. Paspalitrem B contains a 3-hydroxy-3-methylbut-1-(en-1-yl) unit instead of 3-methylbut-2-en-1-yl unit and paspalitrem C differes from paspalitrem A only by the position of attachment of the 3-methylbut-1-en-1-yl substituent to the indole ring.

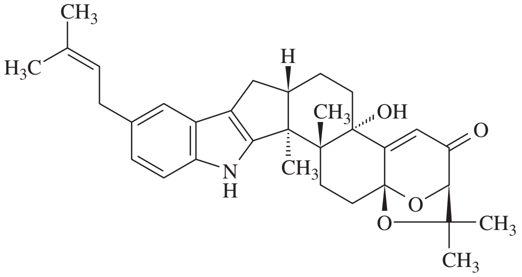
Tremorgens were found in a number of commodities, such as maize, wheat, nuts, silage and other feeds. Tremorgenic mycotoxins



12-127, aflatrem



12-128, paxilline



12-129, paspalitrem A

induce neurologic symptoms ranging from mental confusion to tremors, seizures and death, and are apparently the only class of mycotoxins with significant central nervous system activity. Tremorgens have been implicated in a number of neurologic diseases of cattle, collectively known as staggers syndromes. They pose significant agricultural and health problems for both cattle and humans. Toxicological evaluation of tremorgens is not complete and hygienic limits have not been established.

12.3.1.2.2 Human exposure

Unequivocally, the most important route of human exposure to mycotoxins are contaminated foods, although in certain circumstances a significant risk may be associated with the inhalation of mould spores or dust particles containing mycotoxins (such as when handling contaminated material). Contamination of the pharmaceutical preparations prepared by biotechnological processes, in which the filamentous fungi are used, is also possible. Exceeding of health limits for individual mycotoxins in foods in the European Union happens only in extremely rare cases. Health risks of lifelong (chronic) exposure even to very low concentrations of mycotoxins (often represented by several compounds) are essentially unknown.

12.3.1.2.3 Mitigation

Preventive measures

The optimum way to reduce the occurrence of mycotoxins in human food represents a complex of three basic preventive measures:

- reduction of infection by toxinogenic fungi in the growth period of crops;
- fast and efficient drying of harvested crops and their proper storage;

- use of fungicides to inhibit growth of fungi and fungal spores in the growth period of crops and during crop storage.

In many cases it is also necessary to address the situation when food raw materials or final food product are already contaminated with mycotoxins. Their at least partial rescue can sometimes be solved by using a variety of physical, chemical or biological methods.

Preharvest measures

Measures to minimise contamination of agricultural crops in the preharvest period are closely related to the aspects listed previously. These measures can significantly reduce the incidence of toxins produced by fungi of the genus *Fusarium* (trichothecenes and zearalenone), ergot alkaloids, tremorgens and even aflatoxins. Historically, the oldest successeful method is a reduction in the amounts of ergot alkaloids through effective application of preventive measures, such as crop varieties resistant to mould infestation, crop rotation and application of fungicides. Besides conventional techniques, innovative approaches are now increasingly applied, such as the outputs of genetic engineering or the use of so-called biocompetitive factors. For example, cereals deliberately infected with spores of competitive non-toxinogenic strains of *Aspergillus flavus* contain only traces of aflatoxins.

Postharvest measures

The successful protection of crops against fungal attack begins at the moment of harvest. Crops must be harvested at full maturity, when their humidity is low, or must be dried before storage. With regard to the manufacturing industry, all types of physical methods can extend food shelf life, such as pasteurisation, sterilisation, cooling, vacuum packaging or irradiation, and can be seen as a precautionary measures. In practice chemical methods are also occasionally used, and include the use of various preservatives, such as sorbic, benzoic or propionic acids.

Detoxifying

Although the above discussed preventive measures can help to reduce the occurrence of mycotoxins in the human food chain, exclusion of toxinogenic microflora is technically impossible and in many cases it is necessary to detoxify and decontaminate large amounts of crop or feed in order to protect the health of consumers or livestock, and to prevent economic losses. In practice, detoxification or decontamination procedures include degradation of mycotoxins to inactive products, prevention of new toxic products formation and maintaining the nutritional value of the material. Generally, there are three possible solutions based on physical, chemical or biological principles.

Physical methods A specific feature of contamination of agricultural crops with mycotoxin is the extreme homogeneity of their distribution. Concentrations of mycotoxins in infected grains or seeds may reach as high as tens of mg/kg. For this reason, an effective measure to reduce the risk of food contamination is mechanical removal of attacked particles. A decrease in the content of mycotoxins may be also achieved by washing or milling the infected grains.

Heat treatment of contaminated materials decreases mycotoxin concentrations in many cases. Aflatoxins are especially thermostable and a significant decrease in their content occurs at temperatures of about 200 °C. Ergot alkaloids and zearalenone are also very stable at high temperatures.

The effective removal of aflatoxins from oilseed meals can be achieved by using different solvents (such as acetone or ethanol), but this process is cost-consuming and also leads to a loss of nutrients and may affect the organoleptic properties of oilseed meals. Aflatoxin residues which may be present in crude vegetable oils are removed during refining.

The use of different sorbents for the removal of mycotoxins has been the subject of intense studies. Aflatoxins may be removed from milk, cream or peanut oil using hydrated calcium aluminosilicate clay or bentonite. These mineral materials are sometimes added directly to feed to immobilise mycotoxins in the digestive tract of livestock (reducing the transfer into the blood stream). For example, the addition of hydrated calcium aluminosilicate to the feed of dairy cows decreases excretion of aflatoxin M_1 to milk by 24–44%. Experiments with the immobilisation of zearalenone have been promising. However, the question remains as to whether the use of these chemisorbents does not reduce the intake of some essential minerals (such as copper, zinc and iron) and water-soluble vitamins.

Chemical methods The greatest attention has been paid to the possibility of chemical degradation of aflatoxins. The most important method is decontamination with ammonia. Other agents tested were sodium hypochlorite and hydrogen peroxide. Practical application of the last two agents is problematic due to unwanted oxidation of a number of treated material components. Aflatoxins B_1 and G_1 and patulin are partially degraded by sulfur dioxide.

Biological methods Biological detoxification in practice means biotransformation or biodegradation of mycotoxins by the action of enzymes, which generates metabolites that are non-toxic or less toxic than the starting toxin and can be easily eliminated from the body. Bacteria studied in this respect are *Flavobacterium aurantiacum* and some fungi of the genus *Rhizopus*. Biotechnological methods have many advantages over chemical methods, as they do not use aggressive agents deteriorating material properties and are often beneficial as they improve the digestibility and usability of proteins. Promising results in detoxification of trichothecenes, for example, have been brought about by biotechnological methods utilising microflora of the gastrointestinal tract of monogastric animals.

12.3.2 Bacteriotoxins

In terms of chemical food contamination, mycotoxins undoubtedly represent the most monitored group of pollutants, but many bacterial pathogens that produce diseases similarly have the ability

to produce toxins (toxigenesis). Two main groups of bacteriotoxins are recognised, lipopolysaccharides (lipooligosaccharides) and proteins (polypeptides). Lipopolysaccharides (lipooligosaccharides) are **endotoxins** associated with the cell walls of Gram-negative bacteria. Proteins (polypeptides) are **exotoxins**, which are usually secreted by bacteria or released by lysis of bacterial cells and act at a site removed from bacterial growth. Exotoxins can be further classified by toxic effects at the site of damage. The names of toxins indicate the location for their activity:

- **enterotoxins** are toxins that attack the intestinal mucosa and cause diarrhea are generated in the intestines
- **cytotoxins** are toxic to cells of exposed organisms
- **neurotoxins** interfere with the transmission of nerve impulses.

Bacterial protein toxins are the most powerful human poisons and their production is generally species specific. Usually, virulent strains of the bacteria produce toxins, while non-virulent strains do not. Most cases of food poisoning are infections caused by bacteria, such as *Salmonella* and *Campylobacter*; less common, but fatal, are intoxications caused by bacteria *Clostridium botulinum*. Fortunately, bacterial toxins occur relatively rarely in the human diet and generally accepted hygienic limits have not been established.

The most effective way to minimise food-borne poisoning caused by bacterial toxins is to respect the principles of HACCP (Hazard Analysis Critical Control Points) in food production and handling. Uniform principles for food producers and their responsibility for food safety are governed by Regulation (EC) No. 852/2004 concerning hygiene in production, distribution and sale of food and introduction of critical control points (HACCP) as preventive tools for ensuring food safety. For foods of animal origin, these requirements are further specified in Regulation (EC) No. 853/2004.

12.3.2.1 Botulotoxins

Botulinum toxins (botulotoxins) produced by bacteria *Clostridium botulinum* are extremely toxic proteins consisting of a sequence of about 1300 amino acids, but not all strains of *C. botulinum* produce these toxic metabolites. Seven toxigenogic types of bacteria exist, each producing a distinct form of botulinum toxin that may cause botulism. The toxins are designated A–G, most of which have several subtypes. Particularly toxic are types A, B, E and F. In Europe, the most frequently occurring toxin is the type B toxin. In the United States, the type A toxin is the most significant cause of botulism. Botulinum toxins may enter the human body by ingestion of toxin from foods (food-borne botulism), but also by certain other pathways.

Production of botulinum toxins proceeds under anaerobic conditions, and the optimum conditions for their formation in foods are pH 4.8–8.5 and temperature of about 30 °C, but toxins are also produced at lower temperatures. Botulinum toxins have been known since the 18th century when they were described as a 'sausage poison', because they arose from improperly handled or prepared meat products. Even nowadays, they can be found in very rare cases in non-acidic canned products, such as sausages and some other meat products.

Owing to the extreme danger of botulinum toxins (intoxication might be lethal), the possibility of preventing their occurrence in foods has been studied extensively. The most important aspect of botulism prevention is proper food handling and preparation. The spores of *C. botulinum* can survive boiling (100 °C at normal pressure) for more than 1 h although they are killed by autoclaving. Because the toxin is heat-labile boiling or intense heating of contaminated food (e.g. heating at 80 °C for 10 min or cooking at 100 °C for several seconds) will inactivate the toxin. Food containers that bulge may contain gas produced by *C. botulinum* and should not be opened or tasted. Nitrites have inhibitory effects (see Section 11.2.1.3.2).

12.3.2.2 Other bacterial toxins

Toxic products may, under certain circumstances, produce a range of bacteria. Their toxins might be present in food at the time of consumption, as in the case of some metabolites of the genus *Staphylococcus*, especially *S. aureus*, which produces seven neurotoxins (toxic proteins). The most common cause of staphylococcal food poisoning are toxins of types A and D (individually or in combination). *Clostridium perfringens* (of type A–E) produces four major toxins (α, β, ε and ι). The cause of food poisoning (gastroenteritis) is mainly *C. perfringens* of the type A producing toxin α, which shows the activity of phospholipase C. Another cause of food poisoning (gastroenteritis) is often bacteria *Bacillus cereus*.

In non-invasive infections, bacteria reproduce and produce toxins in the digestive tract. Most attention in this regard is given to toxins produced by the bacteria *Vibrio cholerae* (the causative agent of cholera), the strain 0157:H7 of *Escherichia coli* (a cause of poisoning called colitis) and, finally, to substances produced by bacteria of the genus *Salmonella*, especially *S. enteritidis* PT4 (*Salmonella enterica* ssp. *enterica* serovar *enteritidis*), which causes diarrhea (the poisoning is called salmonellosis, which in people at risk, such as infants, small children and the elderly, can become very serious). Often a cause of diarrhea known as schigellose are toxins of bacteria *Shigella sonnei*. Previously rare, but more often encountered today is campylobacteriose, caused by bacteria *Campylobacter jejuni* and other infections, such as jersiniose (*Yersinia enterocolitica*), vibriose (*Vibrio parahaemolyticus*) and listeriose (*Listeria monocytogenes*). The pathogens present in the food may also include some viruses, such as the hepatitis A virus that causes infectious hepatitis in humans.

12.4 Persistent organohalogen contaminants

An undesirable consequence of some anthropogenic activities in the 20th century was, and still is, a series of environmental contaminations caused by persistent organic pollutants (POPs),

such as polychlorinated biphenyls (PCBs) and polychlorinated dibenzodioxins (PCDD). Persistence in the environment is a characteristic property of certain chlorinated aromatic and cyclodiene pesticides. These compounds are characterised by high resistance to oxidation and hydrolysis (particularly the chlorine bound to the aromatic ring carbon is very stable); therefore their degradation and biotransformation are very slow. Generally, resistance to photolysis and biodegradation increases with the number of halogen atoms in the molecule. POPs are non-ionisable substances with only very limited solubility in water. Their ability to penetrate through the phospholipid structures of biological membranes (which limits their bioavailability) leads to bioaccumulation in tissue lipids of living organisms, including humans. An exception is perfluorinated contaminants that bind to proteins (see Section 12.4.3.2). The bioaccumulation process involves the biological sequestering of a substance that enters the body either by respiration, food intake or dermally. The result of these processes is the growth of its concentration in the sequestering medium (lipids) compared with the surrounding environment. The degree of bioaccumulation depends on the speed and type of intake, the rate of elimination from the body, the extent of biotransformation, lipid content in the organism and environmental factors. Bioaccumulation in food chains is associated with the risk of chronic toxic effects (even if concentrations of POPs in the environment are not high), which increases with the value of the residence time of the pollutant in the body (non-toxic chlorofluoro substituted aliphatic hydrocarbons, although persistent and causing undesirable phenomena in the atmosphere are not classified as POPs). After their release into the environment, POPs can quickly be transported great distances through a series of evaporation, transportation and condensation cycles. As a result of global circulation patterns and the low evaporation rates in cold climates, POPs tend to accumulate in arctic regions where they bioaccumulate in living organisms. A prerequisite is that the vapour pressure of the pollutant is lower than 1000 Pa. The burden of the Arctic ecosystem and mountain areas is particularly worrying. For example, in Canada's Arctic region, the level of POPs in the breast milk of Inuit women has been found to be up to nine times higher than in women living in southern Canada.

Because of their ability to be transported long distances globally by water and air, controlling POPs require global commitment and action. Accumulaton of information on the risks arising from the presence of POPs in the environment (usually as the result of exposure, interference with hormonal processes and damage to some organ systems, neurotoxicity, immunotoxicity, mutagenicity and carcinogenicity) was initiated in 1995 (by the United Nations Environment Programme, UNEP) in a series of intergovernmental negotiations, which culminated in 2001 in the adoption of the Stockholm Convention, which obliges signatory countries to restrict the selected substances, their production, use and release into the environment. The Stockholm Convention requires, in the case of intentionally produced substances (some classic organochlorine pesticides and the production of their intermediates) their prohibition or phasing out of the production, use, export or import (except DDT, which can still be used in the fight against malaria, until safer effective means are found). The case of untargeted

Table 12.25 Properties of substances with a high potential for bioaccumulation (indicative figures).

Criteria[a]		Criteria values
Bioaccumulation	log K_{OW}	>5
	or bioaccumulation factor	>5000
Persistence (half-life)	Water	2 months
	Soil	6 months
	Sediment	6 months
Transport to distant localities (half-life)	Air	>2 days

[a] According to the Stockholm convention.

produced POPs (primarily polychlorinated dioxins and furans) highlights the need to reduce and gradually eliminate the emissions into the environment.

Table 12.25 briefly summarises the basic criteria that must be met by contaminants to be classified as POPs. Table 12.26 lists the original POPs included in the Convention, along with other high-risk pollutants, which were included in 2009 in the light of the (then) latest information. Also linked with efforts to restrict the movement of persistent substances in the environment is the implementation of the new EU policy REACH (Registration, Evaluation and Authorisation of CHemicals), which represents a new chemical control system to ensure that, by 2020 at the latest, only compounds with known properties are used in a manner that protects the environment and human health.

The following sections present, from the perspective of human dietary exposure, the major groups of POPs, representing industrially manufactured products and intermediates and untargeted pollutants. Classical persistent organochlorine pesticides are included, together with modern pesticides, in Section 12.6

12.4.1 Polychlorinated biphenyls

Polychlorinated biphenyls (PCBs) belong to a broad family of man-made organic chemicals known as chlorinated hydrocarbons. They are probably one of the world's most watched groups of POPs. PCBs were manufactured from 1929 until 1979, when their manufacture was banned. They show a range of toxicities and vary in consistency from thin, light-coloured liquids to yellow or black waxy solids. Owing to their low acute toxicity, non-flammability, chemical stability, high boiling points and electrical insulating properties, PCBs were used in hundreds of industrial and commercial applications, including electrical, heat transfer and hydraulic equipment, were used as lubricants, additives to pesticides, plasticisers in paints, plastics and rubber products, in pigments, dyes and carbonless copy paper and in many other industrial applications. Table 12.27 summarises the basic facts of

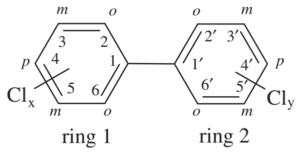
the history of the PCBs production and use. Among other things, there is a documented sequence of new information about the properties of PCBs and continuity of measures that resulted in the restriction of their use and ban.



12-130, polychlorinated biphenyls

12.4.1.1 Structure and nomenclature

PCBs are substances of molecular formula $C_{12}H_{10-(x+y)}Cl_{x+y}$ (**12-130**), where $x+y = 1$–10, $x =$ number of Cl atoms in ring 1, $y =$ number of Cl atoms in ring 2.

Theoretically, 209 individual compounds, called **congeners** (members of the same group), each of which has its own systematic name, can be derived from the basic biphenyl skeleton. Specification of the structure of the individual PCBs (number of chlorine atoms and their position in the aromatic rings of biphenyl) is shown in Figure 12.46. To simplify communication at the level of professional and legislative practice, a uniform nomenclature is used, proposed at the international level (by the International Union of Pure and Applied Chemistry, IUPAC), where congeners have assigned numbers of from 1 to 209 in order of increasing numerical index (2, 3, 4, 22′, 23, 23′, etc.). Existing three isomeric monochlorobiphenyls do not belong to the polychlorinated group of compounds, but are commonly classified as PCBs for practical reasons.

Table 12.27 History of PCB on a global scale.

Year	Events
1881	First synthesis of PCBs
1929	Start of industrial production of PCBs (Monsanto Chemical Company, USA)
1936	Negative health effects in persons who come into contact with the PCBs were demonstarted
1966	Evidence of PCBs occurrence in tissues of animals and humans (Sweden), PCBs classified as global environmental contaminants
1968	Mass poisoning of more than 1000 people by contaminated rice oil (Yushō disease, Japan)
1971	Voluntary restrictions on the distribution of products based on PCBs by Monsanto (only supplied for controlled applications)
1973	WHO working group charged with complex evaluating of PCBs; proposal of restrictions on use of PCBs; restrictions on the manufacture, sale and use of PCBs in OECD countries
1976	Prohibition of the manufacture, processing, distribution and use of PCBs by the US Congress (with the exception of closed systems)
1978	Restrictions on the use of PCBs (except for closed systems) in most advanced industrial countries
1979	Mass poisoning of more than 2000 people by contaminated rice oil (Yu-cheng disease, Taiwan); federal law banned US production of PCBs
1983	Voluntary cessation of production PCBs by the German company Bayer
1987	Ban on all new applications of PCBs in 24 OECD countries; the intensification of solving problems connected with the replacement of the existing PCBs and providing suitable means of PCBs disposal

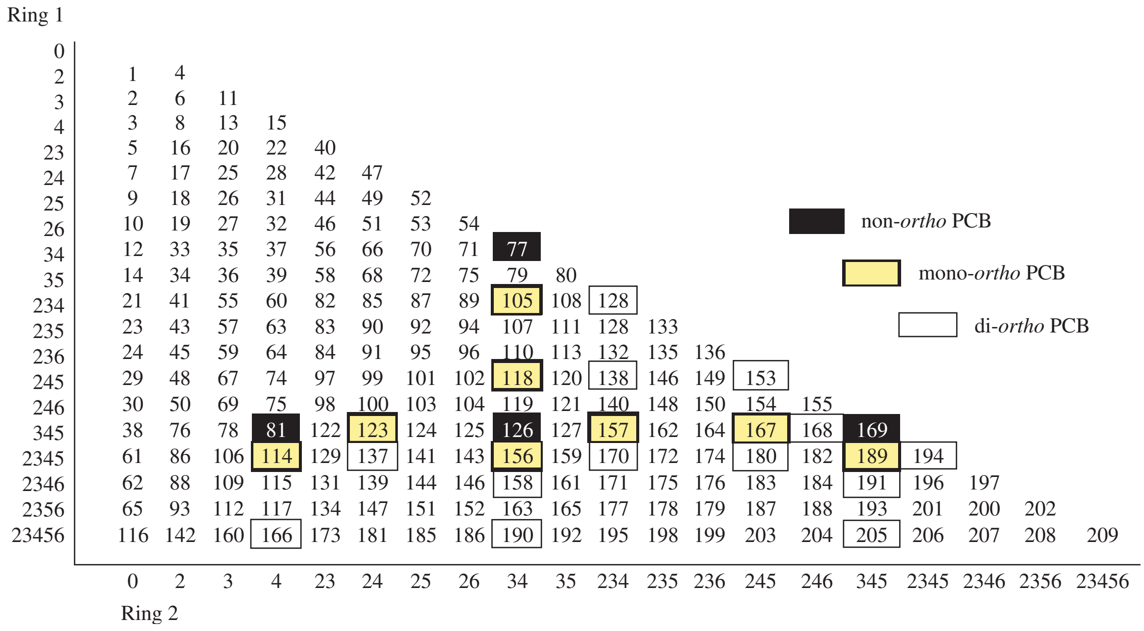


Figure 12.46 Structure of PCB congeners and their labelling according to IUPAC (the axes show the positions of chlorine atoms in the biphenyl aromatic rings, white rectangles = non-*ortho* PCB, grey rectangle = mono-*ortho* PCB).

Table 12.28 Characterisation of groups of PCBs.

Molecular formula of isomer groups	Trivial name	Basic relative molecular weight[a]	Average relative molecular weight[b]	Chlorine content (% w/w)	Number of isomers
$C_{12}H_9Cl$	MonoCB[c]	188.0	188.7	19	3

[a] Isotope ^{35}Cl (relative atom weight = 34.969), ^{12}C (12.011) and ^{1}H (1.008).
[b] Corresponds to the natural occurrence of C, Cl and H isotopes.
[c] CB=chlorobiphenyl.

Planar congeners containing up to two substituents in the *ortho* position are indicated, which are further discussed in the context of their biological activity relative to dioxins. Also highlighted are so-called **indicator congeners** that are employed as markers of contamination. Table 12.28 presents the characterisation of the individual PCBs resulting from the number of bound chlorine atoms.

In unsubstituted biphenyl phenyl, the residues can freely rotate around the single bond connecting the aromatic rings (the planar conformation with the lowest energy content is preferred), however, the conformation of PCBs depends on the number and position of substituting chlorine atoms (they are bulkier than hydrogen atoms in the parent compound), which may prevent rotation. Substituents in the *ortho* position play a particularly important role. At a high degree of substitution, the relative position of aromatic rings is orthogonal and conformations of molecules determine not only the physico-chemical properties of individual congeners, but also their toxic effects.

12.4.1.2 Production

PCBs were manufactured by controlled chlorination of biphenyl catalysed by ferric chloride or iron filings. Technical mixtures used in practice (a chlorine content of 21–68% w/w) were obtained by fractional distillation of the neutralised reaction mixture. The presence of individual congeners in the reaction mixture depends on the conditions of chlorination. Chlorine (substituent of the first order) preferentially enters the *ortho* and *para* positions of biphenyl. Therefore, the presence of certain congeners in technical mixtures of PCBs is very unlikely and they only occur as minor components. In most products only about 100–140 congeners are found in significant concentrations (>0.05% w/w), but technical mixtures with the same chlorine content from various manufacturers are never completely identical. The largest share of manufactured PCBs in the world falls to technical mixtures with the trade name Aroclor, manufactured by Monsanto (USA). A representation of different groups of congeners in these products is shown in Table 12.29 (where the chlorine content in % w/w specify the last two digits in the Aroclor designation). The trademark Aroclor included not only technical PCB mixtures, but also a wide range of products based on polychlorinated compounds, such as Aroclor 5460, which was a mixture of polychlorinated terpenes. Other products also existed on the market, with trade names, for example, Clophen, Phenochlor, Kanechlor, Pyralene and Fenclor. It is estimated that, before their manufacture was halted, global production in countries producing technical PCB mixtures (including the United States, Canada, United Kingdom, Germany, France, Japan, Italy, Sweden, Norway, Finland, Switzerland, Spain, the USSR, Czechoslovakia and Poland) was 1.2×10^6 tons, with most of this amount (about 93%) produced in the United States.

12.4.1.3 Properties

12.4.1.3.1 Physical and chemical properties

The so-called advantageous physico-chemical properties (Table 12.29) which led to widespread use of PCBs are summarised in the following list:

- thermostability
- photostability (resistance to sunlight)
- non-combustibility
- chemical inertness (resistance to acids, bases, oxidation and reduction)

Table 12.29 Distribution of homologues in technical PCB mixtures Aroclor (% w/w) and their lipophilicity.

Number of chlorine atoms	Aroclor 1221	1232	1242	1248	1254	1260
0	10	-	-	-	-	-
1	50	26	1	-	-	-

[a]In μg/l at 25 °C.

- low volatility
- high permittivity (dielectric material, electrical insulators)
- excellent heat transfer properties
- excellent miscibility with organic solvents
- broad interval of melting points (optional consistency)
- relatively high boiling points.

12.4.1.3.2 Persistence in living organisms

Bioaccumulation and bioconcentration are the major events that contribute to the overall occurrence of POPs in biota. As a result, the content of POPs in biota is higher than in the surrounding components of the environment, for example water. The extent of these processes depends on the K_{OW} values. PCBs, as well as other halogenated POPs, are significantly lipophilic substances that have high affinity for the fat in organisms. Table 12.30 represents the average log K_{OW} values and bioconcentration factors (BCF) for fish, which are related by the equation: $BCF = 0.048K_{OW}$. Along with bioconcentration, processes leading to decrease of PCB levels in the organism may also occur (such as metabolic transformation and spawning), so the real level of congeners estimated from bioconcentration factors may sometimes differ significantly. It should be noted that the classification of organic contaminants as POPs considers the bioconcentration factor higher than 5000, which some low-chlorinated PCBs do not meet.

12.4.1.4 Occurrence and main sources

PCBs are found globally in virtually all parts of the environment. Owing to the restrictive measures which have been adopted, their

Table 12.30 Bioconcentration of PCBs in fish.

Trivial names of congener groups	log K_{ow}	Bioconcentration factor (BCF)	Trivial names of congener groups	log K_{ow}	Bioconcentration factor (BCF)
MonoCB	4.7	2500	HexaCB	6.7	250 000
DiCB	5.1	6300	HeptaCB	7.1	630 000
TriCB	5.5	16 000	OctaCB	7.5	1600 000
TetraCB	5.9	40 000	NonaCB	7.9	4000 000
PentaCB	6.3	100 000	DecaCB	8.3	1000 000

concentrations are declining gradually, but some particularly persistent congeners are doing so very slowly. Generally, the composition of PCB mixtures is often significantly different from the profile of PCBs in the environment, especially in biotic samples, where, in addition to differences in physico-chemical properties of individual congeners, often the very different scope of their biodegradation and bioaccumulation is also reflected. To harmonise the communication and interpretation of contamination, seven indicator congeners were selected, these being: PCB 28 (2,4,4′-tetrachloro-), 52 (2,2′,5,5′-tetrachloro-), 101 (2,2′,4,5,5′-pentachloro-), 118 (2,3′,4,4′,5-pentachloro-), 138 (2,2′,3,4,4′,5′-hexachloro-), 153 (2,2′,4,4′,5,5′-hexachloro-) and 180 (2,2′,3,4,4′,5,5′-heptachlorobiphenyl). Sometimes only six PCB markers are followed without congener 118. These congeners are present in technical mixtures in relatively high concentrations and are characterised by medium to high persistence. Sometimes a systematic monitoring includes PCBs 8, 18, 31, 44, 66, 70, 74, 99, 128, 149, 163, 170, 183, 187 and 194 (Figure 12.46). The impetus for the introduction of indicator congeners was a result of the so-called Belgian crisis in 1999, when a feed that was highly contaminated by Aroclors 1254 and 1260 was distributed to many poultry farms and indicator congeners were used for the rapid retrieval of contaminated samples.

The evaluation of health risks is based on the WHO proposal from 1997, which divided PCBs into two groups based on their structure and related toxicity. The first group consists of PCBs able to bind to the Aryl Hydrocarbon Receptor (AHR),[7] which cause toxic effects similar to the toxic effects of dioxins. Among these, the so-called dioxin like PCBs (DL-PCBs), include a total of 12 congeners, four non-*ortho* and eight mono-*ortho* PCBs; the most important in terms of the toxic potential is congener 126 (3,3′,4,4′,5-pentachlorobiphenyl). The second group consists of the non-dioxin like PCBs (NDL-PCBs), which are characterised by different (not necessarily identical) toxicity profiles. The above mentioned seven indicator congeners represent a group of mostly NDL-PCBs, except for mono-*ortho* congener 118.

[7] An Aryl Hydrocarbon Receptor (AHR) is a cytosolic transcription factor in an inactive form bound to co-chaperones. After binding to compounds such as polychlorinated biphenyls and polychlorinated dibenzo-*p*-dioxins, chaperones (special proteins that assist the non-covalent folding/unfolding of many proteins in their correct spatial arrangement) dissociate and AHR is translocated into the cell nucleus, which leads to changes in gene transcription.

12.4.1.4.1 Release into the environment

Owing to their low acute toxicity, until the beginning of the 1970s PCBs were seen as biologically inactive substances. In principle, four types of situations can be identified that lead to PCBs being released into the environment:

- use in open systems (additives for paints and varnishes, plastics, pesticide formulations, inks and print colours);
- storage at authorised landfills (poor technical background);
- illegal or technically imperfect disposal (direct release into the environment and inefficient combustion);
- accidental releases during manufacture, transportation or operation of hydraulic and heat transfer equipment, transformers and capacitors.

It is estimated that about 4×10^5 tons of technical mixtures are released into the external environment, which corresponds to about 31% of worldwide production. Approximately 65% of the total stock of PCBs is now rigorously recorded and used in so-called closed systems. The remaining 4% of PCB production have already been disposed of by safe incineration. Table 12.31 provides an estimate of the distribution of PCBs that leaked into the environment in the United States up until 1981, in the period when the risks associated with these substances were known and legislative measures existed. European studies also state similar values of relative ratios. It is expected that the largest quantity of PCBs is deposited in the North Atlantic. On the mainland, the most important reservoirs of PCBs are freshwater sediments, which are also the primary source of contamination of the food chain of fish and humans. In general, higher concentrations of PCB residues are found in the vicinity of urban and industrial sites and so-called point sources (landfills of manufacturing companies, places of uncontrolled releases or accidents) than in sparsely populated areas and oceans.

Table 12.31 Typical environmental distribution of PCBs at the beginning of the 1980s.

Components of environment	Weight of PCBs (tons)	Components of environment	Weight of PCBs (tons)
Atmosphere	18	Vegetation	1000
Water (rivers and lakes)	20	Wild animals	0.3
Freshwater sediments	4000	Livestock	0.6
Freshwater animals	15	People	5
Soil – natural	1000	Oceans – water and animals	6000
– sewage sludge	4800	– sediments	1000

12.4.1.4.2 Transport between parts of the environment

Transport between the non-living (abiotic) and living (biotic) parts of the environment is a dynamic process that is influenced by many factors. In Table 12.32 the typical concentration of PCBs that are found in various abiotic ecosystems are illustrated. Table 12.33 gives similar orientation data for biotic parts of the environment.

Atmospheric transport

For PCBs and many other environmental contaminants, the most important transport medium is the atmosphere. Especially mobile are the low-chlorinated (more volatile) congeners. After the transition from an aquatic or terrestrial ecosystem, PCBs can be transmitted through the air in gaseous form or sorbed onto dust particles. The length of stay of individual congeners in this form is in an approximate range of 40–70 days, which is influenced, *inter alia*, by the number of hydroxyl radicals ($HO^{\bullet}$). Thanks to long-distance transmission in the atmosphere and re-deposition (wet or dry), PCBs are found in soils, sediments and on the surface of vegetation, even in outlying places far from the primary emission source. The average atmospheric concentrations of PCBs in urban areas are usually much higher than in rural areas or over oceans, and the highest concentrations can be found in the Arctic regions. As a result of the increase in vapour pressure at elevated temperatures, PCB concentrations in the atmosphere are up to five times higher in the summer months.

Contamination of aquatic ecosystem

Ocean waters contain probably the most significant portion of the total quantity of PCBs emitted to the environment (Table 12.32). The content of PCBs (and other organohalogenated substances) in the hydrosphere is in equilibrium with the atmosphere and bottom sediments.[8] Owing to their low solubility and high affinity for the organic components, high-chlorinated PCBs ($>Cl_5$) are primarily accumulated. The PCBs contents of sediments range from

[8]The equilibrium between water and sediments can be described by the equation: $C_S = K_P.C_W$ where C_S = concentration of PCBs in sediments, C_W = concentration of PCBs in water and K_P = equilibrium constant that reflects the character of sediments. To calculate the K_P value, tabulated values of K_{OC} (soil adsorption coefficient) can be used and K_P values calculated using the equation: $K_P = K_{OC}.TOC$ (total organic carbon). For a description of the behaviour (or distribution) of individual PCB congeners between water and sediments a linear relationship between K_{OC} and tabulated K_{OW} values can be used: $\log K_{OC} = 0.85 \log K_{OW} + 0.13$. The relationship is valid within the range of values of $\log K_{OW} = 4.5–7.7$.

Table 12.32 Typical concentrations of PCBs in the abiotic environment in the beginning of the 1980s.

Part of environment	Location and environment part specification	Concentration	Units
Air	Urban agglomerations	0.5–30	ng/m^3
	Rural areas	0.1–5	
	Over the Atlantic Ocean	0.05	
	Around the factory transformers	20–6000	
Water	Rivers – background values	<0.5	ng/l
	– mean contamination	<50	
	– strong contamination	<500	
	Atlantic Ocean	0.3–8	
	Mediterranean Sea – coast	13	
	Rain – countryside	1–50	
	– urban agglomerations	10–250	
Soil	Background values	1–5	μg/kg
	Around the factory transformers	15–18 000	
Sediments	Lakes – background values	0.1–5	μg/kg
	Rivers – normal load	8–20	
	– in the vicinity of PCB leaks	up to 60 000	

Table 12.33 Typical concentrations of PCBs in the biotic environment in the beginning of the 1980s.

Organism	Concentration (mg/kg fat)	Organism	Concentration (mg/kg fat)
Vegetation	0.001–0.01	Marine mammals	0.1–1000
Aquatic zooplankton	0.005–2.0	Birds	0.1–1000
Aquatic invertebrates	0.005–10	Eggs of birds	0.05–500
Fish	0.01–25	People	0.1–50

0.001 mg/kg for normal loads up to 1 mg/kg in heavily polluted areas. PCBs can, however, be found in virtually all other abiotic and biotic components of the aquatic ecosystem, such as plankton, arthropods, molluscs, fish, seabirds and mammals (Table 12.33). There is a significant bioaccumulation of PCBs in the introductory component of a food chain – in this case plankton, where concentrations of PCBs can be higher than in water by several orders of magnitude. Extensive leakages of PCBs into the environment are usually associated with ecological accidents, accompanied by contamination of groundwater. Under these circumstances, the concentrations of PCBs in water can be as high as hundreds of ng/l, which does not correspond to the solubility of technical mixtures of PCBs in water in some cases, but this phenomenon can be ascribed to solubilising effects of various surfactants, such as humic acids.

Contamination of soil and vegetation

The main source of contamination of soil is dry and wet atmospheric deposition. Increased findings are mostly local and related to specific point-source pollution. The extent of PCBs binding to soil particles increases with an increasing proportion of organic carbon, but PCBs may also undergo biodegradation by soil microflora, and there is also the possibility of eventual transfer of PCBs from contaminated soil into plants. This risk may seem especially timely in addressing the disposal of sewage sludge, but significant translocation of PCBs, even in strongly contaminated soil, to the above-ground parts of plants does not occur (with the exception of some low-chlorinated PCBs) and sorbed contaminants remain in the surface layers of the root system. A specific accumulation of PCBs may occur, for example, in carrots, and is associated with a higher concentration of lipophilic carotenoid pigments. Contamination of the aerial parts of vegetation with PCBs is mainly related to atmospheric pollution and, to some extent, to re-emissions of volatile PCBs from soil.

Contamination of animals

The fate of individual congeners of PCBs and their occurrence in various food chain components are different, sometimes very significantly. To animal organisms, PCBs penetrate from outside via food and other sources, but in the aquatic environment penetration from the surrounding medium also plays an important role. Some congeners of PCBs have significant bioconcentration potential. Additionally, biomagnification takes place in predatory organisms. It is reported that biomagnification in fish occurs only when the values of the bioconcentration factor (BCF) exceed the value of 1.15×10^5 (Table 12.30). The PCB burden of the prey is transferred to the predator. Differences in concentrations of PCBs and other POPs between the input and terminal components of a food chain as a result of biomagnification can be up to several orders of magnitude. For example, fish that consume large quantities of zooplankton magnify the PCB concentration in the body. This leads to bioaccumulation factors (BAF) as high as 2.8×10^6 in predatory fish species. Reptiles, birds and mammals, including humans who eat the fish, further accumulate PCBs.

Other processes may proceed simultaneously with bioaccumulation, such as diffusion into the surroundings, biodegradation and excretion (e.g. through fish roe or milk in female mammals). In general, the proportion of these events is species-dependent and also depends on the age and sex of an organism and its living conditions. For example, food availability determines the content and composition of body lipids, which represent a significant reservoir of PCBs. Increasing the total weight as well as the amount of fat in the body is reflected as a decrease in levels of contaminants, but in essence this phenomenon is a mere dilution at a constant load.

The spectrum of PCB congeners observed in invertebrate organisms and fish is not too different from the composition of PCB congeners in the surrounding abiotic environment (due to the low metabolic activity). In warm-blooded animals, especially higher vertebrates, the spectrum of PCB congeners can be substantially different as the biodegradable congeners are partially or completely eliminated, while in PCBs substituted in positions 4,4′ or 3,4′,5 preferential bioaccumulation and an increased tendency to bioaccumulate toxic DL-PCBs can be observed. Figure 12.47 illustrates the differences in the PCB profiles between organisms of different trophic levels. In humans, who are at the top of the food pyramid, highly persistent PCB congeners 138, 153 and 180 of the group of NDL-PCB dominate.

Exposure of livestock to PCB leads to accumulation of PCBs in meat, especially in liver and adipose tissue. A significant proportion of accumulated PCBs are transferred to eggs and milk and to the offspring by the mother's milk. The largest transmission range, roughly 50–60%, can be observed in highly persistent PCB congeners 138 and 153. Unwinding the exposure leads to a relatively rapid decline in PCB concentration, typically to 50% of the original amount, but the next elimination stage is actually very slow.

12.4.1.4.3 Biodegradation

Microbial degradation

Biodegradation is a significant way of eliminating low-chlorinated PCBs from the environment. Biotransformation mechanisms and terminal metabolites are different in individual species. Certain strains of bacteria of the genera *Alcaligenes*, *Pseudomonas*, *Nocardia* and others have the ability to metabolise PCBs, as do some eukaryotic microorganisms (such as fungi). The degradation rate decreases with the number of chlorine atoms and, starting from pentachlorobiphenyls, is, relatively, very low.

Dihydrodiols are produced in the initial stage of aerobic degradation of PCBs by dioxygenases (and monooxygenases in some bacteria and fungi). Degradation starts preferably in the less substituted aromatic ring. Dihydrodiols are then gradually transformed into chlorobenzoic acids, inorganic chlorides and lower aliphatic acids. The use of bacteria, fungi or green plants with biodegradation potential is the essence of bioremediation techniques (use of biological agents to remove or neutralise contaminants, as in polluted soil or water). Their use may represent one of the most effective ways to protect the food chain.

Metabolism in vertebrates

PCBs as well as many other xenobiotics are substrates of enzymes found in liver cells. Like other biotransformation enzymes, the monooxygenase enzyme system cytochrome P450 is located

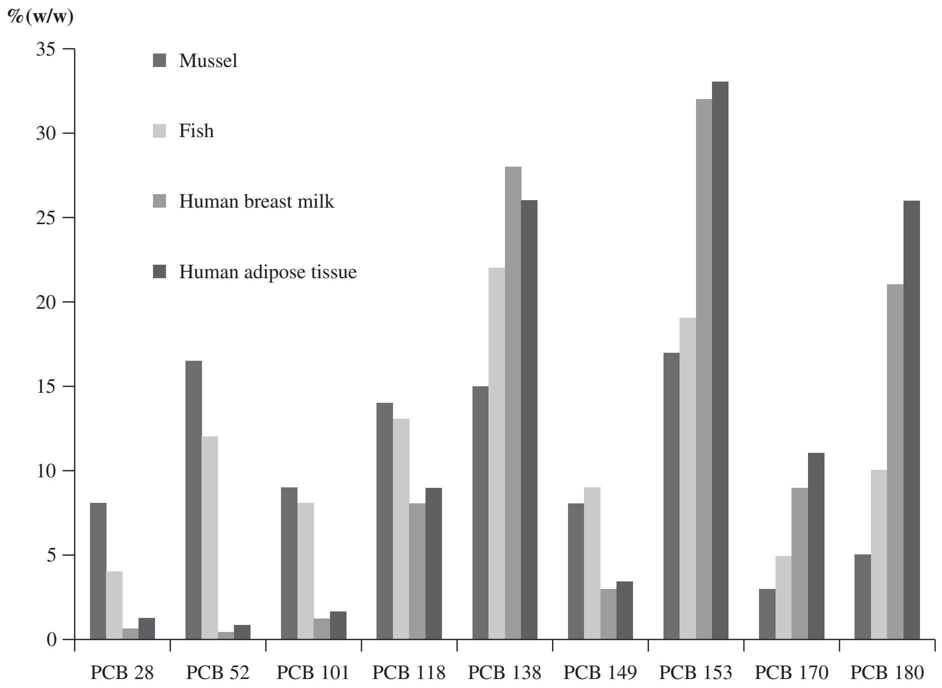

Figure 12.47 Typical relative distributions of selected PCB congeners in organisms at different trophic levels.

primarily in microsomes, artifacts re-formed from pieces of the endoplasmic reticulum in liver cells. Their synthesis increases several fold during long-term (chronic) exposure to a toxic substance.

The first reaction of PCB biotransformation by cytochrome P450 (cytochrome P450, family 2, subfamily B) is the formation of epoxides or hydroxyl derivatives of congeners that form arene oxides with difficulty. The general scheme of metabolic transformations of PCB 101 is illustrated in Figure 12.48.

Congeners with two unsubstituted carbons in the positions *meta* and *para* (such as PCB 52, PCB 95 and PCB 136) can be oxidised at multiple sites. The reactive electrophilic intermediates arene oxides give rise to dihydrodiol-PCBs, polychlorobiphenylols (hydroxy-PCBs) and conjugates with glutathione or adducts with macromolecules (DNA and proteins) and lipids. Dihydrodiols can become the precursors of metabolites with a catechol structure, and may be in equilibrium with hydroquinones and quinones. The major metabolites of PCBs, however, are hydroxylated products. Hydroxy-PCBs may also arise by 1,2-rearrangement of chlorine atoms. Most of these compounds are excreted from the body in a free form or as conjugates (glucuronides or sulfates). From about 50 possible hydroxy-PCB congeners, only five were demonstrated in higher concentrations in the plasma of exposed individuals, either bound to proteins or to transthyretin (carrier of the thyroid hormone thyroxine and retinol binding protein). The affinity of hydroxy-PCBs to lipids in the organism is considerably lower than the affinity of the parent compounds, which leads to their different distribution. PCB congeners with unsubstituted *meta* and *para* positions and chlorinated neighbouring *ortho* and *meta* positions (at least in one ring) are rapidly metabolised. Congeners with free *meta* and *para* positions may become precursors of methylsulfones as a result of sequences of several processes, which involve conjugation with glutathione, degradation to mercapturic acids followed by methylations and oxidations. Methylsulfonyl-PCBs are neutral metabolites with an affinity for lipids that are found in the blood plasma in relatively high concentrations. The key organs of their accumulation are the lungs and liver, where their concentrations may exceed concentrations of the parent PCBs. Some of them are optically active compounds.

12.4.1.4.4 Human exposure

The main source of human exposure (except for professionally exposed persons) is food, which represents more than 90% of the PCB intake. Exposure to PCBs in air, dust and soil is relatively insignificant. Table 12.34 summarises data on the levels found for of six indicator PCBs, which are considered markers of contamination. It is assumed that their contribution to the overall intake of NDL-PCBs is about 50%.

Foods of plant origin contribute to the dietary intake of PCBs to a lesser extent; the degree of contamination varies at levels of ng/kg. Concentrations of PCBs in foods of animal origin (meat, milk and in particular fish) are generally considerably higher, typically μg/kg and their content increases with lipid content. Differences in the profiles of foods of plant and animal origin reflect the ability of the organism to metabolise these pollutants. In foods of animal origin there is lower amount of low-chlorinated PCBs (28, 52, but also 101) as living organisms gradually biotransform these substances and subsequently eliminate them.

The data in Table 12.34 also show the variability of food contamination and higher levels of PCBs primarily in fish oils. The relatively higher levels of PCBs in fish and fish products are caused not only by differences in fat content, but also by different levels of contamination of aquatic ecosystems in various regions. Table 12.35 provides more detailed information, illustrating the

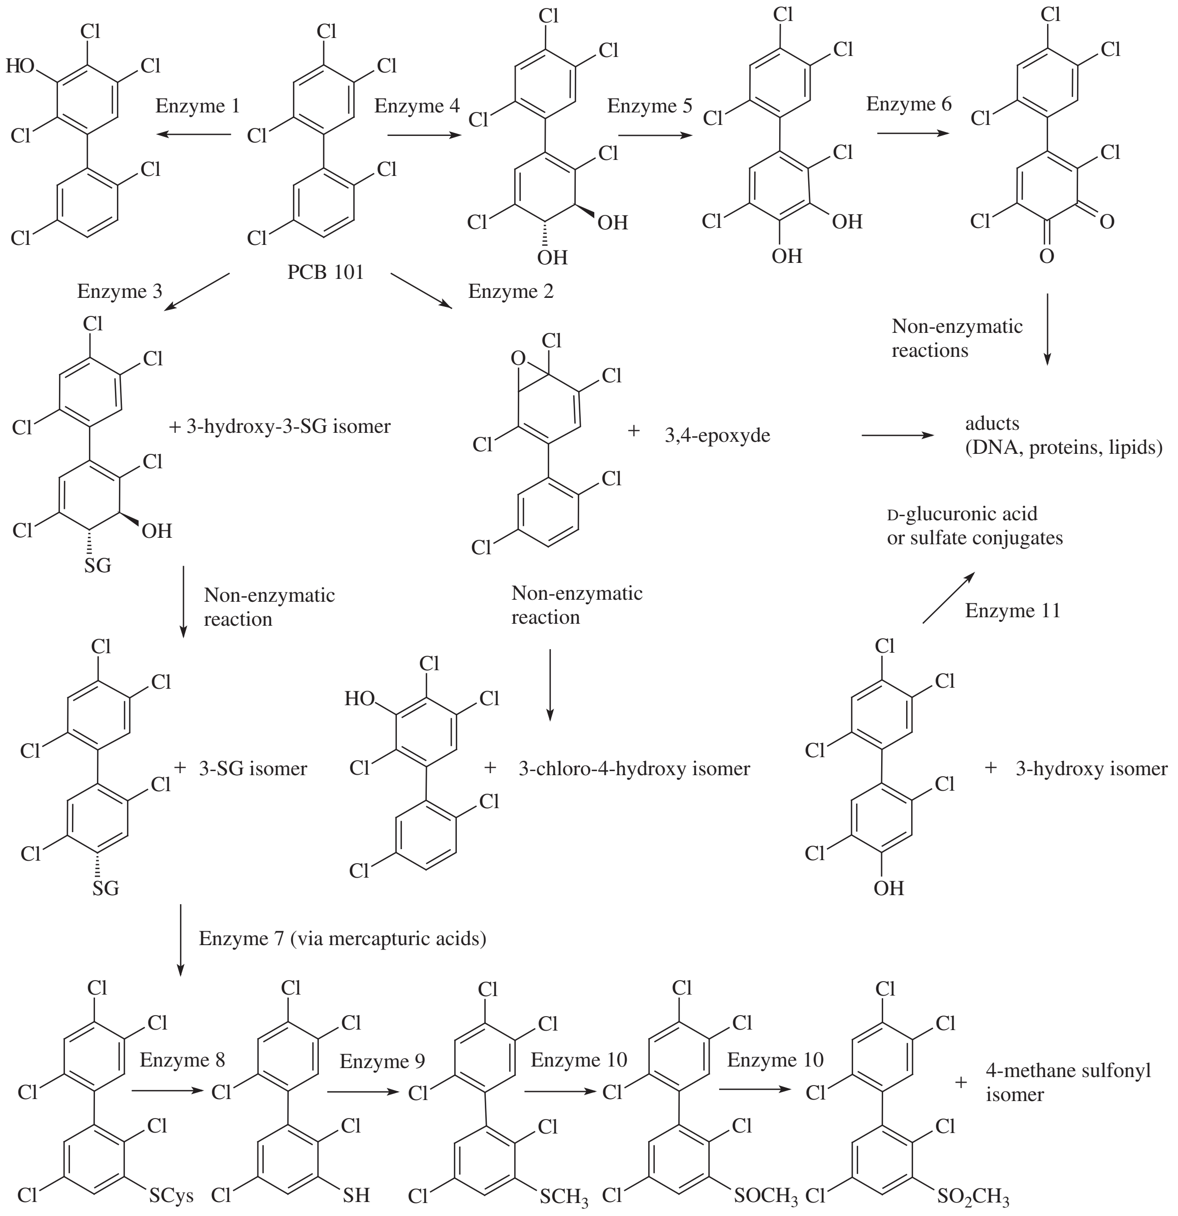

Figure 12.48 Formation of PCB 101 metabolites. Method development. Identification and quantification., Department of Environmental Chemistry, Stockholm University, Doctoral Thesis, 2006. Available at: http://su.diva-portal.org/smash/get/diva2:199492/FULLTEXT01 (accessed 18 October 2013). Fig 2.1.

significant contamination of fish from the Baltic Sea (average concentrations are higher by about 50% when compared with the sum of indicator congeners in fish from other areas) and the associated risk of increased dietary exposure of fish consumers. In Baltic fishermen with a significant proportion of local fish in their diet, the average daily exposure to NDL-PCB may reach as high as 80 ng/kg body weight (based on data from the east coast of Sweden). Also interesting is the significantly higher contamination of salmons compared with herrings. For the European population, the average daily intake of total NDL-PCB of 10–45 ng/kg body weight is assumed. In children under 6 years of age (not including breastfed children), this value is 27–50 ng/kg body weight.

The estimated average exposure to NDL-PCB contained in breast milk is up to two orders of magnitude higher for exclusively breastfed children, and is on average 1600 ng/kg body weight. Levels of population exposure to halogenated POPs are often determined on the basis of their concentrations in breast milk. The WHO study carried out in 2001/2002

examined a total of 102 samples of human milk from 26 countries (including 18 European countries). Data on concentrations of 38 congeners for European countries, including 12 DL-PCB, are summarised in Table 12.36. The contribution of non-*ortho* PCB congeners with the greatest toxic potential to the overall content of PCBs was only 0.04%; the main PCBs were congeners 153, 138 and 180, representing more than 65% on average.

12.4.1.5 Health and toxicological assessment

Toxicological evaluation of PCBs is an extremely difficult problem, as the considered organism is always exposed to mixtures of congeners with different physico-chemical and biological properties. It is practically impossible to distinguish the effects of individual toxic congeners or groups. Food of animal origin in particular may contain NDL-PCBs, DL-PCBs and possibly also polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) simultaneously in different proportions. The acute toxicity of PCBs is low and depends on the degree of chlorination of the technical mixture and the species tested. However, dioxin-like congeners (such as 3,3′,4,4′-tetrachlorobiphenyl) elicit a much higher toxicity. Symptoms of PCB intoxication are manifested by wasting syndrome (progressive weight loss, not related to food consumption), skin disorders, lymphoid involution (immunosuppresion), endocrine and reproductive effects (menstrual irregularities and reduced conception rate, early abortion, excessive menstrual haemorrhage and, in males, testicular atrophy and decreased spermatogenesis); PCB mixtures did not cause mutation or chromosomal damage in a variety of test systems, although adducts with DNA, RNA and proteins could be detected (prior metabolisation is necessary). According to the evaluation of the IARC of PCB mixtures, there is sufficient evidence for carcinogenicity to animals, therefore PCBs are classified as being group 2A agents, and are probably carcinogenic to humans.

[a]PCB 60 in only 27 samples.
[b]Σ_6 (PCB) = sum of six indicator congeners: PCB 28, 52, 101, 138, 153 and 180.
[c]Σ_7 (PCB) = sum of six indicator congeners: 28, 52, 101, 118, 138, 153 and 180.
[d]Σ_{12} (DL-PCB) = sum of 12 DL-PCB congeners: PCB 77, 81, 105, 114, 118, 123, 126, 156, 157, 167, 169 and 189.

12.4.1.5.1 Toxic planar congeners

Individual PCB congeners differ by their biological effects. Toxicological studies have shown that some congeners act by the same mechanisms as polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF), whose toxicity is mediated by interaction with a protein receptor. Other PCBs act by totally different mechanisms.

The assessment of the toxicological risks resulting from exposure to compounds such as PCDD or PCBs uses the system of **toxic equivalents** (TEQs), which considers the different toxicity of individual compounds. TEFs are so-called **toxic equivalency factors** that assign a ranking to various PCB congeners. The toxicity of a toxic substance is rated in relation to the compound with the greatest toxicity, 2,3,7,8-TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin). First, the concentration of this compound is multiplied by the relevant toxic equivalency factor (TEF) to give the TEQ value. The sum of TEQs for the individual toxic substances provides the total concentration of toxic equivalents, related to the effect of the concentration of pure 2,3,7,8-TCDD. WHO-PCDD/F-TEQ is the sum of toxicity equivalents of the 17 toxicologically most important polychlorinated dioxins and furans. The WHO-PCB-TEQ is the sum of toxicity equivalents of the 12 DL-PCBs that have been assigned TEFs, such as the dioxins to classify the toxicity of these PCB congeners relative to 2,3,7,8-TCDD. The sum of WHO-PCDD/F-TEQ and WHO-PCB-TEQ is called the total dioxin equivalent (WHO-PCDD/F-PCB-TEQ). The TEQ values thus represent toxic effects of a large group of toxic compounds, which greatly simplifies the evaluation of toxicological risks.

Determination of dioxin-like compounds utilising *in vitro* bioassays of induced enzymes ethoxyresorufin-*O*-deethylase (EROD) and aryl hydrocarbon hydroxylase (AHH) are now used in many laboratories to quantify global PCDD, PCDF and PCBs toxicity levels. In the case of PCBs, only some congeners induce AHH, but NDL-PCB congeners that do not have the toxicity of dioxins also have their inherent toxicity. For example, some high-chlorinated mixtures of congeners with low TEF are responsible for the formation of liver tumours observed under certain circumstances (at high doses) in animals. New data on the occurrence of high concentrations of DL-PCBs in farmed fish (especially salmon) and the associated risks to consumers were impulses for the EFSA discussion in 2004, when it was found that these substances should be regulated along with dioxins. In 2006, DL-PCBs were included to the maximum value of the TEQ.

12.4.1.5.2 Toxic metabolites

Some hydroxy derivatives of PCBs can, through structural relationship with thyroxine, interfere with the metabolism of thyroid hormones by competitive inhibition of transthyretin (the serum and cerebrospinal fluid carrier of the thyroid hormone thyroxine and retinol binding protein) and hormonal processes in the body. Toxicological studies have confirmed that sulfur metabolites of PCBs may bind to the secretoglobin called uteroglobin (progesterone-binding protein). Arylmethylsulfones accumulate mainly in the lungs and probably play an important role in the aetiology of toxic manifestations of Yushō disease (Table 12.37). Although the toxicity of a wide range of chemicals depends on their biotransformation mediated by monooxidases (or other enzyme systems) to more toxic products, it has been demonstrated that the toxicity of PCBs is not dependent on their metabolic activation. The parent compounds and not their metabolites are therefore responsible for the toxic effects associated with exposure to PCBs.

12.4.1.6 Mitigation

For the active reduction of dibenzodioxins, dibenzofurans and PCBs in foods and feeds, European Commission Recommendation 2006/88/EC has been issued. With respect to risk management evaluation, so-called action levels have been published for dioxins and dibenzofurans and dioxin-like PCBs (WHO-TEQ) in foods and feeds, which may be used by control authorities and manufacturers to decide when it is appropriate to identify a source of contamination and to take measures for its reduction or elimination.

Commision Recommendation No. 1881/2006/EU lists maximum levels for WHO-PCDD/PCDF-TEQ and WHO-PCDD/PCDF-PCB-TEQ. If dioxine-like PCBs are not included

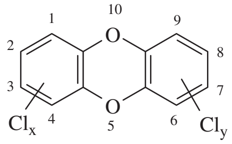
in the sum, the allowed values are approximately half the WHO-PCDD/PCDF-TEQ values. For example, for raw milk and dairy products, (including butterfat, hens' eggs and egg products) 3 pg/g fat of WHO-PCDD/PCDF-TEQ and 6 pg/g fat of WHO-PCDD/PCDF-PCB-TEQ are allowed. The highest values are set for meat and meat products (excluding edible offal) of bovine animals and sheep (3 and 4.5 pg/g fat), while lower values are set for poultry and pigs (2 and 4 pg/g fat and 1 and 1.5 pg/g fat, respectively). Higher values are set for muscle meat of fish and fishery products (4 and 8 pg/g wet weight). The highest values are allowed for liver of terrestrial animals (12 pg/g) and (by Commission Regulation No. 565/2008/EU) also for fish liver and its products (25 pg/g), which is close to the real concentrations in these products.

12.4.2 Polychlorinated dibenzo-*p*-dioxins and dibenzofurans

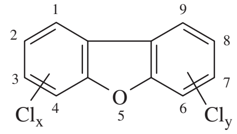
Polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) are, from the toxicological point of view, one of the most important groups of global environmental contaminants. Unlike all other halogen compounds, PCDD and PCDF do not have and have never had any practical use, and thus were never specifically synthesised in large quantities. They thus represent the category of unintentionally produced POPs (Table 12.26). The levles of these POPs that accumulate in food chains and are associated with health risks for living organisms (even in long-term exposure to very low concentrations) are the subject of special attention from experts, politicians and the public.

12.4.2.1 Structure and nomenclature

PCDD (**12-131**) and PCDF (**12-132**) are almost planar tricyclic compounds. Theoretically, the total number of PCDD derivatives is 75 (Table 12.38) and the total number of PCDF derivatives, which contain one to eight chlorine atoms, is 135 (Table 12.39).



12-131, polychlorinated dibenzo-*p*-dioxins



12-132, polychlorinated dibenzofurans

12.4.2.2 Properties

Properties of PCDD and PCDF are similar to other POPs, whose aromatic rings are substituted with halogens.

12.4.2.2.1 Physical and chemical properties

PCDD and PCDF are characterised by relatively high lipophilicity, high values of log K_{OW} and very low solubility in water. The characteristics of individual congeners can be found in specialised literature. Table 12.40 gives examples of some of the data for groups of high-chlorinated isomers of dibenzodioxins and for the perchlorinated congener octaCDD.

12.4.2.2.2 Persistence in living organisms

High-chlorinated PCDD and PCDF are generally characterised by considerable bioaccumulation potential and high persistence. Their exclusion from the exposed organism is very slow. Typical ranges of half-life values for elimination of toxic congeners from human

adipose tissue are summarised in Table 12.41. For comparison, data for the three most toxic DL-PCB congeners are also presented.

12.4.2.3 Occurrence and main sources

PCDD and PCDF arise, unlike most other organochlorine contaminants, almost exclusively as byproducts of anthropogenic activities. Recent research has also confirmed the formation of trace amounts of PCDD and PCDF in enzymatically catalysed reactions. For example, they may be biosynthesised by microbial peroxidases in sewage sludge contaminated with chlorophenols. The most important primary emission sources were or still are:

- industrial syntheses or technologies, such as manufacture of certain pesticides (particularly hexachlorobenzene, pentachlorophenol or phenoxyalkanoic acids), production of technical mixtures of PCBs, production of intermediates of some organic products (especially chlorophenols and chlorobenzenes, but also other organic and inorganic chlorine compounds), bleaching of wood pulp with chlorine dioxide (ClO_2), production of chlorine using graphite electrodes;
- incineration of the above mentioned organic and inorganic compounds containing chlorine, such as waste incineration (municipal or paramedical), disposal of toxic compounds, metallurgy, fires involving burning of organic compounds containing chlorine (such as PVC), but the formation of dioxins can occur also in the presence of a chlorine donor during pyrolysis of unchlorinated materials such as polystyrene, cellulose, lignin or coal;
- photochemical reactions in the atmosphere and reactions of components found in emissions.

In addition to these primary sources, the contamination of the food chain may create various waste products, such as industrial compost, landfill materials, sewage sludges, contaminated industrial products, for example herbicides based on 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), technical PCB mixtures, biocide pentachlorophenol (PCP) and its salts.

Acquired knowledge of the mechanism of reactions leading to the formation of PCDD and PCDF and factors influencing their formation, along with the mapping of pathways of these pollutants

into the environment, led to systematically applied restrictive measures in the related technologies as well as at the level of legislation. The result of the efforts to improve the situation at the turn of the last century is shown in Figure 12.49, from which a dramatic decrease of dioxin emissions from industrial sources is apparent, while emissions from transport or waste incineration and fires did not show such a downward trend.

12.4.2.4 Release into the environment

PCDD and PCDF can be released into the environment, and subsequently to the food chain, not only from these primary sources, but also from secondary sources, such as atmospheric deposition, point source emissions (various incinerators or industrial plants) and contaminated materials in the agroecosystem. For ruminants, the main route of dioxin intake is vegetation. For the aquatic ecosystem the main source of contamination is atmospheric deposition. In the initial phase, PCDD and PCDF (as well as other POPs) accumulate in the benthos, which is fed to animals at higher trophic levels. Often contamination of food sources as a result of violation of mandatory rules for their protection cannot be ruled out. Examples of problems that have occurred in developed European countries have included massive contamination of feed for livestock, which took place in Belgium in the late 1990s. In 1999, 500 tons of a contaminated batch of feed were distributed, which contained about 50 kg of PCBs and 1 g of dioxins. The feed was used in farms in Holland, Germany and France as well as Belgium. Another recent scandal involving contaminated feed for pigs and cattle occurred in Ireland in 2008. The profile of PCBs indicated penetration of transformer oil based on Aroclor. The overall contamination of chicks reached an average value of 170 ± 488 pg/kg for dioxins and 240 ± 2037 ng/kg for PCBs (TEQ in fat), and similarly high findings were discovered in eggs and milk. Contaminated meat was distributed to both the domestic and the foreign markets in the EU. Concentrations of PCDD/PCDF in pork and beef exceeded the safety limits by 80–200 times.

Source of dioxins in nearly 50 affected farms were old bakery products, which were dried by waste gases from contaminated fuel. Food and feed raw materials imported from developing countries may also be hazardous materials. In 2007, the Rapid Alert System for Food and Feed (RASFF) pointed out a high concentration of PCDD/PCDF (exceeding normal quantities by up to 1000 times) in guar gum found by control laboratories in Switzerland. The source of contamination was impurities in low-quality biocidal product

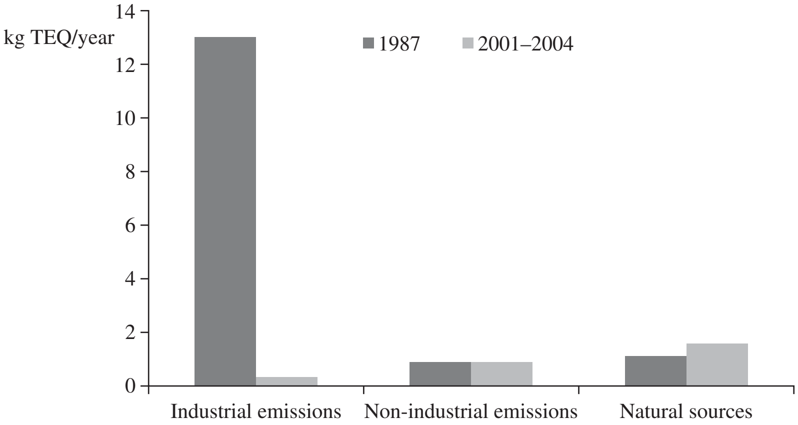

Figure 12.49 Changes in emissions of PCDD/PCDF (according to US Environmental Protection Agency, EPA: Trends in dioxin levels in the environment and in humans. Available at: http://heartland.org/sites/all/modules/custom/heartland_migration/files/pdfs/15201.pdf. Accessed: March 12, 2013.

based on pentachlorophenol (PCP) that has been in contact with the guar gum.

12.4.2.4.1 Occurrence in foods

Under normal circumstances, the concentrations of PCDD and PCDF in food raw materials and products are very low, usually in the range of units to tenths of μg/kg lipids, and only in exceptional cases, for example in fish from contaminated localities, reach values of an order of magnitude higher. Table 12.42 shows the levels of dioxins and DL-PCB in different foods on the Dutch market in 2004. With respect to similar toxic effects, concentrations (TEQ values) of these two types of contaminants are given together. In accordance with the previously mentioned facts, foods of animal origin contained higher concentrations of these contaminants than products of plant origin. This table also illustrates the relatively high contribution of DL-PCBs to the total TEQ value, which even exceeded the contribution of dioxins in some cases.

12.4.2.4.2 Human exposure

Human exposure to PCDD and PCDF occurs mainly via food. As with PCBs, it is expected that dietary intake represents up to 95% of the total amount of PCDD and PCDF. For the purpose of assessing health risks associated with exposure to these POPs, many countries have conducted studies to estimate their daily intake. Examples are given in Table 12.43. Attempts to find a correlation between the amount of PCDD and PCDF in a given area and their contents in human adipose tissue were generally unsuccessful, except in rural areas where a greater proportion of locally produced food is consumed. If an increased contamination is from a local source in these areas, higher levels

[g] Body weight 50 kg.

of PCDD/PCDF in human adipose tissue can be found. It is interesting to compare the data for Japan and the Netherlands. In countries with a high consumption of fish, like Japan, this commodity significantly contributes to the intake of dioxins and related POPs. In the Netherlands there is a relatively low consumption of fish, which is reflected in their small contribution to the total exposure. On the other hand, the significant contribution of milk and dairy products to the overall exposure documents the load of the terrestrial ecosystem by emissions from incinerators and other anthropogenic sources. Increased levels of PCDD/PCDF in milk and dairy products are alarming, because a large part of the population may be exposed via these commodities, including children, who are particularly vulnerable to the toxic effects of xenobiotics (chemical compounds that are foreign to living organisms).

In virtually all cases, the total TEF value is contributed to mostly by 2,3,7,8-tetraCDD, 1,2,3,7,8-pentaCDD, 1,2,3,6,7,8-hexaCDD, 2,3,4,7,8-pentaCDF and PCB 126. The contribution of DL-PCBs varies over a wide range and in some cases exceeds 50%. There is a high risk of increased exposure during lactation, as the gastrointestinal tracts of nursed babies absorb virtually all lipids contained in breast milk, and these lipids represent a reservoir of PCDD, PCDF and other POPs. PCDD/PSDF particularly predominate in breast milk in Belgium, the Netherlands, Luxembourg, Finland

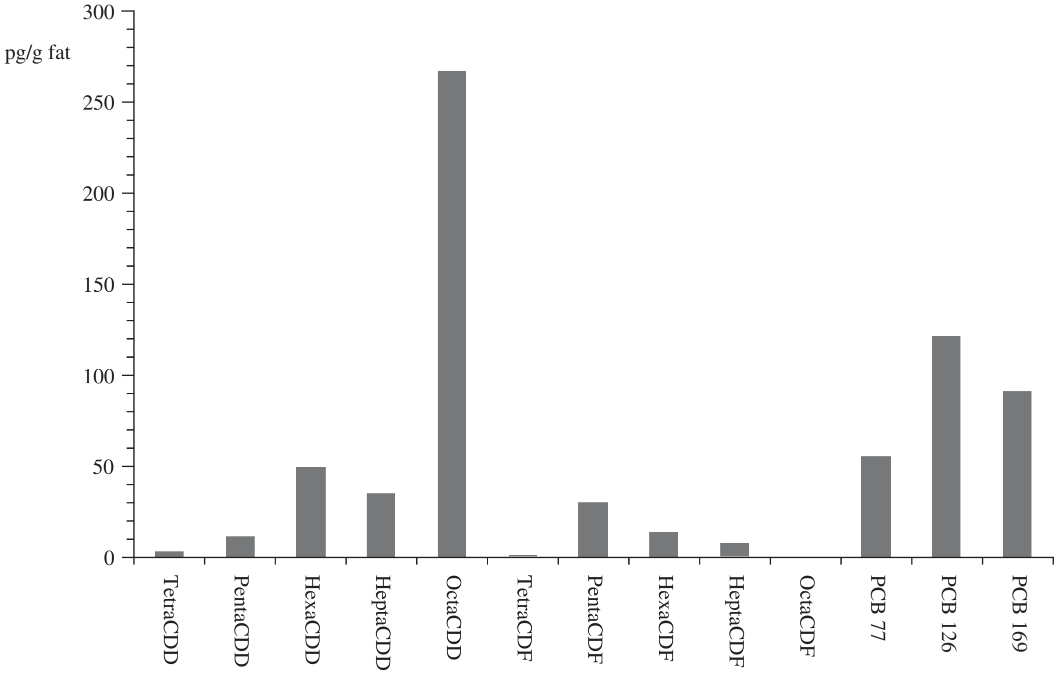

Figure 12.50 Profile of groups of PCDD/PCDF congeners and representatives of DL-PCBs in breast milk.

and Spain, but in some countries (e.g. in the Czech Republic or Ukraine) DL-PCBs significantly dominate. Figure 12.50 illustrates the variability of individual groups of PCDD/ PCDF and DL-PCBs in the milk of mothers that are breastfeeding their first child. In mothers nursing twins, the main breast milk components were hexaCDD, pentaCDF, hexaCDF and heptaCDF. The mobility of individual congeners (rate of their excretion) is not the same, but the total concentration of POPs during lactation decreases (in milk and generally in the organism of the mothers), unless there is a new dietary exposure. The authorities in some Baltic countries even issue recommendations during pregnancy and lactation to reduce consumption of fish from this area in view of their relatively high contamination, as the decrease in dietary intake of PCDD/PCDF is accompanied by decreases in plasma and breast milk.

12.4.2.5 Health and toxicological assessment

Many PCDD/PCDF congeners are characterised by considerable toxicity and their relative effect is related (as in DL-PCB) to congener 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which was selected on the basis of a series of *in vivo* and *in vitro* toxicological studies. The equivalent factor (TEF) of TCDD was set to one.

TCDD and related compounds have negative effects on several organs in different animal species. The most famous case where people were exposed to dioxins was the chemical plant accident in Seves in Italy that occurred in 1976. The most important harmful effects are immunotoxicity, behavioural disorders and reproductive disorders. Subchronic effects in experimental animals include weight loss, pathological changes in the liver, thymus, lymph glands, hair loss, porphyria (decomposition of haemoglobin) and some others. Evidence of the carcinogenicity of 2,3,7,8-tetraCDD is also ambiguous; the IARC classifies this substance as a Class 1A carcinogen.[3] TetraCDD and related compounds act at different levels, through initiation of hormonal mechanisms supporting carcinogenic processes, on the development of the intellect in the foetus just before birth or shortly after birth (doses received by breast milk may exceed the normal dietary intake of adults). As in the case of PCBs, both PCDD and PCDF (depending on the structure of the individual congeners and their planarity, respectively) induce a hepatic microsomal system of oxidases (cytochrome P450) in exposed organisms. The most effective inducer is the above mentioned TCDD. Values of toxic equivalency factors (TEFs) have been the subject of intensive technical discussions for many years. In 2005, an expert group of the WHO-IPCS (International Programme on Chemical Safety) confirmed the correctness of the concept based on the additivity of their effects, and reconsidered older TEF values in terms of new scientific knowledge. Table 12.44 shows the relative toxicity of 2,3,7,8-tetraCDD and other monitored PCDDs and PCDFs for humans and other mammals. TEF values, which were estimated for other species and used in assessing ecotoxicological risks, may be more or less different. A particularly significant difference in the intensity of biological responses and the TEF values is for fish.

12.4.2.6 Mitigation

Measures aimed at reducing emissions of PCDD/PCDF into the environment and contaminations of food chains have undoubtedly influenced the decline in population exposure in recent years. Interesting in this regard is a study of the dynamics of the levels of

Table 12.44 Comparison of TEF values for PCDD and PCDF congeners used to estimate the exposure risk.

Chlorinated dibenzo-*p*-dioxins	TEF-WHO	Chlorinated dibenzofurans	TEF-WHO

PCDD/PCDF in the US population born between 1950 and 1980 (Figure 12.51). While in the oldest persons the levels of bioaccumulated pollutants were on average almost 15 ng/kg fat, people born in the 1980s were exposed to these POPs significantly less.

In 2000, the WHO calculated the TDI values in the range from 1 to 4 pg WHO-PCDD/PCDF-PCB-TEQ per kg body weight. These exposure limits are based on non-carcinogenic effects, with the main ones to be evaluated being immunotoxicity, neurotoxicity and interference with hormonal systems. In 2001, the Scientific Committee on Food (SCF) of the European Union (EU) calculated a tolerable weekly intake (TWI) of 14 pg WHO-PCDD/PCDF-PCB-TEQ per kg body weight. In the same year, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) calculated a provisional tolerable monthly intake (PTMI) of 70 pg WHO-PCDD/PCDF-PCB-TEQ per kg body weight and month. In 2006, the SCF confirmed the provisional tolerable weekly intake of 14 pg TEQ per kg body weight, which corresponds to the value of 2 pg TEQ per kg body weight per day proposed in 2001. Setting these limits causes serious consequences in the restrictive measures aimed at reducing exposure to PCDD/PCDF. Tolerable daily intake must always protect all populations and from this perspective the exposure of infants to breast milk is critical. Despite these facts, from the point of view of nutrition, breastfeeding is considered irreplaceable and so the only way to reduce this risk is by a drastic reduction in population exposure. The target value is 1 pg TEQ per kg of body weight per day. Under normal circumstances, the intake of PCDD/PCDF is much lower. The risks that could arise from ordinary low concentrations of these contaminants are not yet sufficiently documented, so it is recommended to reduce the intake of PCDD and PCDF to a minimum.

Examples of maximum levels set for the sum of dioxins (WHO-PCDD/PCDF-TEQ) and sum of dioxins and dioxin-like PCBs (WHO-PCDD/PCDF-PCB-TEQ) in foods are given in Section 12.4.1.6.

12.4.3 Other persistent organohalogenated contaminants

12.4.3.1 Brominated flame retardants

The development of anthropogenic activities is accompanied, among other things, by the growing use of combustible synthetic materials, which brings an increased risk of fire. One of the ways to prevent economic impacts and the possible loss of human lives is the use of flame retardants, chemicals that reduce the flammability of materials or delay their combustion. For example, many plastics are highly flammable and therefore their fire resistance is increased by adding flame retardants. These synthetic chemicals are used in electronics, upholstery, carpets, textiles, insulation, vehicle and airplane parts, baby blankets, children's clothes and strollers and many other products. Currently, nearly 180 different compounds that increase the fire safety of flammable materials are known. Taking into account their composition, flame retardants can be divided into four groups:

- inorganic compounds (salts)
- organophosphates
- organic compounds containing nitrogen
- halogenated compounds.

In terms of food safety, the most frequently monitored substances are halogenated compounds that are potentially dangerous to

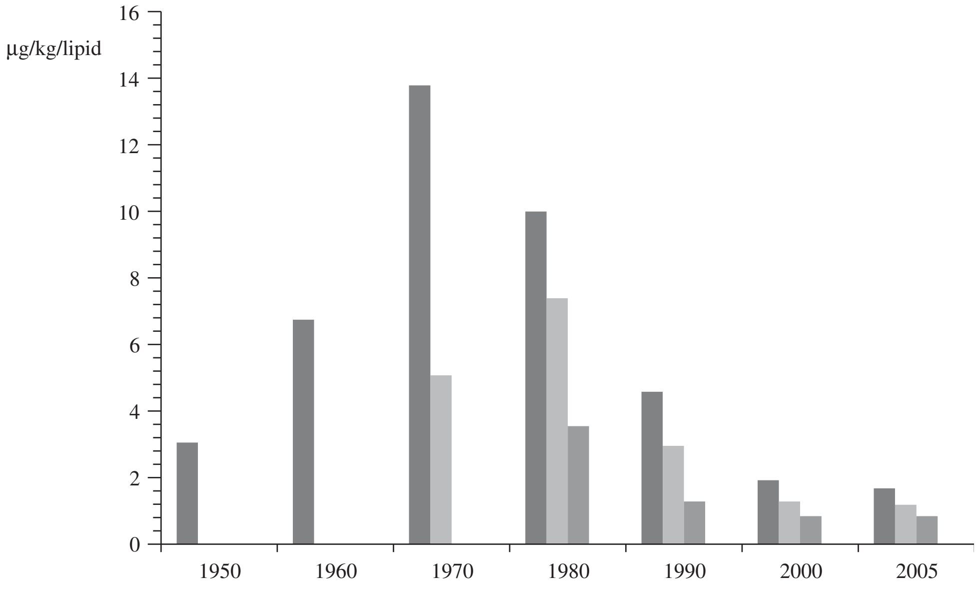

Figure 12.51 Average content of 2,3,7,8-TCDD (ng/kg) in the population of the United States born in 1950, 1970 and 1980.

the environment. The most important flame retardants of this group are brominated flame retardants (BFRs). The first mention of the occurrence of BFRs in the environment was in the late 1970s in Sweden when these substances were identified in fish. Greater attention began to be paid to BFRs during the 1990s when they were found in breast milk. Like PCBs and other persistent organochlorine compounds, residues of BFRs can be found in virtually all environmental components, biotic and abiotic, for example in the air, water, soil, sediments, sewage sludges, fish, birds and mammals, including humans. In addition to leaks during their production, their presence in the environment is related particularly to the use of materials containing flame retardants. An important source of BFRs is the disposal of plastics, electronic equipment and other wastes. These compounds can be leached from landfills, into the environment and, furthermore, polybrominated flame retardants release toxic polybrominated dioxins and furans when burned.

Today there are more than 75 different types of these substances, the classic examples of which include brominated biphenyls, diphenyl ethers, cyclododecane and bisphenol A. The use of individual flame retardants depends on the type of polymer, use of the product, its durability and the desired aesthetic appearance. The most commonly used BFRs are mixtures of polybrominated diphenyl ethers (PBDEs, **12-133**), 2,2′,6,6′-tetrabromobisphenol A (TBBPA, **12-134**) and 1,2,5,6,9,10-hexabromocyclododecane (HBCD or HBCDD, **12-135**), but the regular classic BFRs are still polybrominated biphenyls (PBB, **12-136**).

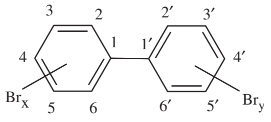
12-135, 1,2,5,6,9,10-hexabromocyclododecane



12-136, polybrominated biphenyls

Table 12.45 shows the total consumption of BFRs in 2001. It is interesting to note the very different use of BFRs in different parts of the world, which naturally corresponds to the different natures of the contaminations. Following the development of the consumption of BFR in recent decades in Sweden (45 tons of PBDEs, 275 tons of TBBPA and 40 tons of HBCD in 1998 and 4 tons of PBDEs, 30 tons of TBBPA and 3 tons of HBCD in 2007) it may appear that the use of BFRs is declining, but in fact it is not, as the types of flame retardants in the market are constantly changing, mainly as a result of changes in legislation (including bans on the

Table 12.45 Consumption of the main types of BFRs on continents in tons.

Compound	Europe	Northern America	Asia	Others	Total
TBBPA	11 600	18 000	89 400	600	11 9600 (59%)
DecaBDE	7600	24 500	23 000	1050	56 150 (28%)

PentaBDE	150	7100	150	100	7500 (4%)
OctaBDE	610	1500	1500	180	3790 (2%)
Total	29 460 (14.5%)	53 900 (26.5%)	11 7950 (57.5%)	2430 (1.2%)	203 740 (100%)

use of certain conventional compounds or their groups). It is very difficult to obtain current information about the production and use of new BFRs, because it is (from the perspective of the industry) sensitive data.

The mechanisms of the actions of flame retardants differs between the groups. In the case of halogenated compounds, the burning process is slowed by removing hydrogen and hydroxyl radicals from the flame. At higher temperatures flame retardants release free bromine or chlorine radicals, which react with hydrocarbons and yield hydrogen bromide or hydrogen chloride that react with combustion products to form water and bromine or chlorine radicals.

According to the method of incorporation into polymers, flame retardants can be divided into two basic groups:

- reactive
- additive.

Reactive flame retardants are added to the monomers, therefore they are covalently linked in the polymer and do not significantly penetrate into the environment. The use of these substances is limited to a few groups of polymers. Additive flame retardants are added into polymers, therefore they are not covalently bound, which is associated with the higher risk of environmental contamination. PBDEs and HBCD are used only as additive flame retardants, while TBBPA is primarily a reactive flame retardant and in only about 10% of cases is it used as an additive flame retardant. For example, the HBCD content in polystyrene foam ranges from 0.4 to 8% and the TBBPA content in polyesters may reach 13–28%.

12.4.3.1.1 Polybrominated diphenyl ethers

Structure and nomenclature

Polybrominated diphenyl ethers (PBDEs, **12-133**) are compounds structurally similar to polychlorinated biphenyls (PCBs). The numbering of 209 individual PBDE congeners is analogous to the IUPAC nomenclature used for numbering PCBs (Figure 12.46). The basic skeleton is diphenyl ether with a different number and location of bromine atoms. 209 possible congeners can be derived, which include 3 mono-, 12 di-, 24 tri-, 42 tetra-, 46 penta-, 42 hexa-, 24 hepta-, 12 octa-, 3 nona- and 1 decabromodiphenylether isomers.

Production

PBDEs are synthesised industrially mainly by bromination of diphenyl ether, which produces a mixture of different compounds. Not all congeners are or have been commercially used. Four technical PBDE mixtures were applied in the industrial production: decaBDE (decabromodiphenyl ether), octaBDE, pentaBDE and tetraBDE. DecaBDE contains about 97% of 209 BDE congeners and 3% of nonaBDE. A technical octaBDE mixture contains mainly heptaBDE and octaBDE, but to a lesser extent hexa-, nona- and decaBDE. The technical mixture pentaBDE contains predominantly penta- and tetrabromodiphenyl ether congeners. The technical mixture tetraBDE, containing tetra-, penta-, hexa- and partly other unidentified PBDEs, has a limited use. Industrial production in the EU and the US has been focused mainly on mixtures containing pentaBDE, octaBDE and decaBDE. The typical composition of PBDEs sold under the trademark Broukal is given in Table 12.46.

Properties

Physical and chemical properties PBDEs are very stable compounds, having a boiling point in the range of 310–425 °C, low volatility, high lipophilicity and low solubility in water (log K_{OW} is in the range of 4–10), which decreases with increasing number of bromine atoms. They are very persistent compounds, having a tendency to accumulate in different parts of the environment. Most studies show that low-brominated congeners are more persistent than the high-brominated congeners, which easily undergo degradation under bromine release. UV light significantly accelerates debromination (the most labile compounds are decaBDEs). It is therefore difficult to balance the contribution of individual technical mixtures of PBDEs to the contamination of environmental components, as these mixtures contain the originally present compounds together with products of photolysis of high-brominated PBDEs. A summary of selected chemical and physical properties of PBDE mixtures is shown in Table 12.47. A brief overview of the use of technical mixtures of PBDEs as flame retardants in

Table 12.46 Composition of technical mixtures of PBDEs (% w/w).

various materials, which can be a source of emissions, is given in Table 12.48.

The most important congeners, which are monitored in the environment, include congeners PBDE 28 (2,4,4′-tribromodiphenyl ether, PBDE 47 (2,2′,4,4′-tetrabromodiphenyl ether), PBDE 99 (2,2′,4,4′,5-pentabromodiphenyl ether), PBDE 100 (2,2′,4,4′,6′-pentabromo diphenylether), PBDE 153 (2,2′,3,4, 4′,5′-hexabromodiphenyl ether), PBDE 154 (2,2′,4,4′,5,6′-hexabromodiphenyl ether) and PBDE 209 (2,2′,3,3′,4,4′,5,5′,6,6′-octabromodiphenyl ether).

Persistence in living organisms The majority of PBDEs are a group of highly lipophilic compounds, which are almost insoluble in water and can therefore accumulate in living organisms by bioaccumulation and biomagnification processes. The bioaccumulation potential of low-brominated congeners is very high (BCF value is higher than 5000).

Occurrence, main sources and release into the environment

Concentrations of PBDE congeners and their amount in the various components of the environment depend essentially on their structure (physico-chemical properties). The most persistent low-brominated congeners (with 4–7 Br atoms) may be found dissolved in water and also in the air, and therefore are transported over long distances. Their behaviour in the environment is similar to the behaviour of chlorinated POPs, such as PCBs or PCDD/PCDF. The majority of PBDEs used are high-brominated congeners, which are (due to their low volatility, low water solubility, lower bioaccumulation and high degree of adsorption on solid particles) less mobile in the environment and are found mostly in sediments, sludges and dust in the vicinity of emission sources. The composition of commercial mixtures replicates the representation of individual PBDEs in abiotic environments (such as sediments). Penta-, octa- and decaBDE congeners are therefore particularly predominant, the latter of which predominates only if photolysis does not occur. The spectrum of PBDEs in living organisms is sometimes fundamentally different due to the selective transfer from food or different biomagnifications.

Contamination of aquatic ecosystem, sewage sludge and soil

Low-brominated PBDE congeners are relatively soluble in water and their concentrations in sediments and soils are lower than the concentrations of high-brominated congeners that are strongly bound to particles in water, sediments and soils, especially to the particles with high organic carbon contents. Sediments, especially sediments in the vicinity of plants using brominated flame retardants, contain increased amounts of these contaminants. The representation of the individual substances in river sediments can vary significantly along the river, due to the presence of a range of local sources of pollution. The dominant congener is often

Table 12.48 Overview of some applications of PBDEs used as flame retardants in polymers.

Type of polymer or resin	Area of application
Acrylonitrile-butadiene-styrene	TVs, computers, hair dryers
Epoxy resin	Computers, electronic components
Phenolic resin	Paper laminates
Polyacrylonitrile	Electronic equipment, light panels
Polyamide	Computers, electronic connectors, garages
Polybutylene	Switches, fuses
Polyethylene	Electrical wiring, insulation materials
Polyethylene terephthalate	TVs, electronic equipment
Polypropylene	TVs, electronics
Polystyrene	Smoke detectors, office equipment, electronics covers
Polyvinyl chloride	Wires, cables, floor coverings
Polyurethane	Furniture, sound insulation, wood imitation
Textiles	Carpets, car interiors, furniture, tents, military safety clothing
Rubber	Conveyor belts
Coatings	Industrial paints, such as paints for protection of container

BDE 209, which can be present in concentrations amounting to 100–1000 μg/kg of dry sediment. Also present are lower congeners, such as BDE 47, BDE 99, BDE 100, BDE 153, BDE 154 and BDE 183 (in tenths, not more than tens, μg/kg dry sediment).

Sewage sludge from waste water treatment plants is considered one of the greatest sources of various contaminants that are only degradable with difficulty, including PBDEs. In many countries, sewage sludge is still used in agriculture for soil enrichment by organic components, which contributes to a substantial increase in the soil contamination (often to thousands of μg/kg dry matter), and consequently to the load of the food chain by PBDE and other undesirable chemicals. Often present in high concentrations is congener BDE 209, TBBPA and HBCD (100–1000 μg/kg dry matter). Information on these substances, however, is limited because frequently they are not the target analytes as are congeners BDE 47, BDE 99, BDE 100, BDE 154 and BDE 153, although they occur in smaller amounts. Representation of these congeners in the abiotic components of the environment replicates the composition of technical mixtures of pentaBDE, where the main component is again BDE 209. Elevated levels of soil contamination are also observed in the site of a conflagration.

Contamination of animals

Owing to the ubiquity and persistence in the environment of brominated flame retardants, it is not surprising that these substances penetrate into the tissues of animals, including humans, where they accumulate. As with other halogenated POPs, their concentration increases with each trophic level in a food chain. A higher range of biomagnification of brominated PBDEs indicates their easier absorption in the body. Concentrations of brominated flame retardators in organisms range from μg/kg fat to mg/kg fat, depending on the dietary habits of the species, age and level of contamination. The highest concentrations are found in the tissues of predatory fish.

The relative representation of individual PBDE congeners may be somewhat different interspecies. However, the dominant PBDE is often tetraBDE 47, which may constitute more than 50% of the total amount of PBDEs. Other relatively frequently occurring PBDEs are congeners 99, 100, 153 and 154. Despite the extensive use and common occurrence in the environment, the amounts of BDE 209 are relatively low. Previously, it was assumed that it is due to the large effective volume of its molecule, which cannot pass through biomembranes and thus accumulates in the tissues of living organisms. However, recent research revealed the presence of BDE 209 in the eggs of raptors (20–430 μg/kg fat) and fish (about 50 μg/kg fat), which clearly refutes the initial hypothesis and suggests instead a relatively rapid elimination of this perbrominated congener from the environment, even before its accumulation occurs. The finding of BDE 209 in the tissues of animals thus indicates the actual exposure of the organism to this type of technical mixtures.

Human exposure

Human exposure to brominated flame retardants occurs in various ways, and a human organism can be exposed to these contaminants and other halogenated compounds even before birth, as they may cross the placenta. Subsequently, the main exposure of infants is dietary exposure through breast milk, and later via the consumption of foods of animal origin with a higher fat content, especially contaminated fish and seafood.

In breast milk the main congener is BDE 47 (32–63%), while other majority congeners are BDE 99, BDE 100, BDE 153 and BDE 154 (minor differences in the spectrum of PBDEs in breast milk samples collected in different parts of the world appear to be linked to the different compositions of technical mixtures of brominated flame retardants). The total content of these PBDE congeners is highest in developed countries. For example, in the United States in 2003, their content was about 7 μg/kg fat, which corresponds to high concentrations of brominated flame retardants in virtually all parts of the environment. It could be expected that the adopted restrictive measures will be reflected in a decrease in the amount of PBDEs in the human environment, which should be associated with a decrease in their concentration in breast milk. In human tissues (as well as in other animal species) congeners BDE 47, 99, 100, 153 and 183 occur in the largest quantities. The subcutaneous fat contains in most cases the dominant congener BDE 153, which is followed

by congener BDE 47. The cause of the different distributions of individual congeners may be due to varying intakes of PBDEs from the air, where high-brominated congeners occur, especially in higher dust concentrations. Different kinetics of accumulation and biotransformation of individual congeners in the body may also play a role. The highest amounts of PBDEs were found in the plasma of workers who dismantled electronic products containing brominated flame retardants.

An important source of human exposure to brominated flame retardants is dietary intake, particularly the consumption of contaminated fish, as well as other foods with a higher fat content, such as meat, eggs, dairy products, fats and oils. Results obtained in Spain in 2000 are summarised in Table 12.49 as an example. The total daily intake of PBDEs was estimated to be 82–97 ng, including intake from fish and seafood at the level of 30 ng, from vegetable oils 24 ng and from meat and meat products 20 ng, which corresponds to a daily intake of 1.2–1.4 ng/kg body weight. Representation of individual congeners in food is consistent with their representation in biotic matrices, including human tissues. The dominant congeners are tetraBDE and pentaBDE. Variations in different countries are mainly caused by differences in the consumer's food basket. For example, in Sweden, the main congeners of the consumer's food basket (fish, meat, dairy products, eggs, fats and oils and bread) are BDE 47, 99, 100, 153 and 154, and the total daily intake of PBDEs is estimated at 51 ng.

Unlike for PCBs and other POPs, another important source of PBDEs is inhalation of contaminated dust or dermal intake. During recent years, much attention has focused on brominated flame retardants in dust, where high-brominated substances are mainly found, which have a higher affinity for solid particles. By far the highest concentration of these substances is found in indoor environments, due to a number of sources (electronics, furniture and various textiles). In the organism, these substances bind to blood lipids and are stored in adipose tissue. During lactation they are excreted to breast milk, and can be further metabolised to lower congeners or different, especially hydroxylated derivatives. The half-life of metabolic transformation of BDE 209 is a few days or weeks, and the half-life of congener 183 is 3 months. The most persistent congener is BDE 153.

Table 12.49 Content of PBDEs in selected foods.

Food	Content	
	ng/kg fat	ng/kg dry matter
Vegetables	-	5-8
Fruits	-	0-6
Cereals	-	0-36
Shellfish	2961-3140	83-88
White fish	2052-2359	37-88

Eggs	482-530	58-64
Milk	525-630	20-24
Dairy products	557-677	34-48
Vegetable oils	795-805	794-804

In 2006, the EFSA's (European Food Safety Authority) panel on contaminants in the food chain (CONTAM) recommended member countries to monitor the following brominated flame retardants in food and feed: PBDE congeners 28, 47, 99, 100, 153, 154, 183 and 209, HBCD (sum of isomers) and PBB congener 153. Monitoring programmes could also include other PBDE congeners, decabromodiphenylethane (**12-143**), hexabromobenzene and bis(2,4,6-tribromophenoxy)ethane.

Biodegradation

To estimate the health risks represented by brominated flame retardants, it is important to consider, in addition to assessment of the potential routes of exposure, the biotransformation of these compounds in the body. The most abundant congener BDE 47 (2,2′,4,4′-tetrabromodiphenylether) occurring in biotic materials is absorbed up to 95% in the gastrointestinal tract of mice , distributed to the tissues and slowly metabolised. Only a small amount is excreted via excrements. Similarly, as in the case of aromatic xenobiotics, by the action of cytochrome, P450 complex epoxides are produced as the primary products, which, on hydrolysis, yield the corresponding hydroxy derivatives (Figure 12.52).

The metabolism of congener BDE 209 (2,2′,3,3′,4,4′,5,5′,6,6′-decabromodiphenyl ether) is somewhat different. In comparison with PDA 47, BDE 209 is a substance with a significantly higher molecular weight, which reduces its absorption by the body to 10–25%. HydroxyoctaBDE, hydroxynonaBDE and hydroxymethoxyhexaBDEs were found in the blood plasma of rodents, and a large number of metabolites were also present in the rodents' faeces. Methoxylated and hydroxylated PBDEs have similarly been found in organisms of other mammals, including humans, the source of which could be fish, marine mammals or cyanobacteria, such as *Oscillatoria spongeliae*, living in symbiosis with marine sponges, algae, mussels and other seafood organisms. Debrominated, hydroxylated and methoxylated metabolites were also found in maize that had been exposed to low-brominated diphenyl ethers. The structures of some metabolites are given in formulae **12-137**.

Health and toxicological assessment

The acute toxicity of commercially used technical mixtures tested on laboratory rats is relatively low (LD_{50} <1 g/kg body weight), but at high doses increased liver weights and changes in the structure of liver tissue have been found. From a toxicological point of view, long-term exposure to low doses of PBDEs is a much greater risk. The evidence of the harmful effects of PBDEs includes interference with the endocrine system, (hormonal processes) as PBDEs

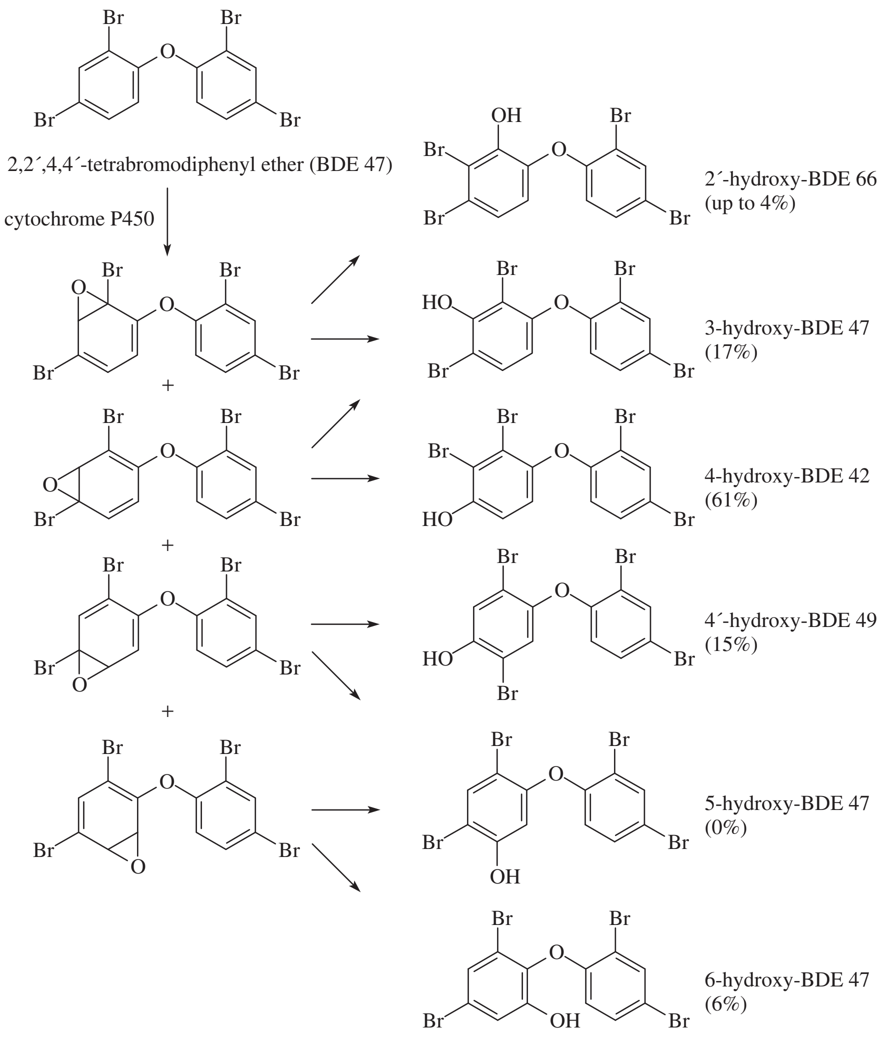

Figure 12.52 Metabolites of BDE 47.

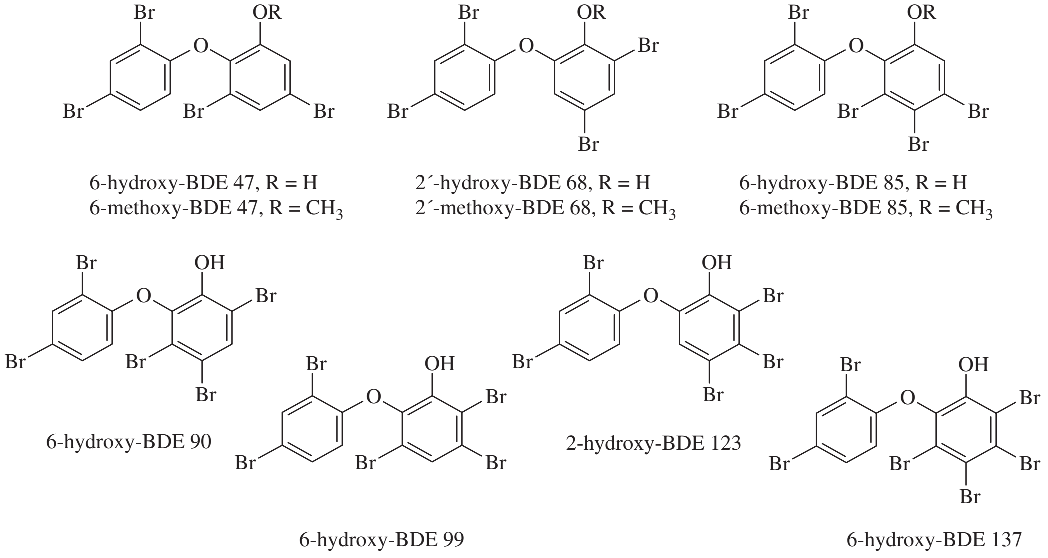
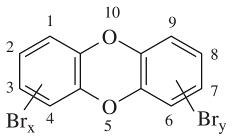
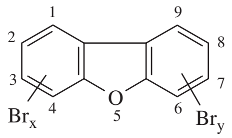


12-137, hydroxy and methoxyl derivatives of polybrominated diphenyl esters

act as endocrine disruptors. One of the most striking symptoms observed in animals was the increase of thyroxine concentration in the blood plasma, because some PBDEs (especially their hydroxyl derivatives) have a structure similar to thyroid hormones. Other possible adverse biological effects include neurotoxicity. In addition to the adverse biological effects induced by PBDEs, there also exists a risk of the formation of toxic substances during photolysis or pyrolysis of parent compounds. The most dangerous products are polybrominated dibenzo-*p*-dioxins (PBDD, **12-138**) and polybrominated dibenzofurans (PBDF, **12-139**).



12-138, polybrominated dibenzo-*p*-dioxins



12-139, polybrominated dibenzofurans

Mitigation

The European Union pushed for the elimination of brominated flame retardants in the 1990s. At present, there is a ban in the EU and US on the production of pentaBDE and octaBDE. Since 2009, the EU has also prohibited the use of decaBDE for electronic equipment. Even so, a large number of products containing these brominated flame retardants are still in use, which results in a continuous release of these substances into the environment.

12.4.3.1.2 Polybrominated biphenyls

Structure and nomenclature

Polybrominated biphenyls (PBBs, **12-136**) represent an older group of brominated flame retardants; 209 possible congeners of PBBs can be derived, but only 101 individual congeners have had registration numbers assigned.

Production PBBs are synthesised by the Friedel–Crafts reaction, in which biphenyl reacts with bromine in the presence of a catalyst ($AlCl_3$ or Fe). Commercial mixtures of PBBs, produced since the early 1970s, contained mainly hexa-, octa-, nona- and decabromobiphenyls.

Properties

Physical and chemical properties PBBs are solids that exhibit high chemical stability and resistance to acids, alkalis, oxidising and reducing agents, and are very thermostable. They are virtually non-volatile and insoluble in water; their solubility decreases with an increasing degree of bromination. Most PBBs have the value of log $K_{OW} > 7$ as they are highly lipophilic substances bioaccumulating in living organisms. A summary of selected chemical and physical properties of commercial mixtures of PBBs are presented in Table 12.50.

PBBs are primarily added as additive flame retardants, for example to acrylonitrile–butadiene–styrene polymers, which have found applications in the automotive industry, electronics and coatings. Since the 1970s, there has been stagnation in the production of PBBs, and the last known commercial production of decaBB was completed in France in 2000.

Occurrence and main sources

Data on the occurrence of PBBs in foods are essentially unavailable. The most serious penetration of these POPs into food chains occurred in the 1970s in Michigan, USA. Contamination of feed by technical mixtures FireMaster BP-6 led to high concentrations in a variety of foods of animal origin.

Health and toxicological assessment

At present, no comprehensive toxicological evaluation of PBBs is available. It can be assumed, however, that due to the structural

log K_{OW}	7.20	-	-	8.58

similarity of PBBs and PCBs, PBB substances can act by the same mechanisms. The lethal dose LD_{50} in laboratory animals after oral administration of commercial mixtures indicates low acute toxicity of these substances (LD_{50} > 1 g/kg body weight). Experimental toxicological tests on laboratory animals have shown a range of adverse effects of prolonged use of PBB mixtures, such as weight loss, dehydration of the body, reproductive disorders, morphological and histopathological changes in the liver and kidneys, thymus shrinkage and swelling of the thyroid gland. PBBs also belong to a group of substances which interfere with the hormone system of the body. Some reports on the carcinogenicity of PBBs suggest that these compounds are not mutagenic themselves, but that their presence supports the carcinogenicity of other substances, such as nitrosamines and polycyclic aromatic hydrocarbons (PAHs).

The toxicities of individual PBB congeners may vary considerably; the most toxic substances are coplanar congeners, which lack a substituent in the *ortho*-position. Also, the degree of bromination can affect the toxicity. The most toxic substance is 3,3′,4,4′,5,5′-hexabromobiphenyl (BB 169), which is present in low concentrations in a commercial mixture under the trade name FireMaster. Conversely, the main component of this mixture, 2,2′,4,4′,5,5′-hexabromobiphenyl (BB 153), is relatively non-toxic.

Some PBBs are considered possible precursors of toxic polybrominated dibenzo-*p*-dioxins (**12-138**) and dibenzofurans (**12-139**), which are formed during combustion. The formation of degradation products of PBBs depends generally on the temperature, the amount of oxygen present and certain other factors. A study of the pyrolysis of the commercial mixture FireMaster BP-6 in the absence of oxygen at 600-900 °C showed the formation of bromobenzenes and lower brominated biphenyls, but polybrominated furans did not result. Pyrolysis in the presence of oxygen at 700–900 °C, however, yielded di- to heptabromodibenzofurans.

Mitigation

In 2006, EFSA recommended monitoring of the PBB congener 153, a marker of contamination by this group of POPs.

12.4.3.1.3 Tetrabromobisphenol A

Tetrabromobisphenol A (TBBPA, **12-134**) is currently the world's most widely used brominated flame retardant. It is produced industrially by bromination of bisphenol A, for example using 50% hydrobromic acid (HBr) in the presence of a solvent, usually carbon tetrachloride or its mixture with water. TBBPA is a colourless, crystalline or amorphous substance containing 58.7% w/w of bromine. A summary of selected physico-chemical properties of TBBPA is given in Table 12.51.

TBBPA has found use as a reactive flame retardant in the production of epoxy and polycarbonate resins added to circuit boards used in computers and in many other devices. In about 10% of cases TBBPA is used as an additive flame retardant, especially in the production of acrylonitrile–butadiene–styrene polymers, polystyrene, papers, textiles, televisions, office equipment and others.

TBBPA is not subject to the process of biomagnification and the main source of exposure is considered to be inhalation. It is assumed that it does not contribute to contamination of the environment as it is easily degraded by UV radiation and various bacteria. The main photodegradation product is 2,4,6-tribromophenol, which is accompanied by di- and tribromobisphenol A, dibromophenols, 2,6-dibromo-4-(bromoisopropylene)phenol, 2,6-dibromo-4-(dibromisopropylene)phenol and 2,6-dibromo-1,4-hydroxybenzene.

Acute toxicity of orally administrated TBBPA to laboratory animals is low (LD_{50} for rats is >5 g/kg body weight), with very little or no effects on body weight, organ abnormalities and behaviour. By contrast, absorption from water by fish is very fast and fish exposed to TBBPA (half-life of its degradation is up to several hours) often have jerking movements, seizures, darker colour, abnormal breathing and various inflammations, increased concentration of thyroid hormone thyroxine in plasma and, in some fish, reduced egg production and juvenile survival.

Table 12.51 Selected physical and chemical properties of tetrabromobisphenol A (TBBPA) and hexabromocyclododecane (HBCD).

Properties	TBBPA	HBCD
Molecular formula	$C_{15}H_{12}Br_4O_2$	$C_{12}H_{18}Br_6$
Relative molecular weight	543.9	641.7

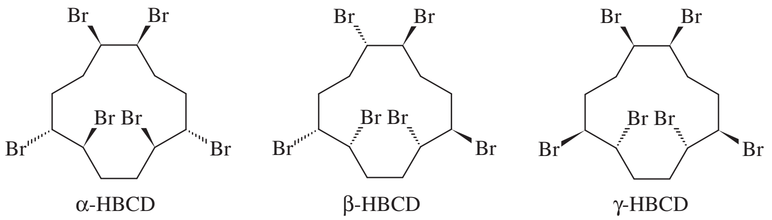
Decomposition point (°C)	316	230
Saturated vapour pressure (mPa)	<0.1	0.63×10^{-7}
Solubility in water (mg/l)	4.16	0.0034
log K_{OW}	4.5	5.6

12.4.3.1.4 Hexabromocyclododecane

1,2,5,6,9,10-Hexabromocyclododecane (HBCD, **12-135**) is a compound with a bromine content of 74.7%. Although 16 different diastereoisomers are known, the commercially manufactured product is a mixture of only three isomers: α (optical antipodes α_1 and α_2), β (β_1 and β_2) and γ (γ_1 and γ_2) (**12-140**). A summary of certain physico-chemical properties of HBCD is shown in Table 12.51.

HBCD is produced industrially by bromination of cyclododecane, or by the addition of bromine to (1*E*,5*E*,9*Z*)-cyclododeca-1,5,9-triene. In both cases a mixture of 1,2,5,6,9,10-hexabromocyclododecane stereoisomers results.

Individual diastereoisomers differ in their melting point temperatures (α: 172 °C, β: 169 °C, γ: 209 °C) and their solubility in water (α: 48.8 μg/l, β: 14.7 μg/l, γ: 2.08 μg/l). At temperatures higher than 160 °C, β- and γ-isomers rearrange to the most thermodynamically stable α-isomer. Commercially used HBCD is produced in two forms, as low melting point and high melting point products, which differ from each other in the content of diastereoisomers. The low melting point mixture contains 70–80% γ-isomer and



12-140, hexabromocyclododecane diastereoisomers

20–30% α- and β-isomers, while the high melting point mixture may contain more than 90% γ-isomer.

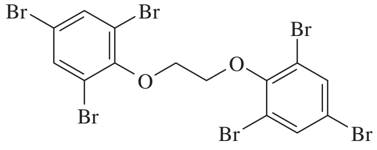
HBCD has been used as an additive flame retardant for more than 20 years. Its main use is in the construction industry, where it is used in polystyrene foams, which are a part of the thermal isolations, and even small concentrations provide sufficient protection against burning. The second major application of HBCD is in the upholstery and textile industries. Products in which the HBCD occurs, for example, include upholstered furniture, various textiles, car seats and upholstery, insulation in trucks and caravans as well as many types of building materials. Unlike other flame retardants, HBCD is not used in electronic circuits.

Currently there is very little knowledge about the possible risks from the use of HBCD. Tests on laboratory animals have found a very rapid absorption in the digestive tract and subsequently elevated levels of HBCD in the blood and certain organs. The acute toxicity of HBCD to mice is very low (LD_{50} for rats is >10 g/kg body weight by oral administration and >20 g/kg body weight for dermal application). At high doses, HBCD can damage the skin or eyes. Prolonged exposure in rats causes an increase in liver weight, reproductive disorders, and affects the nervous and hormonal systems.

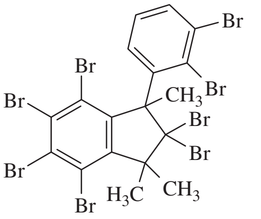
HBCD accumulates in soil, sediments and airborne dust, and is rapidly absorbed in the gastrointestinal tract and accumulates in the fatty tissue of organisms, but has a very short half-life. For example, in fish the half-life of HBCD is only one day. Representation of the individual isomers in the sediments reflects the compositions of commercial mixtures, while the tissues of aquatic animals, especially fish, have a quite different composition of isomers. The dominant substance is the α-isomer; the γ-isomer is present in much smaller amounts and the content of the β-isomer remains virtually constant, which can be explained by the almost selective biotransformation of the γ-isomer to the α-isomer.

12.4.3.1.5 Other flame retardants

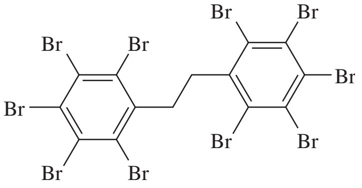
As a result of both gradual voluntary production cuts and legislative measures, production of technical mixtures of PBDEs has decreased and conversely there have been increases in the production of alternative non-PBDE flame retardants. The alternative retardants include bis(2,4,6-tribromophenoxy)ethane (BTBPE, **12-141**), octabromo-1-phenyl-1,3,3-trimethylindane (Br indane, **12-142**), decabromodiphenylethane (DBDPE, **12-143**) and certain other compounds. These substances have similar properties to PBDEs, contain an aromatic nucleus, more bromine atoms and are rarely soluble in water. Some of their physico-chemical properties are summarised in Table 12.52.



12-141, bis(2,4,6-tribromophenoxy)ethane



12-142, octabromo-1-phenyl-1,3,3-trimethylindane



12-143, decabromdiphenylethane

BTBPE is used as an additive flame retardant, replacing octaPBDE, for polystyrene and acrylonitrile–butadiene–styrene products. BTBPE was found in the eggs of birds and especially in the dust and air in plants for the liquidation of electronic waste. Animal studies indicate minimum BTBPE absorption in the digestive tract. The major part of BTBPE is probably excreted, partly as metabolites, such as hydroxylated BTBPE and 2,4,6-tribromophenol.

Br indane is an additive flame retardants, which is manufactured under the name of FR-1808 by reaction of 1-phenyl-1,3,3-trimethylindane with bromine through catalysis with Lewis acids. It is used in technical resins and polystyrene foams. Br indane is kinder to the environment than PBDEs.

DBDPE is an additive flame retardant with similar uses as decaBDE. It is employed in acrylonitrile–butadiene–styrene products, and is added to polystyrene and insulation materials. DBDPE has been detected in air, soil and sludge at concentrations one order of magnitude higher than BTBPE. DBDPE enters the body in small quantities due to its higher molecular weight.

Table 12.52 Selected physical and chemical properties of new brominated flame retardators.

Compound	Molecular formula	M_r	log K_{ow}	Saturated vapour pressure (Pa)

12.4.3.2 Perfluoroalkyl and polyfluoroalkyl substances

Per(poly)fluoroalkyl substances (PFASs) are the result of anthropogenic activities in the latter half of the 20th century. PFASs include many different groups of compounds starting from one-carbon compounds and ending with polymeric substances. Attention was initially focused on research on volatile chlorofluorocarbons (CFCs, known as **freons** by DuPont's brand name), which are also known as greenhouse gases. Polytetrafluoroethylene (PTFE) is a synthetic polymer of tetrafluoroethylene with numerous applications. The best known brand name of PTFE is **Teflon** from the DuPont Company.

The term per(poly)fluoroalkyl substances (PFASs) is the common name for a group of synthetic fluorinated chemicals, including oligomers and polymers. The major areas of use for currently available PFASs are in fire-fighting foams and the chromium-plating industry. PFASs are persistent compounds with bioaccumulation potential that have a negative impact on the environment. Their presence has been confirmed in abiotic and biotic components of the environment around the world.

12.4.3.2.1 Structure and nomenclature

From a chemical point of view, PFASs comprise carbon chains of varied length, in which hydrogen atoms have been wholly (perfluorinated) or partly (polyfluorinated) replaced by fluorine atoms. PFASs include several hundred compounds divided into 23 categories. Important subgroups are per(poly)fluorinated organic surfactants and organic polymers. Commercial products contain per(poly)fluorinated alkyl chains of varying lengths with 4 to 20 carbon atoms. Most of the available data, however, relates to compounds having eight carbon atoms. An overview of these substances is given in Table 12.53. The structure of these groups of compounds is represented by formulae **12-144**. In the environment PFASs are degraded almost exclusively to perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), which are, therefore, the most significant fluorinated contaminants.

12.4.3.2.2 Production

Two main ways of fluorination are used in the industrial production of PFASs. Branched and unbranched fully fluorinated products containing a sulfonic group are synthesised electrochemically; so-called telomerisation (polymerisation in the presence of a chain transfer agent) forms products that are not fully fluorinated, but have a linear perfluorinated alkyl chain with an ethylene group and another functional group. The most important difference between these two production processes is the quality of the final product. Electrochemical fluorination may be used to produce all types of fluorinated compounds, depending on the starting material and its purity. This method was used, for example, by 3M. The telomerisation process is currently used by DuPont, Atofina, Clariant, Daikan and Asahi Glass. The products produced electrochemically contain up to 30% undesirable branched compounds. Substances produced by telomerisation contain very few byproducts, but those which are produced are easy to separate from the desired product.

12.4.3.2.3 Properties

Physical and chemical properties

Perfluorinated compounds have special physico-chemical properties, which make them valuable for use in various industries. They are chemically inert, highly thermally stable and reduce surface tension. They repel both water and oil, so they are both hydrophobic and oleophobic substances. Table 12.54 summarises some physico-chemical properties of perfluorooctane sulfonate (PFOS) potassium salt and perfluorooctanoic acid (PFOA).

In the past PFASs have found use as:

- surface treatment of carpets, fabrics, leather, paper and packaging materials
- manufacture of paints and additives for coatings
- manufacture of detergents for domestic and industrial use
- manufacture of pesticides.

Perfluorinated surfactants do not behave like common organic pollutants. They do not tend to accumulate in adipose tissue or to adsorb, for example to deposits. However, electrostatic interactions play an important role in their distribution in the environment. After entering the organism, these substances preferentially accumulate in the blood plasma and liver (apparently

Table 12.53 Overview of electrochemically produced per(poly)fluoroalkyl substances.

Name	Abbreviation	Classification[a]

through interactions with phospholipids). The bioconcentration factor of perfluorooctane sulfonate (PFOS) is significantly higher than that of perfluorooctanoic acid (PFOA). For example, the bioconcentration factor of PFOS was 4300 in the blood of rainbow trout, while that of PFOA was 27. A considerable amount of PFOS is also deposited through the application of sewage sludge on agricultural land.

12.4.3.2.4 Occurrence and main sources

Release into the environment

Per(poly)fluorinated substances are emitted directly to the environment at the place of manufacture (mostly sorbed on dust particles) and during normal use of products containing PFASs, both in industry and in households. PFOS and related substances may also be emitted from wastewater treatment plants and landfills, where elevated concentrations have been observed. Increased concentrations of PFOS were found mainly in waste water and water leaking from landfills. Fire foams are also a significant source of PFOS emissions. After penetration into the environment, per(poly)fluorinated substances are adsorbed to the organic fraction of the sediment or bioaccumulate in living organisms. A major obstacle in estimating the penetration of PFOS into the environment is degradation of PFOS to several related perfluorinated compounds. The extent of the degradation reactions is not yet fully understood. For example, higher concentrations of PFOS were found in water coming from sewage treatment plants than in the water going into the plants, which points to a possible conversion of perfluorinated substances present in the water to PFOS.

Biodegradation

Owing to the high energy of the C–F bond, many fluorinated organic compounds, except acrylates, are resistant to hydrolysis, photolysis and biodegradation. Figure 12.53 is an example of microbial degradation of *N*-ethylperfluorooctane sulfonamidoethanol (*N*-EtFOSE) in wastewater, which can document biotransformation of some perfluorinated compounds. The end products are PFOS and PFOA, which are stable under aerobic and anaerobic conditions and are not further degraded. Biodegradation of *N*-methylperfluorooctane sulfonamidoethanol (*N*-MeFOSE) also proceeds in the same way.

Contamination of animals

PFOS and related perfluorinated compounds have been found in many organisms around the world. Generally, they are found in the highest amounts in the tissues of predators at the top of the food chain, which have fish as the major food component. In addition to PFOS, perfluorooctane sulfonamide (PFOSA) is usually present, one of the precursors of PFOS. In fish there are often higher PFOSA concentrations than PFOS concentrations, whereas in mammals the opposite is true. This may indicate that mammals have metabolic apparatus that can metabolise PFOSA to PFOS.

In 2002 results were published obtained from the examination of marine mammals, birds, fish, snakes and amphibians (liver, egg yolks, muscle and blood plasma) from all over the globe, including areas of the North and South Poles. PFOS was found in 77% of samples of marine mammals, in 60% of samples of birds, in 38% of fish samples and in 100% of samples of minks and otters. The concentration of PFOS in the liver of seals from the Baltic Sea was 240 μg/kg, in the liver of Canadian polar bears 3100 μg/kg and 1200 μg/kg in the liver of North American minks. Samples from industrial areas, however, contained several times higher amounts of PFOS compared with samples from the Polar Regions. Table 12.55 presents the concentrations of PFOS and PFOA in fish, crustaceans and molluscs.

Human exposure

The first mention of the presence of organic fluorine compounds in human plasma dates back to 1968. Only in the mid-1990s, however, was the occurrence of perfluorinated compounds in plasma confirmed by identification of perfluorooctanoic acid (PFOA). Human exposure to PFASs, including PFOA and PFOS, probably occurs via different exposure pathways, including orally, dermally or by inhalation. Indirect factors such as place of residence, age, type of PFAS and others may also affect the extent of exposure. In general, the concentrations of PFOS in human plasma are higher than concentrations of PFOA. Lower concentrations are found in Europe and Asia, with higher concentrations in the United States and Australia. The exceptions are the Nordic countries Denmark and Sweden, where the findings are comparable to those in the United States. Amounts of PFASs in plasma of men in Germany were twice as high as in the plasma of women and children. In occupationally exposed people, higher amounts of PFASs are generally found (up to thousands of μg/l) with no evidence of association between age and sex, which may be related to the fact that these compounds have a tendency to bind to lipoproteins rather than to neutral lipids, as is the case with PCBs. Table 12.56 presents the concentrations of selected PFASs in breast milk, as an example.

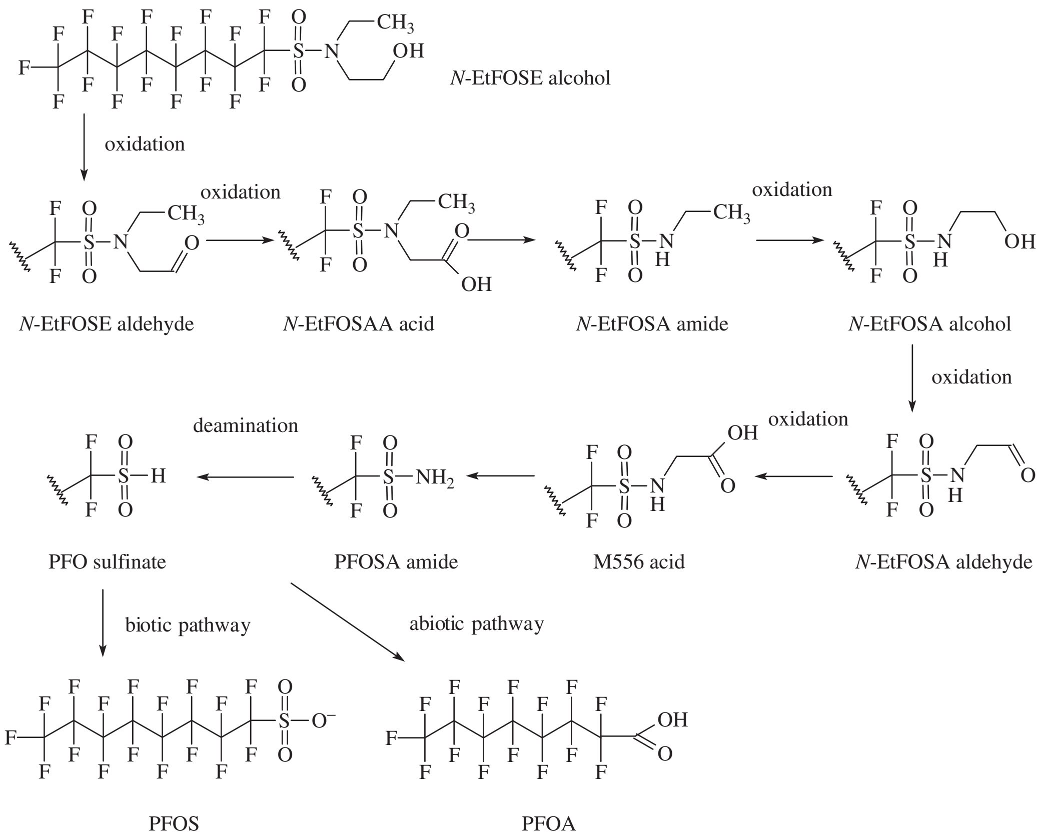

Figure 12.53 Microbial degradation of *N*-ethylperfluorooctane sulfonamidoethanol in sewage sludge.

Table 12.55 Concentrations of perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) in aquatic fauna.

Continent	Species	PFOS (μg/kg)	PFOA (μg/kg)
Europe	Fishes	15.3	0.73
	Crustaceans	184	-
	Molluscs	69.1	-
Asia	Fishes	7.01	3.05
	Crustaceans	2.99	1.4
	Molluscs	5.44	5.2
North America	Fishes	129	1.56
	Crustaceans	0.35	0.17
	Molluscs	0.28	-

Two recent studies from the United Kingdom and Spain on the occurrence of PFASs in the food basket proved that the most important sources of human exposure are fish, fish products and drinking water (surface water is considered one of the major sources of perfluorinated substances). The PFASs occurring in the highest concentrations were PFOS and PFOA, which are the substances most commonly found in the environment. Table 12.57 summarises the amounts of PFOS and PFOA in selected foods in Spain, as an example.

12.4.3.2.5 Health and toxicological evaluation

The mechanisms of the toxic effects of perfluorinated compounds are not yet fully understood. Among the possible harmful effects may be effects on the transport and metabolism of fatty acids in the biological membranes or the bioenergetic processes in the mitochondria. PFOS is practically non-toxic (also in evaluation of subchronic and chronic toxicities) for freshwater algae and higher plants, but shows a slight toxicity to invertebrates. Fishes are much more sensitive to the presence of this substance than algae, plants and invertebrates (the lowest LC_{50} value was 7.8 mg/l for rainbow trout). PFOA is also virtually non-toxic for all tested species of freshwater organisms (bacteria, algae and fish).

After PFOS enters the human body orally, it is relatively easily absorbed and distributed mainly to the liver and blood serum, but is not metabolised. It is excreted in the urine and faeces, but its excretion is very slow. It is estimated that half of the received dose may be removed from the human body in approximately 9 years. PFOA can enter the human body not only orally, but also (to a lesser extent) by inhalation and dermal absorption. It is not accumulated in the adipose tissue, but is covalently bound to macromolecules, especially proteins in the liver, plasma and testes of males. It is not metabolised and is excreted from the body in urine and faeces. It is estimated that half of the ingested amount can be removed from the human body in 1–3 years.

Table 12.56 Concentration of selected per(poly)fluorinatedalkyl substances (PFASs)[a] in breast milk (μg/l).

Country	PFOS	PFOA	PFHxS	PFOSA	PFBS
China	0.045	0.110	0.009	-	0.003

12.4.3.2.6 Mitigation

Contamination of the environment and the human food chain with PFASs influenced the chemical industry to such an extent that the world's largest producer of PFASs, the sole US manufacturer 3M, announced a voluntary shutdown of production in 2000. The U.S. Environmental Protection Agency (EPA) issued two Significant New Use Rules (SNURs) under the Toxic Substance Control Act (TSCA) in 2002 to restrict 88 PFOSs-related chemicals. SNURs allow only three specific, technically essential low volume, low exposure, low release uses to continue: for the photographic/imaging industry, the semiconductor industry and the aviation industry. The final SNUR for 183 PFAS chemicals was published in 2007. The goals were to achieve, no later than 2010, 95% reduction in emissions to all media and products the contents of PFOA, PFOA precursor chemicals and related higher homologue chemicals measured from a year 2000 baseline, and to work toward elimination of PFOA and PFOA precursors and related higher homologue chemicals from emissions and products by 2015.

The European Food Safety Authority (EFSA) has been involved in PFASs in food since 2004, when recommendations to EU member states to monitor these substances were first issued. In 2009, PFOS, its salts and perfluorooctane sulfonyl fluoride (PFOSF) were subjected to restrictions on production and use and were added to Annex B of the Stockholm Convention on Persistent Organic Pollutants (POPs). For PFOS, the lowest No-Observed-Adverse-Effect Level (NOAEL) was established at 0.03 mg/kg body weight per day and a TDI was derived at 150 ng/kg body weight. Based on the occurrence of PFOS in fish and fishery products and drinking water, together with consumption data from four Member States, an indicative figure of 60 ng/kg body weight per day for human exposure was selected. The estimated indicative exposure of high consumers of fish and fishery products is approximately three times as high (200 ng/g body weight per day). Non-food sources of PFOS were estimated to contribute in the order of 2% or less to average

dietary exposure. Drinking water appears to contribute less than 0.5%. For PFOA, an indicative figure of 2 ng/kg body weight per day was established for average human exposure (6 ng/g body weight per day for the exposure of high consumers of fish and fishery products). At these estimated intakes, non-food sources could contribute up to 50% of the average dietary exposure, whereas drinking water would contribute less than by 16%. The TDI value was estimated at 1.5 μg/kg body weight, and the average daily intake for the European population was estimated to be in the range of 2–6 ng/kg body weight.

12.5 Chlorinated aliphatic hydrocarbons

Chlorinated Aliphatic Hydrocarbons (CAHs), a family of compounds that are commonly used in many areas of human activity, are increasingly being detected in soil and groundwater. The most prevalent of these CAHs are tetrachloroethylene (perchloroethylene, PCE), 1,1,2-trichloroethylene (TCE) and 1,1,1-trichloroethane (TCA) illustrated in formulae **12-145** to **12-147**. At the beginning in the 1960s, CAHs were used as industrial solvents primarily for degreasing in the dry cleaning, electronics, industrial manufacturing and machine maintenance industries, and as solvents for varnishes and paints, fats, waxes, resins and alkaloids. For example, dichloromethane (methylene chloride, DCM) is used in the manufacture of urethane polymers and aerosols, and to extract caffeine during the manufacture of decaffeinated coffee. Trichloroethylene is used as a heat transfer medium, as a raw material for the production of trichloroacetic acid and fluorinated hydrocarbons, and together with tetrachloroethylene is used as an industrial solvent for fats, oils, tars, rubber and gums and as a cleaning and degreasing agent in the metals-processing industry. Trichloromethane (chloroform) and 1,1,2-trichlorethylene were previously used as inhalation narcotics, while carbon tetrachloride

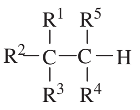
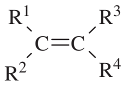
dichloromethane, $R^1 = R^2 = Cl$, $R^3 = R^4 = H$
trichloromethane, $R^1 = R^2 = R^3 = Cl$, $R^4 = H$
tetrachloromethane, $R^1 = R^2 = R^3 = R^4 = Cl$



12-146, chlorinated ethane derivatives
1,1-dichloroethane, $R^1 = R^2 = Cl$, $R^3 = R^4 = R^5 = H$
1,2-dichloroethane, $R^1 = R^4 = Cl$, $R^2 = R^3 = R^5 = H$
1,1,1,-trichloroethane, $R^1 = R^2 = R^3 = Cl$, $R^4 = R^5 = H$
1,1,2-trichloroethane, $R^1 = R^2 = R^4 = Cl$, $R^3 = R^5 = H$
1,1,2,2-tetrachloroethane, $R^1 = R^2 = R^4 = R^5 = Cl$, $R^3 = H$



12-147, chlorinated ethane (ethylene) derivatives
trichloroethylene, $R^1 = R^2 = R^3 = Cl$, $R^4 = H$
tetrachloroethylene, $R^1 = R^2 = R^3 = R^4 = Cl$

and 1,1,2-trichlorethylene were used as anthelmintic agents (against foodborne diseases called helmintoses caused by parasitic worms), especially in veterinary medicine. Later they were forced out by the less toxic perchloroethylene. As a result of leakage of CAHs from storage tanks and machinery, they are now appearing in groundwater and also in foods at concentrations which may be unhealthy and even hepatotoxic, nephrotoxic or carcinogenic. Some of their properties are shown in Table 12.58.

Food contamination can occur in various ways. In the vicinity of factories for dry cleaning of clothing and textiles high concentrations of trichlorethylene (together with trichloromethane) in butter and lard (up to 0.76 mg/kg) were found. Other solvents found in foods include chloroethylene (vinyl chloride), which is used to make polyvinyl chloride (PVC), 1,1-dichloroethylene (vinylidene chloride), used to produce copolymers with vinyl chloride (see Section 12.9.1.5), and (*Z*)- and (*E*)-1,2-dichloroethylene, which are used for various syntheses and as solvents.

A number of chlorinated hydrocarbons arise during reactions of alkanes and alkenes with various chlorinated compounds, or by degradation of other chlorinated compounds. For example, as components of acid protein hydrolysates by traditional technology (hydrolysis with hydrochloric acid), 1,2-dichloropropane and 1,3-dichloropropane (see Section 12.2.4.1) are produced, the precursors of which are residual triacylglycerols found in oilseed meals.

Most CAHs damage the kidneys, cause liver parenchyma and have carcinogenic effects. The legislation defines the permissible amounts of chlorinated aliphatic hydrocarbons in food generally as the sum of all the substances listed in Table 12.58. Minimum amounts are: for milk 0.001 mg/kg, dairy products and fish (0.002 mg/kg), cheeses and poultry (0.003 mg/kg), potatoes (0.004 mg/kg), spirits (0.005 mg/kg), eggs, flour, butter, lard and fats (0.01 mg/kg). The highest levels are set for decaffeinated coffee (3 mg/kg).

12.6 Pesticides

Efforts to protect food supply against attacks by various pests have been documented since ancient times. The Chinese treated cereals and other plants seeds with soda ash and olive oil before storing and used preparations containing arsenic to protect crops during the growing season. The Ancient Greeks and Romans used the antiseptic properties of combustion gases resulting from the burning of sulfur to ward off pests. Substances acting against insect pests are found in many plants that have been used in the past in many countries. Traditional natural pesticides include the alkaloids nicotine and anabasine (see **10-7**), so called **nicotinoids**,

Table 12.58 Overview of physical and chemical and other properties of chlorinated aliphatic hydrocarbons.

Compound	M_r (Da)	Melting point (°C)[a]	Boiling point (°C)[a]	Solubility[b]	LD_{50} (ml/kg)[c]

contained in extracts from leaves and roots of tobacco, mainly from arborescent tobacco species *Nicotiana glauca* (Solanaceae) native to Argentina. Anabasine also occurs in the leaves of *Anabasis aphylla*, a plant belonging to the Amaranthaceae (formerly Chenopodiaceae) family, which grows in the steppes of Central Asia. Plants of the genus *Pyrethrum* (Asteraceae), in particular *P. cinerariaefolium* originating from the Balkans and the Adriatic Sea islands and *P. carneum* growing in the Caucasus and around the Black Sea, contain active components called **pyrethroids** (**12-148**), which have a strong insecticidal effect. Extracts (called pyrethrum) are a mixture of three structurally related esters of a monoterpenoid called chrysanthemic acid (pyrethrins I) and three esters of pyrethrinic acid (pyrethrins II). Pyrethrins later became prototypes of synthetic pyrethroids. One of the most significant natural insecticides and acaricides (pesticides that kills mites and ticks) is (5′*R*,6a*S*,12a*S*)-rotenone (**12-149**) from the group of isoflavones (see **10-95**) called **rotenoids** that are highly toxic to all life forms. Rotenoids occur in some plants of the family Fabaceae, for example in the roots of *Derris elliptica* lianas native to Indonesia and liana species *Lonchocarpus utilis*, *L. urucu* and *L. nicou*, which are native to South America. Powders of lianas are used by natives as a fish poison, but its toxic effects on insects and mites have also been shown. The extract of quassia (also known as bitterwood, *Quassia amara*, Simaroubaceae) likewise has an insecticidal effect. It grows in Central and South America. This extract contains a group of bitter substances called **quassinoids**. A typical representative is quassin (**8-249**).

The beginning of a scientifically conceived, systematic study of the applications of chemical compounds for crop protection dates back to the mid-19th century. In 1867, the so-called Paris green began to be used as an insecticide and rodenticide (Paris Green is also known as Emerald Green, Schweinfurt Green, Imperial Green, Vienna Green, Mitis Green and Veronese green), which is copper(II) acetoarsenite, $4Cu^{2+}(As_3O_6^{3-})_2(CH_3COO^-)_2$. For the prevention of fungal infections in vineyards and potatoes, the Bordeaux mixture (also called Bordo Mix) is used, which is a mixture of copper

sulfate, lime and water invented in the Bordeaux region of France in 1886. This fungicide has been used for over a century and is still used today. A number of other inorganic compounds have since been tested; however, a significant milestone was the introduction of organic mercury compounds for the protection of seeds in 1913. A significant expansion of the use of organic compounds that had pesticidal effects began in the 1930s. Among the first herbicides designed to kill weeds in fields were dinitroderivatives of *o*-cresols, the fungicide thiram from the dithiocarbamates group and pentachlorophenol to combat wood-destroying fungi. One of the first insecticides was the organophosphate tetraethyl pyrophosphate (TEPP).

In 1939, the highly efficient contact insecticide DDT (an abbreviation of the technically incorrect name dichlorodiphenyltrichloroethane) was introduced to the market. Its use, as well as the use of several other organochlorine compounds, spread worldwide in the following years. Important active substances that appeared on the market in the period after World War II include carbamate insecticides and herbicides. Also significant was the discovery of herbicidal phenoxyacetic acids, which represent the first group of the so-called hormonally active pesticides. Around the middle of the last century a number of other biologically active substances were discovered, many of which, such as herbicides based on substituted urea, *s*-triazines (1,3,5-triazines), quaternary ammonium salts or insecticidal synthetic pyrethroids and many others, are still used in many countries around the world.

Alarming signals regarding the occurrence of residues of DDT and of other lipophilic organochlorine pesticides (such as aldrin and dieldrin) in virtually all parts of the global ecosystem and their adverse ecotoxicological effects that began to emerge in the 1960s, however, substantially contributed to the documentation of the potential risks arising from the use of pesticides. DDT and related compounds were progressively banned in almost all countries of the world. This helped initiate research aimed at studying the possibility of environmental protection, including human food chains, against continuing contamination by such persistent pollutants.

In general, the use of pesticides and related biologically active compounds has become an indispensable means of intensifying agricultural production. Besides agriculture, pesticides are also used in forestry and water management and in communal hygiene. The use of these agrochemicals not only provides an increased harvest, but very often manifests into higher nutritional, sensory and technological quality of treated crops. The FAO estimates that crop losses caused by various harmful agents worldwide, if protective agents are not used, could be as high as 30%, and in developing countries even higher. Of course, the extent and type of damage in the given region is subject to weather conditions and the character of the agroecosystem.

In addition to the indisputable positive aspects arising from the use of pesticides, however, there are also negative impacts of the chemical processing of agriculture on the biotic components of the environment, including humans. According to the Stockholm Convention on Persistent Organic Pollutants, 9 of the 12 most persistent organic pollutants are pesticides. Consumers are particularly sensitive to the potential presence of pesticide residues in food, which is one of the main incentives for the increasing interest in foodstuffs produced from so-called ecological and organic farming, which exclude the use of synthetic pesticides.

Knowledge of the basic physico-chemical properties of pesticides, methods of their application, their fate in the environment and especially in food chains, along with information on their changes during storage and processing of food materials and products, is an essential prerequisite for successful adherence to legislative measures and the related reduction of the risk of exposure of consumers to possible pesticide residues.

12.6.1 Classification and nomenclature

A pesticide is any substance or mixture of substances specifically intended to prevent, repel, destroy or lessen the effect of pests, undesirable microorganisms, plants and animals during the production, storage, transport, distribution and processing of agricultural commodities, foods and feeds. The term also includes compounds administered to animals for the control of ectoparasites, growth regulators, desiccants and germination inhibitors applied to crops either before or after harvest.

Pesticides are substances representing a wide range of chemical compounds, often of very complex structure. To facilitate communication, pesticides are known by their **common name**, **trade name** and by their **chemical name**. The common name is name of the active ingredient, the biologically active substance that controls the pest. The trade name is the prominent brand name that the manufacturer gives to the pesticide. Pesticides with different trade names can contain the same active ingredient or ingredients. In practice, the names predominantly used are the common and the trade names. The chemical name is the name of the chemical structure of the active ingredient and is used by scientists. Common names of pesticides and other agrochemicals have been adopted by the Technical Committee of the International Organization for Standardization, created in 1953 (ISO/TC 81). Principles for the selection of common names of pesticides and other agrochemicals are explained in ISO 257:1988, and revised by ISO 257:2004. For example, fungicide containing captan as the active ingredient, the chemical name of which is *N*-trichloromethylthio-4-cyclohexene-1,2-dicarboximide, is called by the trade name Captan or Maestro. The insecticide carbaryl (1-naphthyl methylcarbamate) has the trade names Sevin, Vet-Tek amongst others.

Table 12.59 Classification of pesticides by target harmful organisms.

Group of pesticides	Target harmful organism	Group of pesticides	Target harmful organism
Acaricides (miticides)	Mites	Ovicides	Insect eggs
Algicides	Algae	Larvicides	Insect larvae
Avicides	Birds	Adulticides	Adult insects (imago)
Bactericides	Bacteria	Molluscicides	Molluscs
Fungicides	Fungi, parasitic fungi	Nematicides	Worms
Herbicides	Weeds	Rodenticides	Rodents
Insecticides	Insect	Virucides	Viruses

At present, about 1000 compounds are registered globally that are used as pesticides or other agrochemicals (particularly as herbicides to protect cultivated plants). A common criterion used for their classification is the target (usually harmful) organisms. The most common types of pesticides used are listed in Table 12.59. Table 12.60 summarises the most important groups of pesticides used over the past decades, of which many are still in use. They are classified according to their biological effects. Naturally, the list does not include all registered pesticides, but focuses mainly on the new generation pesticides often referred to as **modern pesticides**. For completeness, substances that can generally be described as **traditional pesticides** or **historical pesticides** are listed. Their use globally is practically nil.

12.6.2 Properties and structures

12.6.2.1 Physical and chemical properties

Pesticides that have been applied in practice represent an extremely large and varied range of chemical compounds (Table 12.60), which is, of course, reflected in a wide variability in their physico-chemical properties. Detailed characterisation of individual compounds obviously goes beyond the scope of this book; therefore, comments here are restricted to some of the major groups of pesticides with regard to their fate in food chains and the changes taking place during technological or culinary processing of contaminated materials. The following characteristics are generally critical for the description and assessment of a pesticide's properties and its behaviour in different systems, and also to predict its levels in human nutrition.

Solubility in water is one of the key characteristics of pesticides that determines their distribution and the stability of the individual components in the environment and in plants. Retention (sorption) of particularly soluble polar pesticides to soil particles is relatively small, but they can penetrate into underground water resources. Polar pesticides are not very stable in the environment and are biodegradable; they can be easily hydrolysed and oxidised. Their limited stability is then the cause of a relatively rapid decrease of their residual amounts in contaminated agricultural products during thermal processing. On the other hand, the loss of polar pesticides by volatilisation from the environment is not significant (a certain prediction of their behaviour provides Henry's law constant, k_H). Pesticides with good solubility in water can generally be easily washed away from the surface of plants, but for lipophilic compounds this occurs with difficulty or not at all.

The saturated vapour pressure is another factor that is directly related to the fate of pesticides after their application. It is assumed that substances with saturated vapour pressure values lower than approximately 1×10^{-7} mPa are associated with solid particles; otherwise they are in the form of vapour. During culinary and technological processes such as drying, milling, baking or frying, higher losses of more volatile compounds can be expected. The extent of these losses, however, depends on the type of food.

The octanal–water partition coefficient K_{OW} in equilibrium at a given temperature usually correlates directly with the degree of pesticide sorption to soil particles and sediments. Generally, substances with a high K_{OW} value (e.g. classical organochlorine pesticides) have a high affinity for the lipidic components of living organisms and are accumulated. Particularly fat-soluble compounds typically have the pK_{OW} value (–log K_{OW}) higher than 4.

The dissociation constant K_a indicates the ability of pesticide residues to dissociate under normal environmental conditions (pH values are in the range of 5–8). In general, the degree of ionisation determines the solubilisation processes, evaporation from aqueous media and the extent of photolysis. Dissociation is obviously influenced by the sorption of pesticides to sediments and soil particles, and by their bioaccumulation.

The octanal–water partition coefficient K_{OC} normalised to the organic carbon content indicates the sorption ability of pesticides to soil or sediment particles. Pesticides with high values of K_{OC} are often very persistent in the environment, since the bound (adsorbed or absorbed) residue is immobilised and can only leach, evaporate or be biodegraded with difficulty.

The bioconcentration factor (BCF) of hydrophobic pesticides indicates the degree of their transition from the aqueous environment, and is a measure of their bioconcentration in the respective organism. The BCF value corresponds to the ratio of the equilibrium concentrations organism/water and is directly proportional to the values of pK_{OW}.

Table 12.60 Classification of pesticides into groups according to the target organism, application method, activity and structure.

Pesticides	Names of pesticides representing a given group[a]
Non-systemic insecticides	
Organochlorine compounds	Aldrin, DDT, dieldrin, dicofol, endosulfan, endrin, heptachlor, chlordan, γ-HCH (lindane), methoxychlor, toxaphen
Organophosphorus compounds	Azinphos-methyl, diazinone, dichlorvos, ethione, etrimphos, fenitrothione, fomophos, phosalone, chlorfenvinphos, chlorpyriphos, chlorpyriphos-methyl, quinalphos, malathione, mecarbam, methidathione, mevinphos, parathione-ethyl, parathione-methyl, pirimiphos-methyl, sulfotep, terbuphos, tetrachlorvinphos, tolclophos-methyl, triazophos
Carbamates	Phenoxycarb, formethanate, carbaryl, methiocarb, methomyl, propoxur
Synthetic pyrethroids	Acrinathrin, allethrin, biphenthrin, bioresmethrin, cyfluthrin, cypermethrin, deltamethrin, fenvalerate, etofenprox, fenpropathrin, flucythrinate, fluvalinate, lambda-cyhalothrin, permethrin, piperonylbutoxide, tau-fluvalinate
Benzoylureas	Diflubenzurone, flucycloxurone, flufenoxurone, lufenurone, teflubenzurone, triflumurone
Others	Fipronyl, pyridabene, thiocyclam, thiodicarb, thiophanox
Systemic insecticides	
Organophosphorus compounds	Acephate, dimethoate, disulfotone, phorate, formothione, phosphamidone, heptenophos, methamidophos, mevinphos, thiometone, trichlorphon, vamidothion
Carbamates	Aldicarb, bendiocarb, benfuracarb, ethiophencarb, furathiocarb, carbofuran, carbosulfan, methomyl, oxamyl, pirimicarb
Others	Acetamiprid, bensultap, buprofezine, cyromazine, diaphenthiurone, hexaflumuron, imidacloprid, triazamate
Specific acaricides	
Without fungicide activities	
Organochlorin compounds	Chlorobenzilate, tetradifon
Organotin compounds	Cyhexatin
With fungicide activities	
Dinitro compounds	Binapicryl, dinocap
Molluscicides	
Aquatic	
Botanic	Endod

Pesticides	Names of pesticides representing a given group[a]
Organotin compounds	Fentin
Chlorinated aromatic compounds	Dichlone, diclorane, chlorothalonil, quintozene (PCNB), tecnazene (TCNB)
Cation-active tensides	Dodine, glyodine
Others	Iprodion, procymidone
Systemic curative fungicides	
Antibiotics	Blasticidine, cyclohexamide, kasugamycine, streptomycine
Benzimidazoles	Benomyl, thiabendazole, thiophanate-methyl
Morpholines	Dodemorph, tridemorph
Pyrimidines	Bupirimate, ethirimol
Piperazines	Triforine
Others	Metalaxyl, propiconazole, triadimefon
Herbicides applied to leaf	
Systemic or translocated	
Phosphonoamino acids	Gluphosinate, glyphosate
Benzoic acid derivatives	Dicamba, chlorophenprop-methyl, 2,3,6-TBA
Chlorinated aliphatic acids	Dalapon, TCA
Oxyphenoxyacid esters	Cycloxydim, diclofop-methyl, fenoxaprop-ethyl, fluazifop-butyl, haloxyfop-methyl, quizalofop-ethyl
Phenoxyalkanoic acids	2,4-D, 2,4-DB, dichlorprop, mecoprop, MCPA, MCPB, silvex, 2,4,5-T
Quaternary ammonium compounds	Diquat, paraquat
Applied to leaf, contact	
Benzonitriles	Bromoxynil, dichlobenil, ioxynil
Benzothiadiazoles	Bentazone
Carbanilates	Phenmedipham
Cyclohexenones	Cycloxydim, clethodim, sethoxydim
Dinitrophenols	Dinoseb
Diphenylethers	Acifluorfen, lactofen, nitrofen, oxyfluorfen
Applied to soil	
Acetanilides	Alachlor, butachlor, metolachlor, propachlor
Amides and anilides	Benzoylprop-ethyl, difenamide, naptalam, pronamide, propanil
Carbanilates and carbamates	Asulam, barban, bendiocarb, carbetamide, chlorpropham, propham, triallate
Dinitroanilines	Benephin, pendimethalin, trifluralin
Pyridazinones and pyridinones	Amitrol, dimethazone, fluridone, norflurazone, oxadiazone, pyrazone
Pyridineoxy- and picolinic acids	Fluroxypyr, clopyralid, picloram, triclopyr
Phenylureas or other substituted ureas	Dimefurone, diurone, fenurone, fluometurone, chlorbromuron, chlorotoluron, isoproturon, linuron, metobromuron, metoxuron, monolinuron, siduron

Table 12.60 (*continued*)

Pesticides	Names of pesticides representing a given group[a]
Sulfonylureas	Amidosulfuron, flupyrsulfuron-methyl, chlorimuron-ethyl, chlorsulfuron, metsulfuron-methyl, nicosulfuron, primisulfuron-methyl, prosulfuron, rimsulfuron, sulfometuron-methyl, sulfosulfuron, thiameturon-methyl, triasulfuron, tribenuron, triflusulfuron-methyl
Thiocarbamates	Butylate, cycloate, EPTC, molinate, pebulate, thiophencarb, triallate
Triazins	Ametryne, atrazine, desmetryne, hexazinone, cyanazine, methoprotryne, metribuzine, prometone, prometryne, propazine, simazine, terbumetone, terbuthylazine, terbutrizine, terbutryne
Uracils	Bromacil, lenacil, terbacil
Desiccants and defoliants	
Organophosphorus compounds	Merfos
Derivatives of phenols	Dinoseb
Quaternary ammonium compounds	Diquat, paraquat
Growth regulators and growth promoting substances	
Auxins	2,4-D, MCPB, NAD
Cytokinins	Adenine, kinetin
Gibberellins	GA_3, giban
Substances producing ethylene	Ethephon
Growth inhibitors and retardators	
Quaternary ammonium compounds	Chlormequate, mepiquate
Hydrazides	Daminozide, maleinhydrazide
Triazoles	Paclobutrazola, uniconazole
Rodenticides	
Fumigants and anticoagulants	
Hydroxycoumarins	Brodifacoum, difemacoum, coumafuryl, coumatetralyl, warfarin
Indanediones	Diphacinone, chlorophacinone, pindone
Without coagulation activities	
Arsenic compounds	Sodium arsenite, arsenic trioxide
Benzeneamines (anilines)	Bromethaline
Thioureas	Antu, promurit
Natural compounds	Red squill (*Drimia maritime*, Asparagaceae), strychnine
Others	Fluoroacetamide, sodium fluoroacetate, zinc phosphide, sodium norbormide

[a] Abbreviated names are derived from chemical or common names: DDT (dichlorodiphenyltrichloroethane), HCH (1.2.3.4.5.6-hexachlorocyclohexane), PCNB (pentachloronitrobenzene), TCNB (1,2,4,5-tetrachloro-3-nitrobenzene), 2,3,6-TBA (2,3,6-trichlorobenzoic acid), TCA (trichloroacetic acid), 2,4-D [(2,4-dichlorophenoxy)acetic acid], 2,4-DB [4-(2,4-dichlorophenoxy)butyric acid], MCPA [(4-chloro-2-methylphenoxy)acetic acid)], MCPB [(4-chloro-o-tolyloxy)butyric acid)], 2,4,5-T (trolamine or 2,4,5-T-triethylammonium), EPTC (*S*-ethyldipropylthiocarbamate), GA_3 (gibberellic acid or gibberellin A_3).

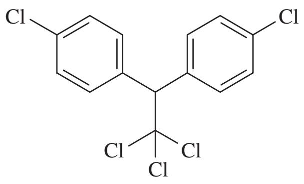
12.6.2.1.1 Persistent chlorinated hydrocarbons

Organochlorine pesticides are chlorinated hydrocarbons which were used extensively from the 1940s in agriculture and pest control. Most of these compounds were banned in 2004 when the Stockholm Convention went into effect. Measures to reduce or eliminate these persistent organic pollutants (POPs) were: elimination of their production and use (category A, which includes aldrin, chlordane, dieldrin, endrin, heptachlor, hexachlorobenzene, mirex and toxaphene and also polychlorinated biphenyls and hexachlorobenzene, which also has use as an industrial chemical), and restriction and control of their production and use (category B, which includes DDT). Pentachlorophenol, formerly used as a herbicide, insecticide and fungicide, is now used mainly as a fungicide to protect wood or as a biocide in masonry. Its use as a herbicide is banned. Lindane is currently being examined at an international level and its worldwide ban is being considered.

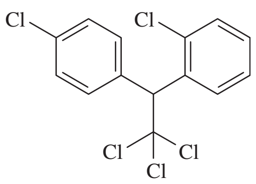
Organochlorine pesticides are mostly contact insecticides with neurotoxic effects that are characterised by their high lipophilicity and related high potential to accumulate in the adipose tissues of living organisms. These properties, along with high chemical stability and limited biodegradability, are the reasons why many organochlorine pesticides were banned, but their residues are still commonly found in the environment, either as the parent insecticides or some of their persistent metabolites. Some organochlorine pesticides are still registered for use in certain countries. The spectrum of the major contaminants in the food chain is due to their persistence. They are mainly present in fish and other aquatic animals, but also in tissues of higher mammals, including humans.

DDT

The insecticide DDT, 1,1,1-trichloro-2,2-bis(4-chlorophenyl)-ethane (technical grade DDT), was composed of up to 14 chemical compounds, of which only 65–80% was the active ingredient, *p,p′*-DDT (**12-150**). The other components included 15–21% of the nearly inactive isomer *o,p′*-DDT (**12-151**), up to 4%



12-150, *p,p′*-DDT



12-151, *o,p′*-DDT

of *p,p′*-DDD, dichlorodiphenyldichloroethane, up to 1.5% of 1-(4-chlorophenyl)-2,2,2-trichloroethanol, lower amounts of *o,p′*-DDD and closely related compounds with low insecticidal properties, *p,p′*- and *o,p′*-isomers of DDE, 1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene. The physical and chemical properties of DDT and derived compounds are listed in Table 12.61.

DDT was first introduced in World War II (in 1940) as a very effective agent to wipe out malaria by killing the mosquitoes that carry the disease. Since that time, DDT, DDE and other components of technical grade DDT have entered the environment (Figure 12.54). DDT stays in the environment for long periods and can travel long distances from where it was originally used. Both compounds, DDT and DDE, have even been found in Arctic and Antarctic animals, even though DDT was never used in those regions. DDE also enters the environment as a DDT metabolite, which is produced by enzymatically catalysed biotransformation (dehydrochlorination) of DDT in living organisms. In adipose tissue of animals, the DDT dechlorination product DDD can also frequently be found. In air, DDT, DDE and DDD are rapidly broken down by sunlight (the estimated half-life is about 3 days), and they are sorbed strongly to soil. Most DDT in soil is broken down slowly to DDE and DDD by microorganisms; half the DDT in soil will break down in 2–15 years, depending on the type of soil. Biodegradation of DDT, for example, by white rot fungus *Phanerochaete chrysosporium* yields polar, water-soluble metabolites including DDD, FW-152 and 4,4′-dichlorobenzophenone (DBP) and 2,2,2-trichloro-1,1-bis(4-chlorophenyl)ethanol (dicofol), one of the intermediates of DDT

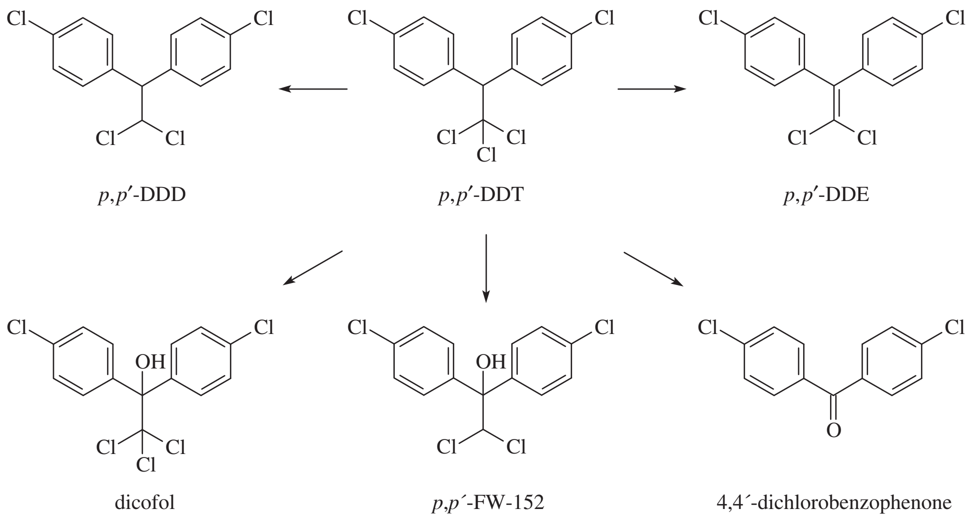

Figure 12.55 Transformation products of *p,p′*-DDT.

synthesis, effective against red spider mite, which was formerly used as a miticide (Figure 12.55).

Typical levels of DDT and derived compounds in different parts of the ecosystem in the mid-1970s can be seen in Figure 12.56. As a result of biomagnification, in some clams and fish, concentrations of DDT are ten times greater than those in the plankton, and the process of biomagnification goes up the food chain from one trophic level to the next. Gulls, which feed on clams, can accumulate 40 or more times the concentration of DDT that was in their prey. This represents a 400-fold increase in concentration along the length of this short food chain. The people applying the pesticides are exposed primarily to DDT, whereas nearly all of the general population is exposed to the metabolite DDE in the diet or drinking water. For example, in 1991, the IARC reported that the mean concentrations of DDT in the population have declined in much of the world: from 5–10 mg/kg to around 1.0 mg/kg of milk fat or even lower over the last three decades. DDT residues (residues of *p,p*'-DDT, *o,p*'-DDT, *p,p*'-DDE and *o,p*'-DDE) in human fat (1995–1997) in the UK were 1.0–9.3 mg/kg (47 cases), 0.1–0.9 mg/kg (135 cases) and 0.01–0.09 mg/kg (19 cases), which may reflect the measures taken since DDT was banned. DDE is mostly found in autopsy or biopsy samples of organisms, and also in the breast milk of mammals, often in much higher concentrations than the parent insecticide DDT. The ratio of these two substances (conversion rate) thus indicates the time from the primary organism load. The major metabolite detected in faeces and liver samples is *p,p′*-FW-152, 2,2-dichloro-1,1-bis(4-chlorophenyl)ethanol.

The amount of DDT in food has greatly decreased since DDT was banned, and should continue to decline. Between the years 1986 and 1991, the average adult in the United States, for example, consumed an average of 0.8 μg of DDT a day. Adults consumed slightly different amounts based on their age and sex. The largest fraction of DDT in a person's diet comes from meat, poultry, dairy products and fish. Leafy vegetables generally contain more DDT than other vegetables, possibly because DDT in the air is deposited on the leaves. Infants may be exposed by drinking breast milk. The changes of concentrations of DDT and related compounds during industrial and culinary processing of foods are minimal due to their relatively low volatility and considerable resistance to degradation. Health standards have laid down very strict criteria for DDT content in food. For example, in the EU the maximum concentration of DDT in drinking water is 0.1 μg/l, while the United States is more tolerant, with a limit set at 50 μg/l. Maximum residue

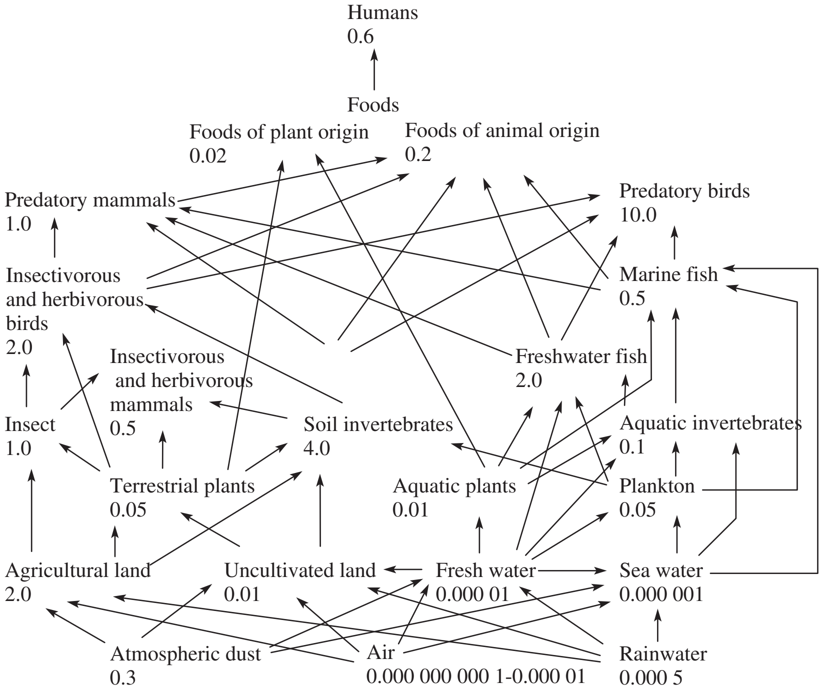

Figure 12.56 Typical levels (in mg/kg) of DDT and derived compounds in different parts of the ecosystem.

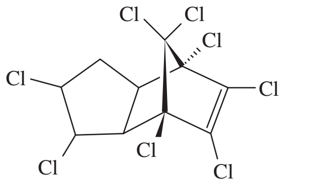
levels expressed as the sum of *p,p′*-DDT, *o,p′*-DDT, *p,p′*-DDE and *o,p′*-DDE for fresh and frozen fruits and nuts are 0.05 mg/kg.

Potential mechanisms of DDT action on humans are genotoxicity and endocrine disruption. Acute toxicity is moderate, while chronic toxicity has been linked to diabetes. A number of studies have found a prevalence of diabetes in a population with increased serum levels of DDT or DDE. The IARC classified DDT as a Group 2B agent.[3]

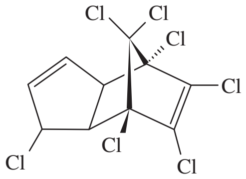
Other chlorinated hydrocarbons

From a toxicological point of view, the most hazardous chlorinated insecticides are cyclodienes known as **aldrin** and aldrin epoxide **dieldrin**, named after the Diels–Alder reaction, which was used for the synthesis of aldrin. Aldrin, 1,2,3,4,10,10-hexachloro-1, 4,4a,5,8,8a-hexahydro-1,4:5,8-dimethanonaphthalene, was widely used until the 1970s, when it was banned in most countries. Dieldrin, chemical name 1a*R*,2*R*,2a*S*,3*S*,6*R*,6a*R*,7*S*,7a*S*)-3,4,5,6, 9,9-hexachloro-1a,2,2a,3,6,6a,7,7a-octahydro-2,7:3,6-dimethano-naphtho[2,3-*b*]oxirane, is an extremely persistent insecticide that tends to biomagnify as it is passed along the food chain. It was widely used from the 1950s until the early 1970s. Dieldrin is also produced by photooxidation of aldrin, as is another product, photodieldrin, and a highly toxic stereoisomer of dieldrin known as **endrin** and certain other compounds (Figure 12.57). Endrin was primarily used as an insecticide and also as a rodenticide.

Chlordane, 1,2,4,5,6,7,8,8-octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindane (**12-152**), also known as chlorindane and chlorotox, is another cyclodiene produced by chlorinating cyclopentadiene to form hexachlorocyclopentadiene, and condensing the latter with cyclopentadiene. Chlordane is an insecticide used primarily in agriculture for the treatment of maize and citruses, and in



12-152, chlordane



12-153, heptachlor

households against termites. It was banned in the United States in 1988, but in some countries it is still used. Cyclodiene **heptachlor** (**12-153**), 1,4,5,6,7,8,8-heptachloro-3a,4,7,7a-tetrahydro-4,7-methano-1*H*-indene is about 3–5 times more active as an insecticide, and is also produced via the Diels–Alder reaction of hexachlorocyclopentadiene and cyclopentadiene. This was used similarly to chlordane between the 1960s and 1970s in agriculture, but also in households as an insecticide to kill ants, termites and worms. It is still in use in some countries against ants and in the protection of underground electrical cables or around transformers. The use of heptachlor is now restricted to controlling fire ants in power transformers. Heptachlor is also a component of the insecticide chlordane. **Mirex**, 1,1a,2,2,3,3a,4,5,5,5a,5b,6-dodecachlorooctahydro-1*H*-1,3, 4-(methanetriyl)cyclobuta[*cd*]pentalene (**12-154**), produced by the dimerisation of hexachlorocyclopentadiene in the presence of aluminium chloride, was used in agriculture to control ants and termites. In the 1960s, mirex was used as a flame retardant in plastics and building materials.

Another persistent chlorinated insecticide is **toxaphene**, a complex mixture of about 200 structurally related chlorinated terpenes (containing 6–11 chlorine atoms) derived from camphene by

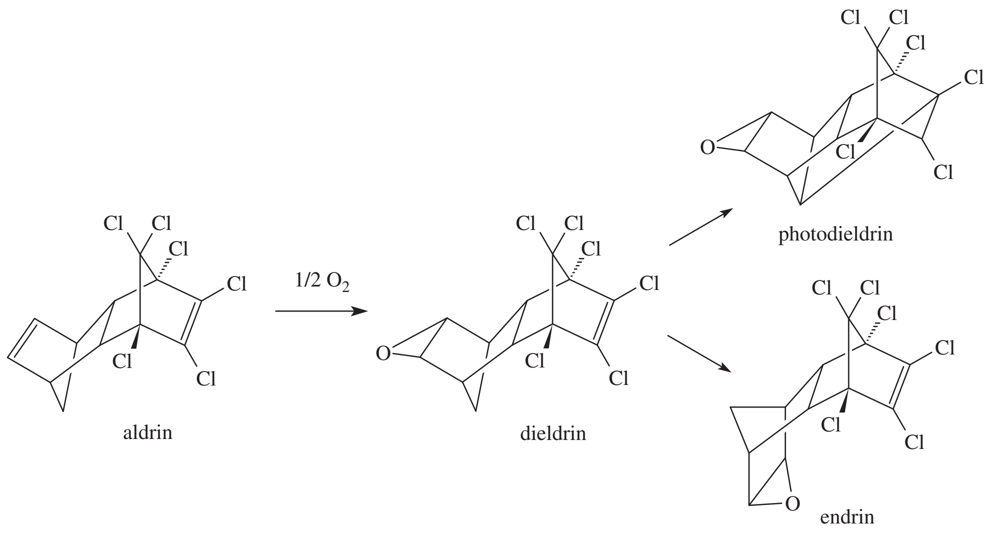


Figure 12.57 Transformation products of aldrin.

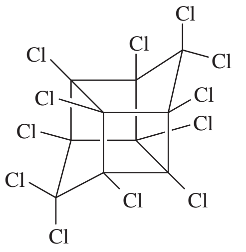
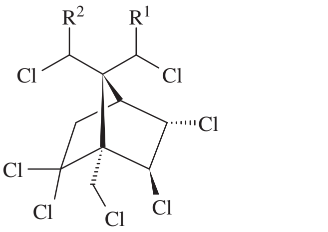


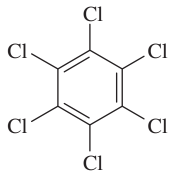
12-154, mirex

chlorination to an overall chlorine content of about 70%. Very little is known about the mode of action and metabolic fate of these compounds. They differ not only in their toxicities, but also in their stabilities in the environment. In technical preparations, octachlorobornanes known as toxicants A-1, A-2 and B (**12-155**) are predominant. For example, toxicant A-1 has the chemical name 2,2,5,6-tetrachloro-1,7-bis-chloromethyl-7-dichloromethylbicyclo[2.2.1]heptane. It was used mainly in the 1970s, and in 1982 it was banned for most situations, and in 1990 it was banned for all uses in the United States.

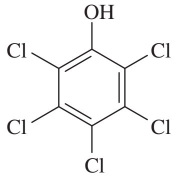
Important chlorinated insecticides of the group of alicyclic and aromatic chlorinated compounds are **hexachlorobenzene** (HCB), also known as perchlorobenzene or benzenehexachloride (BHC, **12-156**), **pentachlorophenol** (PCP, **12-157**) and **hexachlorocyclohexane** (HCH). Hexachlorobenzene is environmentally very dangerous, because due to its volatility, high stability and bioaccumulation it is able to spread over large distances. For example, similarly to DDT, it has been demonstrated in the air, water and tissues of animals and humans living in the Arctic region, although it was never used there. The technical product HCH is a mixture of eight stereoisomers, of which the most effective insecticide is γ-HCH, (1α,2α,3β,4α,5β,6β)-hexachlorocyclohexane, also called **lindane**, hexachloran or gammexan (**12-158**). This isomer is accompanied by α-HCH, which is (1α,2α, 3β,4α,5α,6β)-isomer, β-HCH (1α,2β,3α,4β,5α,6β)-isomer, δ-HCH (1α,2α,3α,4β,5α,6β)-isomer, ε-HCH, (1α,2α,3α, 4β,5β,6β)-isomer, ζ-HCH (1α, 2α,3α,4α,5α,6α)-isomer, η-HCH (1α,2α,3α,4α,5β,6β)-isomer and ξ-HCH (1α,2α,3α,4α,5α,6β)-isomer.



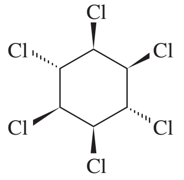
12-155, toxicant A-1, R^1 = Cl, R^2 = H
toxicant A-2, R^1 = H, R^2 = Cl
toxicant B, $R^1 = R^2$ = H



12-156, hexachlorobenzene



12-157, pentachlorophenol



12-158, γ-1,2,3,4,5,6-hexachlorocyclohexane

The IARC classified aldrin, dieldrin and endrin as Group 3 chemicals not classifiable as to their carcinogenicity to humans, but all the other chlorinated hydrocarbons (chlordane, heptachlor, mirex, toxaphene, hexachlorobenzene, pentachlorophenol and

hexachlorocyclohexanes) were classified as Group 2B compounds, probably carcinogenic to humans.[3]

12.6.2.1.2 Modern pesticides

Table 12.62 gives some of the physico-chemical characteristics of modern pesticides. Structures of some of these pesticides are given in formulae **12-159** to **12-200**. Commonly used compounds were selected, residues of which have been and still are found in foods relatively frequently. In comparison with the previous group of persistent organochlorine compounds, modern pesticides are mostly substances that have higher solublity in water and lower pK_{OW} values.

12.6.2.2 Biological activity

The inhibition or elimination of harmful factors by the use of pesticides includes a wide range of mechanisms. Their detailed specification is not possible, therefore only some illustrative examples are listed.

The basis of insecticidal effects typical of classical organochlorine compounds, such as DDT, and pyrethrins, such as pyrethrin I and the synthetic pyrethroids, organophosphates or carbamates, is their neurotoxicity, but the mechanism of action is not identical for all compounds. In insects DDT and pyrethrins act on the voltage-gated sodium channel by prolonging the inactivation current. Other chlorinated hydrocarbons, including lindane and octachlorobornane toxicant A-2 (the principal active ingredients of hexachlorocyclohexane and toxaphene) and the cyclodienes are neurotoxicants with a different target that was finally defined as the heteropentameric γ-aminobutyric acid (GABA)-gated chloride channel. Organophosphates and carbamates, such as carbaryl, ethephon, dichlorvos, dimethoate and acephate, inhibit the enzyme acetylcholine esterase (they act as serine hydrolase inhibitors) by phosphorylation or carbamoylation of the bound serine hydroxyl group in the active centre of the enzyme (acetylcholine is the only neurotransmitter employed in the motor division of the somatic nervous system and the principal neurotransmitter in all autonomic ganglia). Insecticidal benzoylureas, by contrast, are inhibitors of chitin synthesis, and thus inhibit the construction of insect cuticles. The mechanism of action of fungicides is actually heterogeneous as the attack targets may be the fungal hyphae and their spores. For example, the fungitoxic effect of widely used ethylenebisdithiocarbamates (EBDC) or phthalimides is based, among other things, on the inhibition of enzymes containing sulfhydryl groups. The toxicity of another important group of fungicides, benzimidazoles, is based on their interference with the biosynthesis of DNA (its replication during cell division). Herbicidal effects are based on an extraordinarily diverse range of mechanisms. For example, phenoxyalkanoic acids and derivatives of benzoic acids cause an atypical growth of sensitive plants (targeted weeds), which is based on disorders of nucleic acid metabolism caused by herbicide applied on the leaves, which is similar to the effect of plant hormones or plant growth regulators termed auxins. Total (non-selective) herbicides from the group of quaternary (bipyridylium) ammonium compounds interfere with the process of photosynthesis, which is mainly due to irreversible changes in cell membranes, in which they catalyse the oxidation of fatty acids. The effect of nitroaniline is based on retardation of weed seed germination, inhibition of root development and cessation of mitosis. Herbicides, such as triazines, phenylureas or uracils inhibit electron transport during photosynthesis (the Hill reaction in chloroplasts). The Hill reaction is formally defined as the reduction of an electron acceptor by electrons and protons from water, with the evolution of oxygen, when chloroplasts are exposed to light.

12.6.3 Occurrence and main sources

12.6.3.1 Release into the environment

With the exception of certain fumigants, pesticides are rarely used as pure compounds. In addition to the active ingredients, commercial preparations (formulations) contain various other components (solvents, emulsifiers and adhesives) that facilitate or improve the storage, handling and biological effects of pesticide formulations in the period after application. The treatment of crops (or livestock) is done by pesticide formulations in the form of sprays, aerosols, powders or granules. Unlike other groups of environmental contaminants, the entry of pesticides into the environment should be under controlled conditions and in accordance with the principles of good agricultural practice.

Conditions under which pesticides are used (with regards to data of producers, these are approved at the national level) must ensure effective and reliable pest control, but the quantity and method of use must also ensure that pesticide residues in treated products are minimal. Pesticides are often applied to the leaf surface, however the target organism is not necessarily the plant itself, but parasitic fungi or insects. Pesticides with **systemic effects** penetrate through the leaf cuticle and are translocated within the plant. The mobility of substances with **quasi-systemic effects** (some fungicides and insecticides) is lower and only a limited amount of the active agent penetrates the cuticle. The third category of substances are called **contact pesticides**, which exhibit a local effect only in places where their surface deposits are found. Pesticides may also be applied directly to the soil or get there during the crop treatment, which accounts for about 35–50% of the pesticide used, depending on the type of plant and density of vegetation. Systemic pesticides in soil are taken up by the roots and transported to the aerial parts of the plant. Availability of the pesticide from the soil is mainly determined by its solubility and the organic carbon content of the soil (due to the possibility of its immobilisation by sorption), and for non-polar compounds is inversely proportional to the value of K_{OC}.

Application of pesticide formulations, in particular in the form of sprays and powders, can lead to significant contamination of the atmosphere. On average, 10–20% of the pesticide used is thus in the form of vapour or droplets associated with the solids and transported by air flow to more or less remote locations, which may cause the pollution of agroecosystems. Pesticides with higher vapour pressure may be re-evaporated from the terrestrial or aquatic environment. Long-range transport of residues is particularly relevant in the case of persistent organochlorine compounds. After application, pesticides are affected by several chemical, physical and biological factors. Under field conditions, these factors can be applied individually or simultaneously depending on the type of application and the properties of the active substance. In general, pesticides used today, which are classified as modern, are characterised with respect to their physico-chemical properties, by

short-to-medium persistence and accumulation in the food chain is low to negligible. Insecticides, herbicides and fungicides to which harvested crops were exposed during the growing season have **preharvest withdrawal times** (the minimum interval between the last application and harvest) and following label directions will ensure that residues of these pesticides either do not remain on the plant material or remain there in amounts that do not exceed the maximum residue limits (MRLs) when crops are harvested, eaten or fed to livestock.

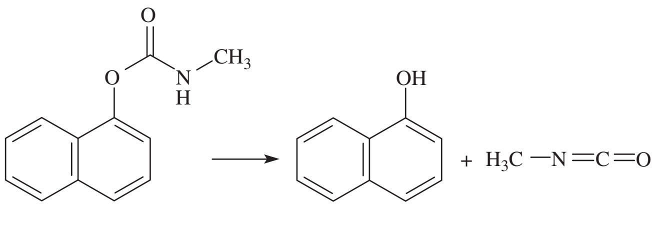

Figure 12.59 Thermal decomposition of carbaryl

12.6.3.1.1 Degradation in abiotic environment

Physical factors applied during the degradation of pesticides are mostly the energy from light and heat. In particular, photolysis of residues (occurring on the surface of leaves, in soil, atmosphere or in the aquatic environment is one of the most important processes leading to elimination of a number of pesticides from the environment. Along with singlet oxygen (see Section 3.8.1.8.4), reactive hydroxyl and superoxide radicals, and other free radicals generated by photochemical reactions, play an important role. Direct photolysis by solar radiation is involved only in part of the photodegradation processes. An example of these reactions is photolysis of aldrin (Figure 12.57).

An important reaction to which pesticides are subjected in the environment is hydrolysis, which is especially rapid at extreme pH values. As an example, hydrolysis of the synthetic pyrethroid insecticide permethrin to isomers of dichlorovinyl derivatives of chrysanthemic acid and 3-phenoxybenzyl alcohol (Figure 12.58) may be mentioned. A relatively rapid hydrolytic cleavage of ester bonds also occurs in many organophosphates. Examples of pesticides that are easily degraded by heating are *N*-methyl carbamates. For example, carbaryl is degraded to naphthalen-1-ol (1-naphthol) and methylisocyanate (Figure 12.59). Decomposition of fungicide benomyl analogously yields butylisocyanate and carbendazim, which has similar effects as benomyl. Carbendazim is slowly hydrolysed and decarboxylated to 2-aminobenzimidazole. Decarboxylation of butylcarbamic acid produces butylamine as a minor product, which reacts with butylisocyanate to yield *N*,*N*′-dibutylurea (Figure 12.60). Of course, the ease of decomposition of pesticides is also reflected in the length of the withdrawal period.

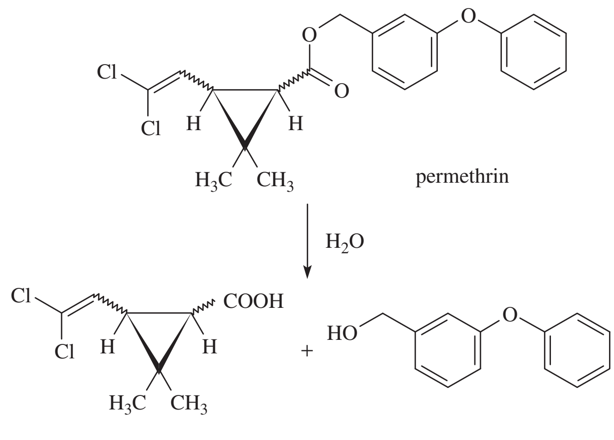

Figure 12.58 Hydrolysis of permethrin.

12.6.3.1.2 Degradation in biotic environment

Biological factors involved in the degradation of pesticides in soil and aqueous environments include particular microorganisms, various bacteria, fungi and actinomycetes. In principle, there are two types of degradative processes:

- **co-metabolism**, when the pesticide biotransformation proceeds by normal metabolic processes in a microorganism that is incapable of using the substrate as a source of energy or building material (the organism is actually growing on a second substrate and is transforming the pesticide without gaining the benefit);

- **catabolism**, when the pesticide becomes a substrate for a given microorganism (a source of carbon or nitrogen), adaptations can be found especially in bacteria during repeated exposure to xenobiotics.

Biodegradation of pesticides, however, also takes place in exposed plants and animals, whether they are target or non-target organisms, and the formed products can reside in the human food chain. In particular, vertebrates (especially birds and mammals) have active enzyme systems capable of effective degradation of xenobiotics. A brief description of these processes is presented in the following discussions, along with some specific examples.

Activation of protective mechanisms occurs when the harmful substance penetrates into the body. The penetration rate of pollutants and their distribution in the body, however, as well as the range of detoxification or elimination mechanisms, is subject to anatomical, physiological, biochemical and other factors. Phase I biotransformation typically involves changes catalysed by hydrolases and oxidases, in which polar functional groups are

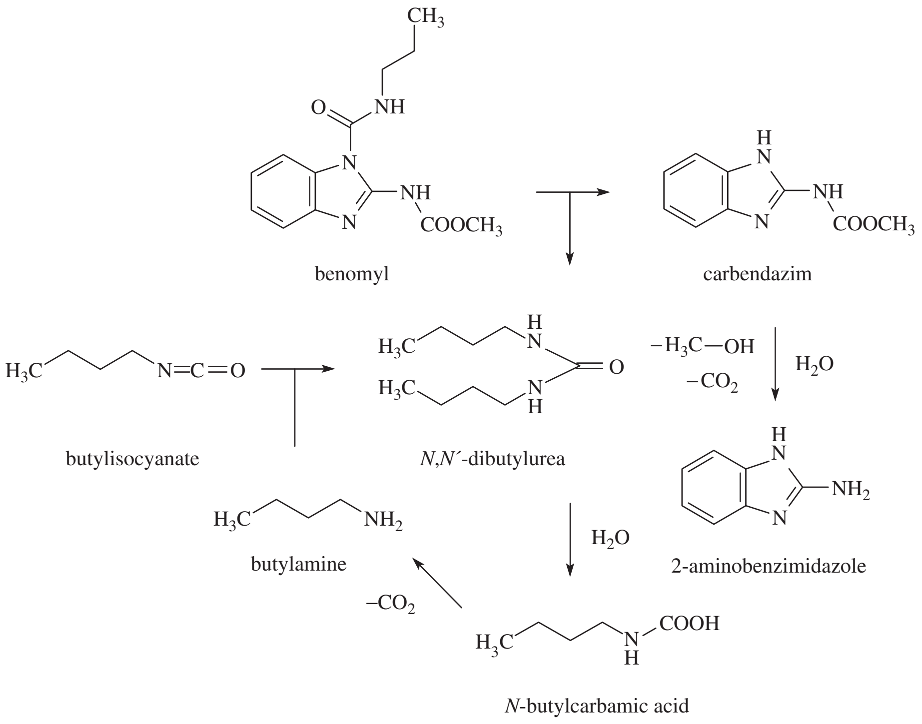

Figure 12.60 Decomposition of benomyl.

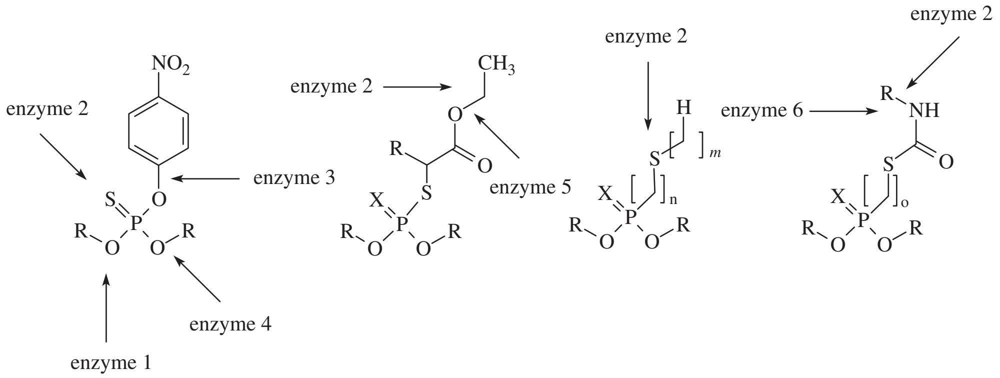

Figure 12.61 Enzymes involved in the biotransformation of organophosphorus compounds.

introduced to the molecule of the parent compounds, or these groups are formed from the parent molecule by degradation. For the example of organophosphates, Figure 12.61 shows the places of enzymatic attack in the initial phase of the biotransformation. The resulting primary metabolites often additionally enter into secondary reactions of phase II, which leads to their conjugation with small polar endogenous molecules to produce products that can be easily excluded from the organism. The type of resulting secondary metabolites is characteristic of each species. For example, in plants and invertebrates conjugation with D-glucose predominates. In plants, the waste products are apparently stored in lignin structures. In mammals, birds and certain fish, conjugation with D-glucuronic acid and reduced glutathione (GSH) primarily takes place, while in other fish conjugation with glycine occurs too. The metabolites in animals are transported by blood and excreted.

The complexity of degradation processes that take place in the biotic environment is demonstrated by a widely used herbicide atrazine (Figure 12.62). Substances of this group (symmetrical 1,3,5-chlorotriazines known as *s*-chlorotriazines) may be hydrolysed non-enzymatically to hydroxytriazines, which no longer exhibit herbicidal activity. Cleavage of a chlorine atom from the carbon C-2 is catalysed by the naturally occurring benzoxazinoid hydroxamic acids, such as (*R*)-2,4-dihydroxy-7-methoxy-2*H*-1,4-benzoxazin-3(4*H*)-one, which is known under the acronym DIMBOA (see Figure 10.12). Together with other derivatives, glucoside of this benzoxazinoid hydroxamic acid is present in plants tolerant to triazines, such as maize, wheat, rye and other monocotyledonous plants. Alternative detoxification of atrazine is an enzymatically catalysed conjugation with glutathione. Resulting products are also inactive as herbicides. As is evident from

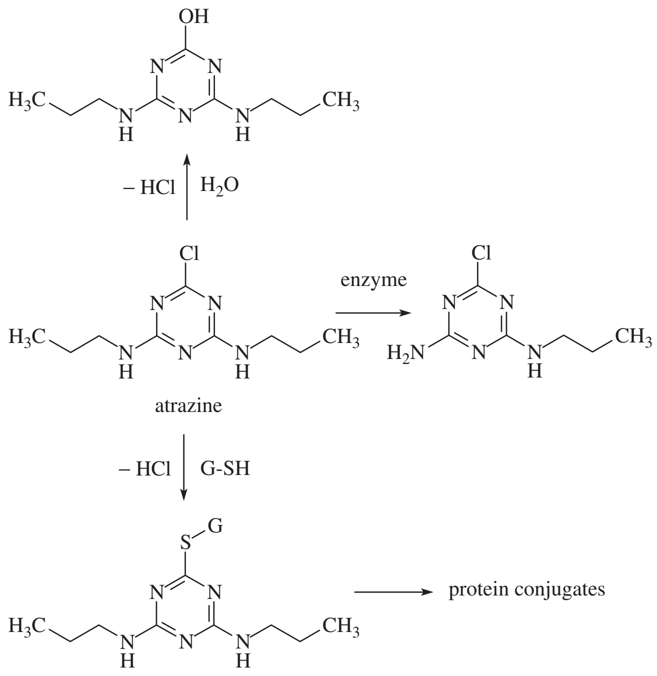

Figure 12.62 Biodegradation of atrazine (G-SH = reduced glutathione, enzyme = microsomal monoxidase).

Figure 12.62, another possibility of atrazine biodegradation may be dealkylation on the secondary amino group at carbons C-4 and C-6. Dealkylated metabolites partly retain the herbicidal activity of the parent compound.

Figure 12.63 provides another example of the diversity of metabolic processes to which pesticides are subjected after application. In the case of the carbamate insecticide carbaryl, the predominant processes are oxidation and hydrolysis, which may be followed by conjugation of primary metabolites with glutathione. The character of metabolic transformations is closely related to the pesticide selectivity (toxicity) to target and non-target organisms.

12.6.3.2 Contamination of foods

Transformation processes generally have a detoxifying nature, but can also lead to the formation of products that show more or less similar toxic effects on the target harmful organisms and on humans. Examples include formation of dicofol from DDT (Figure 12.55), carbendazim from benomyl (Figure 12.60) or aldoxycarb from aldicarb (Figure 12.64). In some cases, the formed substances can even be significantly more toxic than the parent compound. For example, the *in vivo* activation (desulfuration) of the insecticide parathione leads to the formation of paraoxone (Figure 12.65), the active form of the insecticide and a very potent inhibitor of acetylcholinesterase. A typical pro-insecticide is carbosulfan, which is hydrolysed in the insect body to biologically active carbofuran (Figure 12.66). In mammals, this reaction does not take place (the case of a highly selective compound), which explains the very low acute toxicity of carbosulfan for mammalian organisms.

Toxic compounds may likewise be produced from relatively non-toxic precursors during storage or handling of contaminated materials. Probably the most significant example is the formation of ethylenethiourea (ETU), which is one of many degradation products of extensively used fungicides known as ethylenebisdithiocarbamates (EBDCs, Figure 12.67). According to the IARC, ETU is not classifiable as to its carcinogenicity to humans. In the late 1980s, special attention was devoted to the formation of the *N*,*N*-dimethylhydrazine from the popular growth regulator daminozide used for fruit ripening, which is a potential carcinogen of Group 2B (Figure 12.68). Phenoxyalkanoic acids can yield relatively persistent chlorinated phenols as decomposition products, which can accumulate in the human food chain. Chlorinated phenols also arise from other precursors, for example from the pesticides lindane and pentachlorophenol.

12.6.3.2.1 Influence of technological and culinary operations

The operations used in the processing of farm crops or domestic culinary procedures usually have a significant impact on the residue levels in the final products. Generally the following can occur:

- a decrease in the level of pesticide residue due to pesticide degradation, volatilisation or selection of the edible portion with lower pesticide content;
- concentration of the pesticide residue in the edible portion due to the uneven distribution of residues in the commodity or higher affinity of the pesticide to the edible portion;
- formation of toxic degradation products from relatively non-toxic precursors.

Information on the effects that cause an increase or decrease in levels of pesticide residues in food raw materials and the final products are very important, because in estimating health risks from dietary exposure to residues of pesticides, it is necessary to consider the form in which the given food is consumed. In most cases, technological and culinary processes lead to a reduction, and often to the complete removal, of pesticide residues.

Drying

Under certain circumstances, drying may instigate an increase in pesticide concentration caused by an increase in the dry matter content. The level of volatile pesticides, on the other hand, decreases in the surface of the product. Drying in the sun can also cause photolysis of some pollutants. Freeze-drying does not usually result in lower levels of pesticide residues.

Removal of surface layers

Removal of surface layers may, in crops such as bananas, pineapples, kiwi, citruses, melons and others, result in a marked reduction in the levels of non-systemic pesticide residues applied directly to the crop

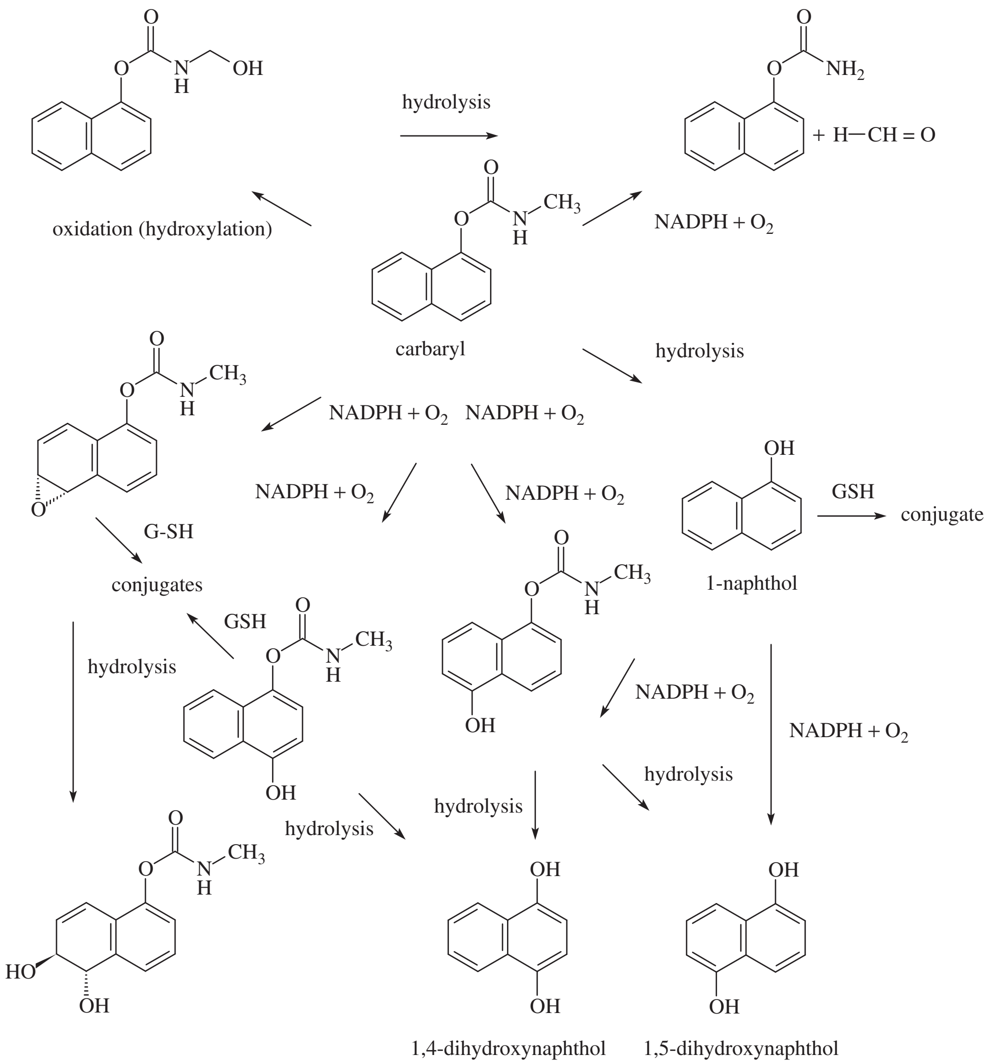

Figure 12.63 Biodegradation of carbaryl (G-SH = reduced glutathione).

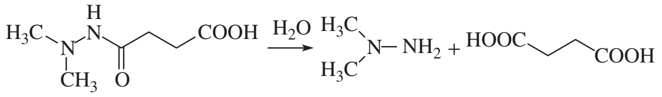

Figure 12.68 Transformation of daminozide into *N*,*N*-dimethylhydrazine.

before or after harvest. A similar effect can be achieved by removing the surface leaves of some vegetables (such as cabbage) and the surface layers of potatoes or cereals. For example, decontamination of potatoes grown in soil containing phorate was accomplished by peeling, which reduced the residue levels by 30%. Removing the outer husks of the rice grain treated with insecticide based on pirimiphos-methyl (to obtain brown rice) and, especially, removing the bran (the rest of the husk and the germ to obtain white rice), may lower the pesticide residue level to 70–90% of the original content. In the case of systemic pesticides, however, this process does not lead to product decontamination. Feeding livestock contaminated waste often leads to inadvertent infiltration of pesticide residues into the human food chain, especially in the case of lipophilic pesticides that may bioaccumulate.

Washing and blanching

Most of the technological processes used in fruit and vegetable processing include washing and blanching. The decrease in the levels of pesticide residues is possible particularly in the case of pesticides that are soluble in water, or in the case of contact pesticides deposited on the plant surface that can be mechanically removed. The overall effects resulting in a reduction of pesticide residues depend on a number of factors, the most important of which are:

- localisation of residues – only residues on the surface can be removed and not systemic compounds;
- age of residue – after application to the surface of the crop, pesticides gradually penetrate into the deeper layers of the cuticle and cannot, therefore, be easily removed later;
- solubility in water – increased lipophilicity of residues increases their affinity for cuticular waxes and washing is not very effective (lipophilic insecticides such as parathione, fenitrothione and diazinone, for example, are relatively difficult to remove);
- temperature and type of bath – a higher temperature or the addition of a detergent will solubilise residues, meaning they can be better removed from the surface; in an alkaline bath (containing sodium hydroxide), sometimes used to facilitate peeling of fruits and vegetables, the level of pesticides can be significantly reduced or even eliminated.

Boiling

Hydrothermal processes lead to a large reduction of residue levels, which is associated not only with volatile substances that vaporise with water vapour, but also with elevated temperatures that accelerate the hydrolysis of pesticides. For example, the loss of malathione can reach almost 100% in cooked spinach and 92% in cooked rice, while cooking tomatoes contaminated with carbaryl can decrease the pesticide concentration to 31%, and cooking meat contaminated with organophosphate insecticides similarly has a decontaminating effect.

Changes in concentrations of some groups of pesticide residues during heat treatment are not significant. For example, the decrease in concentrations of synthetic pyrethroids during cooking, baking or frying of foods of plant origin is negligible. Similarly, the decrease of thiabendazole concentration during the baking of potatoes is also negligible.

Milling

The active ingredients of pesticide products used in the treatment of grains in the postharvest period are found mainly in the surface layers of the grains. The levels of residues present in bran are therefore high. Concentration factors of frequently used organophosphorus insecticides and synthetic pyrethroids thus often reach values in the range of 2–4. For products made from wholemeal flour, however, the risk of residues is higher than for products made from white flour (Table 12.63). The husking (de-hulling) process for removing the rice hull from the rough rice removes up to 90% of the pesticide residues.

12.6.3.2.2 Vegetable oils and animal fats

The treatment of oilseed plants during the growing period leaves only very low or undetectable pesticide residues, but the risk of contamination is significantly higher in the case of postharvest application of pesticides. In particular, relatively lipophilic

Table 12.63 Influence of wheat processing on pesticide content in cereal products.

Pesticide	Pesticide content in cereal products (%)[a]				Concentration factor
	Wholemeal flour	White flour	Whole grain bread	White bread	Bran/Wheat
Bioresmethrin[b]	5	64	43	80	4.0
Deltamethrin[c]	29	91	69	94	3.3
Diflubenzurone	31	83	22	66	2.2
Glyphosate	46	55	64	93	2.2
Permethrin	9	65	68	84	3.2

[a] Content in wheat = 100%.
[b] Bioresmethrin occurs in resmethrin and makes 35–40% of that insecticide.
[c] Unlike other pyrethroids, deltamethrin consists of one pure compound.

Table 12.64 Distribution and changes of selected pesticides in production of vegetable oils.

Pesticide	Raw material	Concentration factor raw oil/seeds	Loss of pesticide during deodorisation (%)
Dichlorvos	Soybeans	5.3	100
Etrimfos	Rapeseeds	2.7	98
Chlorpyrifos	Soybeans	4.1	100
Malathione	Soybeans	3.9	100
Parathione	Olives	4.5	-
Pirimifos-methyl	Peanuts	1.7	-
Permethrin	Sunflower seeds	0.7	17

pesticide residues pass to the crude oil during pressing or extraction. Concentration factors >1 were found primarily for the group of synthetic pyrethroids (such as cyhalothrin, cypermethrin, fenvalerate and permethrin) and some organophosphates (diazinone, dichlorvos, etrimfos, malathione, parathione, pirimifos-methyl and chlorpyrifos). Pesticide residues can be found especially in virgin oils, but are found only sporadically in refined oils (mostly traces of pyrethroids). A significant reduction of pesticide concentrations occurs during oil refining, especially during deodorising (Table 12.64).

12.6.3.2.3 Fruit juices

The amounts of pesticides passing from raw materials into fruit juices depend on the distribution of residues between the solid (skin or flesh) and liquid fruit portions. Moderately to highly lipophilic pesticides, such as parathion, captan, folpet or synthetic pyrethroids, usually pass to the raw juices only to a very limited extent. A further decrease of their contents may occur during operations such as clarification or ultrafiltration. The risk of infiltration of residues into the human food chain, however, exists when the solid waste with higher concentrations of pesticides is used as an animal feed.

12.6.3.2.4 Alcoholic beverages

The transition of residues of pesticides used to protect the grapes as far as the final product depends on their solubility in water and the rate of their degradation, particularly hydrolysis. For example, a total transfer of polar benomyl residues to final products can be expected. Conversely, a lower transition of frequently used fungicides such as folpet, captafol, propiconazole, triadimefon and vinclozolin from grapes to wine can be expected, mainly due to sorption of these compounds to the solid waste (Table 12.65). In beer, pesticide residues are found only exceptionally, due not only to dilution, but also to degradation during technological operations and sorption to yeast cells.

12.6.3.3 Residues in foods

The presence of pesticide residues in the human diet is mainly due to their targeted preharvest and postharvest applications. The source of contamination of agricultural crops by some more persistent compounds may be atmospheric transport from distant places. It is necessary to consider the possibility of translocation of residues from soil contaminated in previous growing seasons; various agrochemicals may also contain water from rivers and

Table 12.65 Changes in levels of selected pesticides in wine production (%).

Pesticide[a]	Must	Clarified must	Wine	Pesticide[a]	Must	Clarified must	Pesticide
Benomyl	0	0	0.8	Iprodion	45–70	60–80	70–78
Captafol	50	95	100	Metalaxyl	0	30–50	66
Folpet	50	95	100	Vinclozolin	59–88	80	89–93

[a]Pesticide content in grapes = 100%.

reservoirs. Foods of plant origin contain mainly residues of modern pesticides or their metabolites. Foods of animal origin may become a source of persistent organochlorine pesticides that accumulate in fat tissues. Residues of modern pesticides occur rather rarely and their presence can be attributed, for example, to contamination of feeds or to pesticides used in protecting animals. For illustration, Table 12.66 brings together data obtained from reports on pesticide monitoring published in various countries. Only pesticides found in more than 10% of cases during the investigation of the given commodity are summarised. In particular, pesticide residues are frequently found in cereals, where all of them are used in postharvest applications. Particularly

Table 12.66 Combination pesticide/commodity with a frequent incidence of positive residue findings (monitoring in different countries).

Pesticide	Commodity	Number of analysed samples	Samples with pesticide resudues (%)
Carbaryl	Barley	188	17.6
Carbaryl	Oat flakes	130	33.9
Carbaryl	Sorghum	156	96.8
Chlorpyrifos	Kiwi	127	20.5
Chlorpyrifos	Tomatoes	3613	27.8
Chlorpyrifos	Bell peppers	1428	27.7
Chlorthalonil	Celery leaves	375	65.6
Dicofol	Citrus fruits	1022	14.5
Dimethoate	Green peas	837	11.5
Dithiocarbamates	Apples	135	19.9
Dithiocarbamates	Grapes	285	17.9
Dithiocarbamates	Tomatoes	866	27.8
Dithiocarbamates	Cucumbers	613	11.9
Endosulfan	Spinach	183	21.9
Endosulfan	Melons	925	26.9
Endosulfan	Lettuce	2169	16.8
Endosulfan	Cucumbers	1659	19.8
Endosulfan	Green beans	574	11.7
Fenitrothione	Cereals	12 759	74.5
Permethrin	Celery leaves	422	15.4
Permethrin	Lettuce	2451	18.3
Permethrin	Spinach	183	12.6
Vinclozolin	Strawberries	509	48.1
Vinclozolin	Kiwi	126	43.7

frequent are findings of residues in fruits and vegetables with a waxy surface. Taking into account all available data (more than 200 combinations pesticide/commodity), the most commonly detected pesticides include acephate, benomyl/carbendazim, carbaryl, chlorothalonil, chlorpyrifos, cypermethrin, deltamethrin, dicofol, dimethoate, dithiocarbamates, endosulfan, fenitrothione, fenvalerate, malathione, parathione, permethrin and vinclozolin. Only a small proportion of residues exceed the values set by the national health limits. The upper limit of incidence of residues above the limit stated is 5% in most sources, but mutual comparability of data is very difficult for many reasons.

12.6.4 Health and toxicological assessment

Pesticides can be naturally toxic to non-target organisms, including humans, in particular if the effect of a substance is based on interference with similar processes, which take place in the human organism. In terms of the possibility of pesticide poisoning, the most discussed risks are associated with long-term exposure to residues obtained in the diet. Generally, the level of these risks, as well as other high-risk groups of food components, are derived not only from the dose received, but also from the mechanism of absorption, distribution, metabolism and excretion of pesticides from the body. A general methodology of pesticide toxicity classification was issued by the WHO.

The mechanism of toxic effects to mammals is accurately described for only a few groups of pesticides. As already mentioned, the toxicity of organophosphates and carbamates is due to inhibition of acetylcholinesterase, toxic effects of dinitrophenols and polychlorinated phenols lie in the inhibition of oxidative phosphorylation. The increased toxicity of certain pesticides may proceed *in vivo* by mechanisms that have been previously listed. This mainly concerns the formation of oxoanalogues of organophosphates, which are more potent acetylcholinesterase inhibitors than the parent thionophosphates and thiophosphates. Pesticides that accumulate in human fat (DDT, lindane and others), although not easily metabolised, may be mobilised under certain conditions (e.g. during starvation or breast feeding), which may lead to a significant increase in their concentration in blood serum with the manifestation of toxic effects.

None of the pesticides used today are classified by the IARC as a human carcinogen, yet some of them (particularly the classic pesticides DDT and toxaphene and modern pesticides amitrole and phenoxyalkanoic acids) are classified as potential human carcinogens. In recent years, in the context of assessing the exposure risks, the ability of certain pesticides to interfere with hormonal processes of vertebrates, including humans, and to cause so many side effects, is often discussed. Pesticides which show oestrogenic effects as xenooestrogens (anthropogenic oestrogens) include only some organochlorinated pesticides with high accumulation potential, such as toxaphene, dieldrin, heptachlor, DDT and derived compounds, especially DDE, but also modern pesticides represented by herbicides 2,4-D, atrazine and alachlor, fungicides benomyl and ethylenebisdithiocarbamates and insecticides carbaryl, dicofol, permethrin, parathione and others.

12.6.5 Mitigation

Legislative measures concerning the presence of pesticide residues in food are generally set at the EU level. Limits introduced in the past in national regulations were harmonised with the relevant EU limits. Maximum residue limits of pesticides (MRLs) in foods and crops and rules for their application are currently set at two different levels – global (Codex Alimentarius) and European, and in each case the limits for a large number of pesticide–commodity combinations are always given. Based on Regulation (EC) No. 396/2005 from September 2008, all responsibility for assessing the risk associated with the MRLs of pesticides was transferred to the European Food Safety Authority (EFSA), which is responsible for assessing the risks of new MRLs, but also for the periodic review of existing MRLs. Currently, EFSA coordinates revision of MRLs for more than 300 substances. In the case of previously used persistent pesticides that are still found in foods due to contamination of the ecosystem, the so-called Extraneous Residue Limits (ERLs) are set. Unlike in other groups of contaminants, inputs of which into the human food chain are difficult to completely eliminate, in the case of pesticides alternative ways to protect crops from harmful agents to minimise pesticide residues are increasingly being sought. In particular, emphasis is put on the integrated protection incorporating complementary practices, including breeding of resistant plants and the use of biological pesticides.

For foods listed in Annex I to Regulation (EC) No. 396/2005 (315 foods, including fruits, vegetables, cereals, spices and foods of animal origin), if the relevant MRL value for a particular pesticide is not declared in Annexes II (list of MRL values) or III (temporary EU limits), then the default limit is 0.01 mg/kg. This of course does not apply to pesticides referred to in Annex IV (52 pesticides for which MRLs are not declared, referring to the low risk) or Annex V (pesticides with other limits than 0.01 mg/kg). Annexes to the Regulation (EC) No. 396/2005 are gradually amended by other extensive regulations. Owing to the vast number of MRLs given by combinations of several hundred pesticides with many types of food, and due also to the need for constant updating of the pronounced values, the legislation concerning pesticides is very confusing and difficult to use in practice.[9] Carcinogenic and mutagenic substances, or substances acting as endocrine disrupters, are banned. However, they may obtain exemption if there is no substitute and they are proved to be necessary for pest control. Immunotoxic and neurotoxic pesticides are included in the list of candidates that will be replaced with safer alternatives where such alternatives exist.

12.7 Veterinary drugs

The production of high quality and hygienically acceptable foods of animal origin in agriculture implies ensuring the overall health and welfare of livestock through good nutrition and reducing

[9] Current MRLs can be found at http://ec.europa.eu/sanco_pesticides/public/index.cfm.

stress. Livestock production is therefore not possible without the use of veterinary drugs. Veterinary drugs (pharmaceuticals) are pharmacologically and biologically active chemicals used for the treatment, prevention and diagnosis of diseases in animals. With ever-increasing demands on productivity, growth in livestock production is manifested by the high concentration of animals in factory farms and their frequent geographic relocation, which promotes the spread of infectious diseases. As a result, the use of veterinary drugs in animal production has greatly increased over the last few decades. In pursuit of high productivity, inadequate sanitary conditions were in many cases replaced by increased use of pharmaceuticals, with the aim of preventing deterioration of the health of farm animals. An extreme way of increasing productivity can be the illegal use of pharmacologically active compounds as growth promoters, such as anabolic steroids, thyreostatics and antibiotics in low doses.

12.7.1 Classification, structure and properties

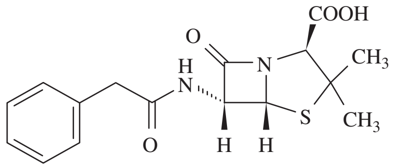
The veterinary products for a variety of animals, including pets, livestock and numerous exotic species, comprise several hundreds of pharmaceutical, biological, diagnostic, feed medications and parasiticide products. The most widely used groups of veterinary drugs include:

- antimicrobial substances
- antiparasitic agents.

Also often used as veterinary drugs are:

- anti-inflammatory agents called **antiflogistics**
- drugs acting on the nervous system, which include anaesthetising agents or **anesthetics** and sedative agents or **tranquilisors**
- drugs acting on the kidney, known as **diuretics**
- preparations acting on the digestive tract, such as against diarrhoea that are called **antidiarrhoics**
- hormones
- vitamins
- trace mineral elements and others.

In the European Union, approximately 700 pharmacologically or biologically active chemical compounds are currently either lodged for registration or registered for use in the Member States. Examples of the most important groups of pharmacologically active substances used in veterinary medicine are given in Tables 12.67 and 12.68. The structures of selected pharmaceuticals are illustrated by formulae **12-201** to **12-230**.



12-201, benzylpenicillin

Table 12.67 List of frequently used veterinary antimicrobial drugs.

Pharmaceuticals	Name	Pharmaceuticals	Name
Antibiotics		Macrolide	Tylosin
β-Lactam			Spiramycin (selectomycin)[a]
Penicillins	Benzylpenicillin (penicillin G)		Erythromycin[b]
	Ampicillin	Chloramphenicol group	Chloramphenicol
	Amoxicillin		Thiamphenicol
	Cloxacillin	Lincosamides	Lincomycin
Cephalosporins	Ceftiofur		
	Cephaloridine	***Sulfonamides***	Sulfadiazine
Tetracycline	Tetracyclin		Sulfadimidine
	Chlortetracycline		Sulfadoxine
	Oxytetracycline		Sulfadimethoxine (dinosol)
Aminoglycoside	Dihydrostreptomycin		Trimethoprim
	Gentamycin		
	Kanamycin[c]	***Quinolones***	Enrofloxacin

[a] Contains three components: spiramycins I, II and III.

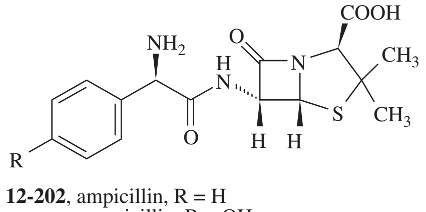
[b] Erythromycin A is the main metabolite, other components are erythromycin B (without an OH group in C-12 position of aglycone called erythronolide) and erythromycin C, which contains instead of cladinose (2,6-dideoxy-3-*C*-methyl-3-*O*-methyl-L-*ribo*-hexopyranose also known as 3-*O*-methylmycarose) saccharide known as mycarose.

[c] Pharmaceuticals contain 95% of kanamycin A and 5% of kanamycin B; kanamycin C is produced from kanamycin B.

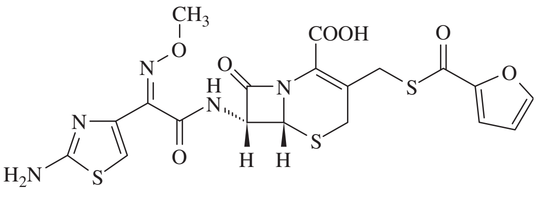
Table 12.68 Other important groups of veterinary drugs.

Pharmaceuticals	Name[a]
Antiparasitic agents[b]	
Coccidiostats[c]	Monensin, dicarbazim, narazin
Anthelmintics[d]	
Benzimidazoles[e]	Thiabendazole, albendazole
Probenzimidazoles[e]	Netobimin, febantel
Macrolide endectocides[f]	Ivermectin,[l] doramectin
Pyrethroids[g]	Permethrin
Organophosphates[g]	Foxim
Other agents	
Non-steroid anti-inflammatory agents (antiflogistics)	Carprofen, ketoprofen
Analgetics, antipyretics[h]	Salicylic acid
Substances effecting the autonomic nervous system[i]	Clenbuterol
Substances effecting the central nervous system	Pentobarbital Amphetamine[m]
Sedatives[j]	
Analeptics[k]	

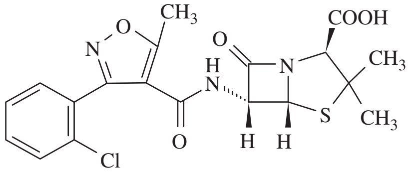
[a]Thiabendazole and permethrin structures (see Section 12.6.2.1.2), salicylic acid structure (see Section 8.2.6.1.6).
[b]Drugs used against external (ectoparasitica) and internal (endoparasitica) parasites.
[c]Drugs used primarily to protect chickens against coccidiosis (enteritis or cachexia).
[d]Drugs used in the treatment of helmintoses, infections caused by lower parasitic worms.
[e]Endoparasitica.
[f]Endoparasitica and ectoparasitica.
[g]Ectoparasitica (insecticides).
[h]Analgesics are drugs that decrease or inhibit the perception of pain of various origins, antipyretics reduce abnormally elevated body temperature, while they do not affect the normal body temperature (often also having an analgesic effect).
[i]Bronchodilator effect.
[j]Drugs causing a decrease of increased excitability of the central nervous system.
[k]Drugs with stimulating effect on the central nervous system acting on circulatory and respiratory centra in the medulla.
[l]Contains about 80% of dihydroavermectin B_{Ia} (22,23-dihydroavermectin) and 20% of dihydroavermectin B_{Ib}.
[m]Mixture of enantiomers.



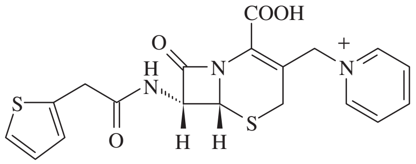
12-202, ampicillin, R = H
amoxicillin, R = OH



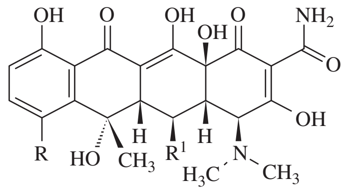
12-204, ceftiofur



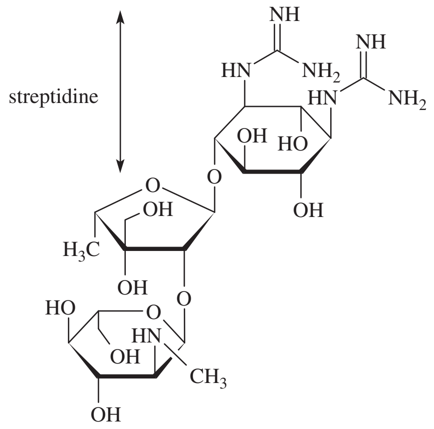
12-203, cloxacillin



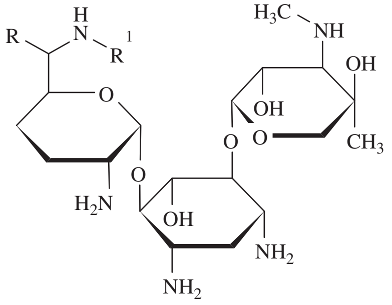
12-205, cephaloridine



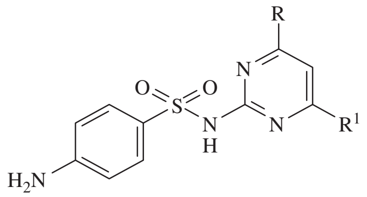
12-206, tetracycline, $R = R^1 = H$
chlortetracycline, $R = Cl$, $R^1 = H$
oxytetracycline, $R = H$, $R^1 = OH$



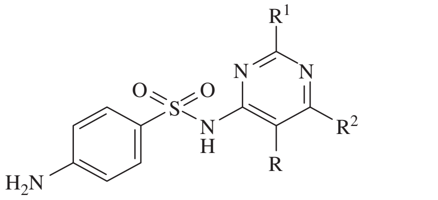
12-207, dihydrostreptomycin



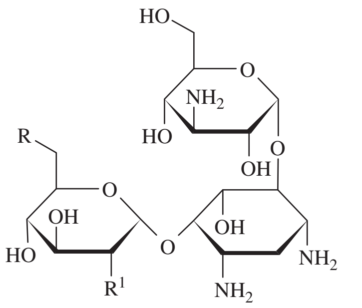
12-208, gentamicin C_1, $R = R^1 = CH_3$
gentamicin C_2, $R = CH_3$, $R^1 = H$
gentamicin C_3, $R = R^1 = H$



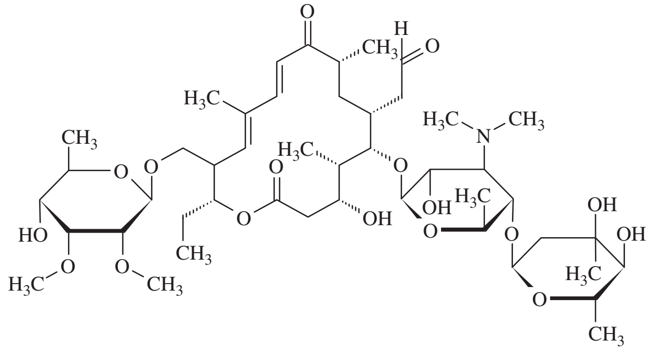
12-209, sulfadiazine, R = R1 = H
sulfadimidine, R = R1 = CH_3



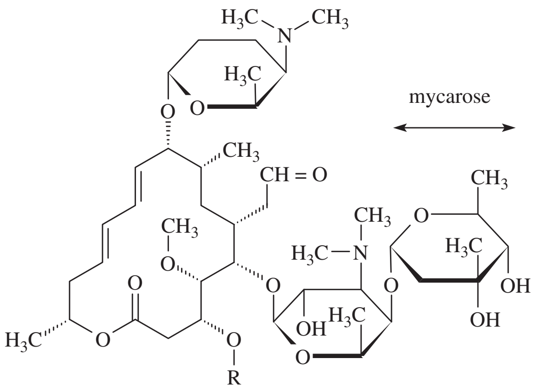
12-210, sulfadoxine, $R = R^1 = OCH_3$, $R^2 = H$
sulfadimethoxine, $R = H$, $R^1 = R^2 = OCH_3$



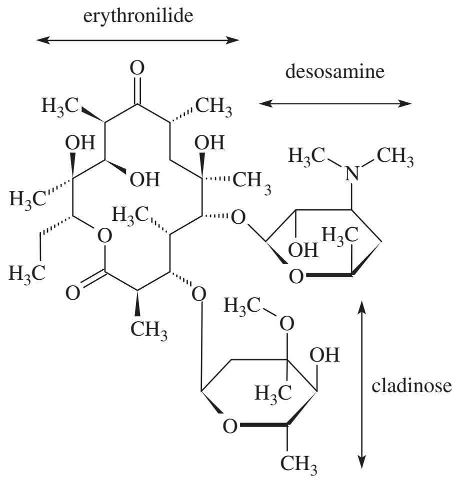
12-211, kanamycin A, $R = NH_2$, $R^1 = OH$
kanamycin B, $R = NH_2$, $R^1 = NH_2$
kanamycin C, $R = OH$, $R^1 = NH_2$



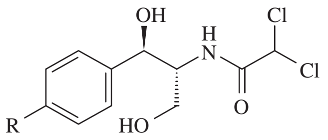
12-212, tylosin



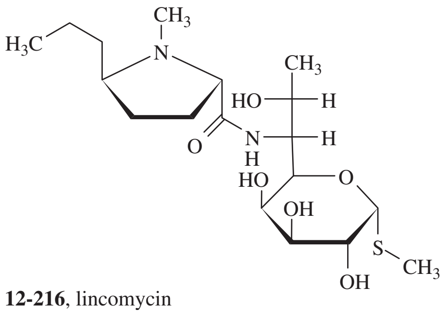
12-213, spiramycin I, R = H
spiramycin II, $R = C(=O)CH_3$
spiramycin III, $R = C(=O)CH_2CH_3$



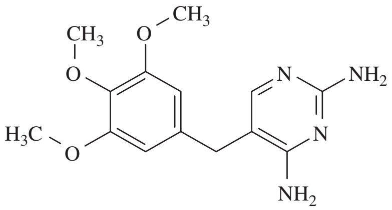
12-214, erythromycin A



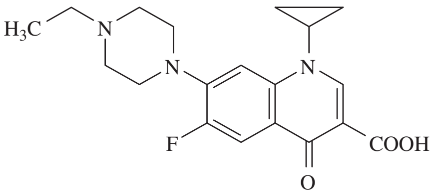
12-215, chloramphenicol, R = NO_2
thiamphenicol, R = SO_2CH_3



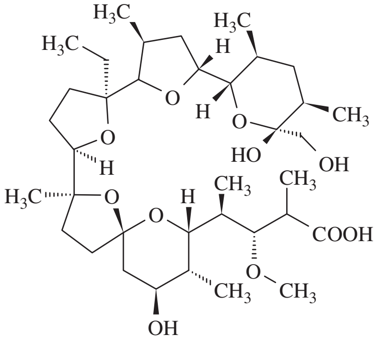
12-216, lincomycin



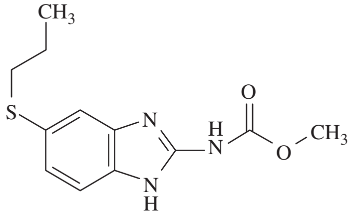
12-217, trimethoprim



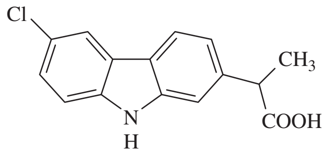
12-218, enrofloxacin



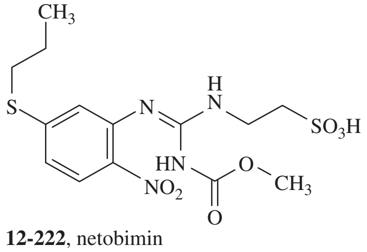
12-219, monensin



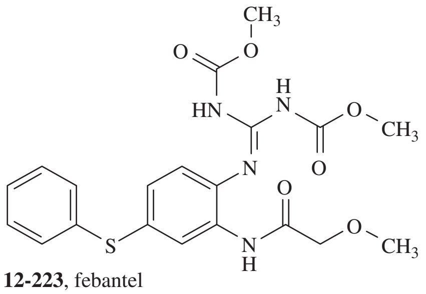
12-220, albendazol



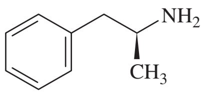
12-221, carprofen



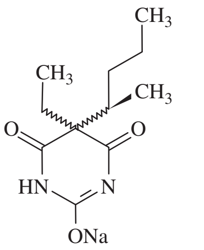
12-222, netobimin



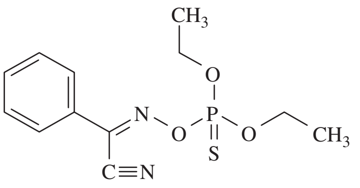
12-223, febantel



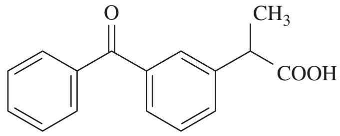
12-224, (*S*)-amphetamine



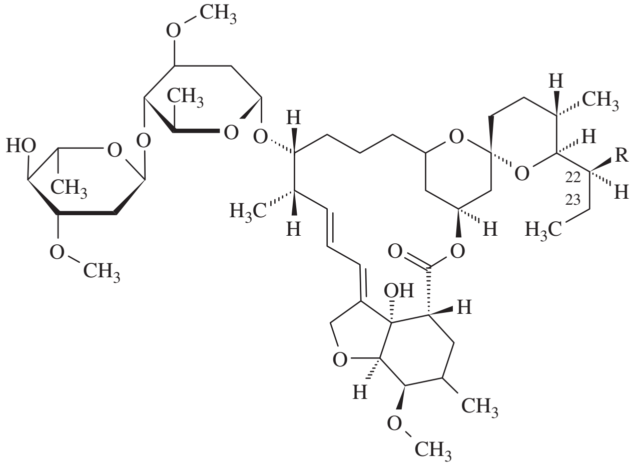
12-225, (+)-(*R*)-pentobarbital (sodium salt)



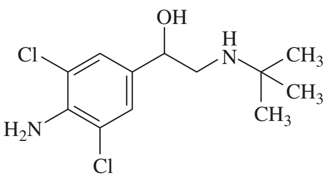
12-226, foxim



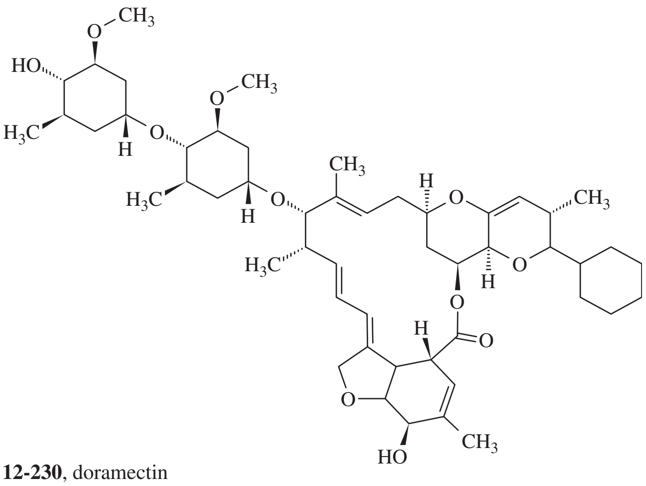
12-227, ketoprofen



12-228, dihydroavermectin B_{Ia}, R = CH_2CH_3
dihydroavermectin B_{Ib}, R = CH_3



12-229, clenbuterol



12-230, doramectin

12.7.2 Occurrence in foods

The supply of veterinary drugs into the body of livestock necessarily leads to the occurrence of residues in the muscle, various organs, milk and eggs, so trace amounts of veterinary drugs may be correspondingly found in meat, milk, meat, dairy and other products.

In terms of food quality, veterinary drugs are considered extraneous, contaminating substances whose presence is undesirable, although often inevitable. In this context, these substances are classified in the same group as environmental contaminants, such as mycotoxins, pesticides, polychlorinated biphenyls (PCBs) and other persistent organic pollutants (POPs). Like other types of contaminants, residues of veterinary drugs in foods present a potential health risk to the consumer. Therefore, the incidence and levels of veterinary drug residues in tissues have to be effectively and consistently controlled.

12.7.2.1 Residues in tissues

The levels of veterinary drug residues are subject to pharmacokinetic parameters: absorption, tissue distribution, metabolism and excretion. The degree of absorption depends on the physico-chemical properties of the compounds and the method of administration, which may, for example, be:

- **peroral** (through the gastrointestinal tract: such as in capsules, food or drinking water)
- injected, **intramuscular** (within a muscle) or **subcutaneously** (under the skin)
- **dermal** (on skin surface).

Generally speaking, the absorption from the gastrointestinal tract depends on the solubility of the drug in water (degree of ionisation at a given pH) and lipophilicity, which determines the transition across biological membranes. Lipophilic compounds, such as certain antiparasitic drugs (organophosphates and pyrethroids), exhibit a relatively high degree of absorption after application to the skin. On the other hand, the injection preparations in the form of an oil suspension can lead to up to several months of persistence of residues at the injection site, with the risk of occurrence of extreme levels of residues in food (particularly in meat) prepared from the given tissue.

Accumulation of residues in the liver and kidneys generally exceeds levels in muscle. Some compounds, such as benzimidazoles, show the highest concentration in the liver, while the majority of antibiotics are located in the highest amounts in the kidney. Lipophilic chemical compounds, such as some organophosphates, accumulate in adipose tissue.

The most important factors affecting the transfer of veterinary drugs from the blood plasma into milk (mammary gland cells) are:

- degree of ionisation

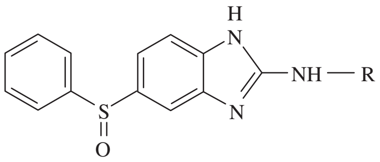
- lipophilicity
- binding to proteins
- relative molecular weight.

At the lower pH of milk, the ratio between milk and plasma for weak organic bases (such as antibiotics erythromycin and tylosin) is >1, while for organic acids (benzylpenicillin, sulfadimethoxin) it is ≤1. For example, during mammary gland tissue inflammation (mastitis), the pH of milk increases and this ratio of the organic bases decreases. Specific examples are given in Table 12.69.

12.7.2.2 Metabolism and excretion

The elimination of most veterinary drugs from the body depends on the metabolic rate and mechanism of the excretion process. Examples of differences in the rate of elimination of veterinary drugs from the body of selected animal species are presented in Table 12.70. Metabolism proceeds in two phases. The initial stage involves oxidation, reduction and hydrolysis, while the second phase leads to conjugation with endogenous components, for example with D-glucuronic acid and glutathione, or the drug is acetylated or otherwise transformed. In most cases, the metabolic process yields water-soluble, easily eliminated products that lack pharmacological activity. A summary of the most common biotransformation processes is given in Table 12.71.

In some cases, however, one or more metabolites exhibit similar biological effects. An example is oxfendazole (**12-231**) in the tissues, which is in equilibrium with the corresponding sulfide (fenbendazole), which shows an anthelmintic effect, and with some other metabolites (such as the corresponding sulfone), which already lack pharmacological activity. A related compound is febantel (**12-223**) from which oxfendazole is produced *in vivo*.



12-231, oxfendazole, R = $COOCH_3$
oxfendazole amine, R = H

The major excretory organs are the kidneys, but veterinary drug metabolites can also be excreted to the bile and milk. Renal excretion is the primary elimination for drugs that are ionised at physiological pH, and compounds with low lipophilicity. Drugs excreted unchanged include many antibiotics, such as penicillin, cephalosporins, and aminoglycosides, oxytetracycline and most diuretics. The process of renal excretion of drugs is very complex, therefore in addition to the parent compound, pharmacologically

Table 12.69 Transition of antimicrobial substances from the blood plasma into milk.

Veterinary drug	pK_a	pH of milk	Ration of concentrations Milk ultrafiltrate/ plasma ultrafiltrate	
			Theoretical	Experimental

Table 12.71 Various ways of biotransformation of veterinary drugs.

Functional group/skeleton	Biotransformation
Aromatic ring	Hydroxylation
Hydroxyl group	
Alcohols	Side chain oxidation, conjugation with glucuronic acid and sulfate (to a lesser extent)
Phenols	Ring hydroxylation, conjugation with glucuronic acid and sulfate, methylation
Carboxylic group	Conjugation, side chain hydroxylation
Alifatic and aromatic substances	Conjugation with glucuronic acid and glycine
Primary amines	Deamination
Alifatic	Side chain hydroxylation, acetylation
Aromatic	Conjugation with glucuronic acid and sulfate, methylation
Sulfhydryl group	Conjugation with glucuronic acid, methylation, oxidation
Ester and amide bonds	Hydrolysis

active metabolites must always be analysed. Individual maximum residue limits (MRLs) are set according to the occurrence of residues in the body for the meat and various edible organs, such as the liver and kidneys.

12.7.2.3 Effect of heat treatment

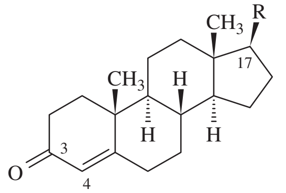
Until recently, there were surprisingly few studies dealing with the impact of processed raw materials of animal origin on residues in consumed foods. Knowledge of this area is still too limited to allow any generally valid conclusions. For example, cooking and baking meat containing residues of the antiparasitic drug ivermectin leads to reduced levels of this drug, on average down to 50%. Similarly, oxytetracycline residue levels decrease by 35–94% depending on temperature and type of heat treatment. On the other hand, under standard cooking or baking procedures no changes were found in the concentration of residues of clenbuterol, which is sometimes used illegally as a growth stimulator. Frying of beef liver containing the antiparasitic drug oxfendazole leads to changes in the relative ratio of oxfendazole residues and the main metabolites, such as oxfendazole sulfone, fenbendazole and some others. Oxfendazole amine is produced as a product of hydrolysis of oxfendazole.

12.7.3 Health and toxicological evaluation

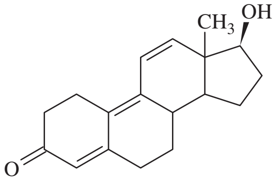
In recent years increasing attention has been devoted at both the national level and by international organisations to the risk assessment of veterinary drugs occurring in foods, and to the implementation of effective measures to reduce this risk.

12.7.3.1 Hormones as growth promoters

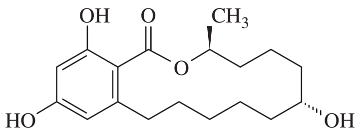
The use of hormones as growth promoters is banned in the EU. Other states, namely the United States, Australia and Argentina, allow the controlled use of hormonal preparations. The drugs used include natural steroid hormones which have an anabolic effect, such as oestradiol, (17β)-oestra-1,3,5(10)-trien-3,17-diol (see **10-93**), testosterone, (17β)-hydroxyandrost-4-en-3-one, or progesterone, pregn-4-en-3,20-dione (**12-232**). Another group consists of synthetic hormones with corresponding effects, such as trenbolone (17β)-17-hydroxyoestra-4,9,11-triene-3-one (**12-233**) or non-steroidal substances having an oestrogenic effect, such as zearalenol (α-zearalenol, the product of reduction of mycotoxin zearalenone, Figure 12.43) and α-zearalanol (**12-234**), with



12-232, testosterone, R = OH
progesterone, R = $COCH_3$



12-233, trenbolone

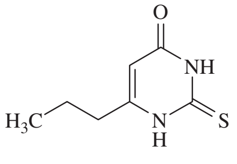


12-234, α-zearalanol

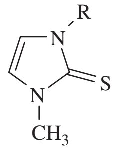
a reduced double bond, which is also called zeranol in veterinary terminology.

The opinions of professionals as to the potential risks from hormone residues are not uniform. Their potential carcinogenic effects in humans (particularly in reproductive organs and mammary glands) are the areas predominantly discussed. Altogether it is considered that the residual amounts of used hormones are low and are within the normal, physiological values of endogenous hormones, so that there is no significant risk to the consumer health. Their ban in European countries is mainly based on the negative attitudes of the general public to this type of increased production. In this context, other legitimate factors which are unacceptable from an ethical point of view are also discussed, such as the burden upon the animal by excessive growth stimulation or excessive production of milk or eggs.

Similar effects to those for hormones are seen in antithyroid substances (strumigens), which inhibit the synthesis of thyroxine in the thyroid gland. Heterocyclic compounds containing thiourea residues in their molecules, for example thiouracils and mercaptoimidazoles, are very potent strumigens. Examples of the main antithyroid drugs include propylthiouracil (6-propyl-2-sulfanylpyrimidin-4-one, **12-235**), which was in the past used in human medicine. In 2009, the U.S. Food and Drug Administartion (FDA) published an alert notifying healthcare professionals of the risk of serious liver injury, including liver failure and death, related to the use of propylthiouracil. As a result, propylthiouracil is no longer recommended for non-pregnant adults or children. Examples of other antithyroid agents are methimazole (1-methyl-3*H*-imidazole-2-thione, **12-236**) carbimazole (ethyl 3-methyl-2-sulfanylideneimidazole-1-carboxylate, **12-236**), which acts as a pro-drug, because after absorption it is converted into the active form, methimazole.



12-235, propylthiouracil



12-236, methimazole, R = H
carbimazole, R = $COOCH_2CH_3$

12.7.3.2 Risk of bacterial resistance

There is also evidence that the excessive and indiscriminate use of drugs in veterinary medicine leads to some undesirable effects. Discussions take place at the international level, especially in the case of antibiotics, the excessive use of which may result in resistance of pathogenic microorganisms in the tissues of treated animals, which reduces the effectiveness of the drugs. A similar phenomenon is known in human medicine, where effective antibiotics are very difficult to find for certain infections. A very important issue is the risk of transmission of resistance in livestock pathogens from one strain to another. Even more serious is the possibility of infection of food consumers with resistant strains of pathogenic microorganisms or induced cross-resistance to antibiotics used in human medicine only. A typical example is the finding from Denmark in 1995, when the preventive use of the antibiotic avoparcin (used as a feed additive to promote growth in chickens and pigs) led to the emergence of the resistant enterococci *Enterococcus faecium*. Based on the structural similarity, this strain, which was highly pathogenic to humans, also showed cross-resistance to vancomycin, which is only used against pathogenic enterococci in human medicine. *E. faecium* resistant to vancomycin was also isolated from raw chicken and pork from the retail network. Based on the above information, the use of avoparcin was banned as an additive in animal feed. Under pressure (especially in Scandinavian countries), in 1999 the EU member states also prohibited the use of other antibiotics (bacitracin, tylosin, virginiamycin and spiramycin) as growth stimulators in animal feed.

12.7.3.3 Mitigation

The actual production, distribution and testing of veterinary drugs (including medicated feed) are summarised in The Rules Governing Medicinal Products in the European Union (Eudralex).[10] The approval process for a new veterinary drug in the EU includes, according to Regulation (EC) No. 726/2004, the evaluation of its therapeutic efficacy, side effects in animals, environmental impact and ensured good manufacturing practice. Documentation provided by the manufacturers (pharmaceutical companies) must include information about the structure of substances, the recommended route of administration and dosage, pharmacokinetics (absorption from the gastrointestinal tract, distribution and accumulation in tissues, metabolism and excretion in farm and laboratory animals), acute (short-term) toxicity (single dose), subchronic and chronic toxicity (repeated daily dosing of laboratory animals for ≥90 days in two species, such as mouse and dog), embryotoxicity (disorders of foetus and fertility development), mutagenicity (such as gene mutations, chromosomal disordersand DNA reparation), carcinogenicity (ability to cause tumour growth through daily, lifelong use by laboratory animals), specific effects as needed (such as neurotoxicity and allergies), the influence of

[10] Details can be find at http://ec.europa.eu/enterprise/pharmaceuticals/eudralex/eudralex_en.htm.

substances with antimicrobial properties to the normal composition of intestinal microflora and cultural microorganisms used in technological processes (fermentation), adverse reactions observed in treated animals, and the side effects of eventual use in humans.

For some veterinary drugs, as in the case of pesticides, a withdrawal time is set, defined as the time required after administration of a drug to assure that drug residues in the marketable product (e.g. meat, milk and eggs) are below a determined maximum residue limit (MRL). The reasons for the introduction of withdrawal times are not only toxicological (protection against potentially harmful effects of residues on the consumer's health), but also technological (protection of fermentation processes against residues of antimicrobial agents) and ethical (to prevent involuntary exposure of consumers to therapeutic doses of drugs in food). The length of withdrawal periods, determined for the individual form of drug (including those taken by injection, oral intake and others), animal species and raw materials (meat, milk and eggs) can vary from several days to several weeks, and in exceptional cases to several months.

Maximum residue limits of veterinary medicinal products in foods of animal origin established according to Council regulation (EEC) No. 2377/90 represent internationally generally accepted thresholds, which indicate the amounts of drug residues that may occur in foods of animal origin. With regard to the character of veterinary drugs, MRLs are classified into four groups:

- group I, where MRLs are set
- group II, where MRLs are not set (with respect to the identified harmlessness for human health)
- group III, where MRLs are set only temporarily in the European Union
- group IV, where drugs dangerous for human health are listed, which can not be used on animals intended for food production.

Group I includes numerous chemotherapeutics and antibiotics, non-steroidal anti-inflammatory drugs, corticosteroids, antiprotozoa agents, endo- and ectoparasitica and drugs affecting the nervous and reproductive systems. Examples of MRL values (reflecting the diversity of species and distribution of residues between various tissues and organs of animals) are listed in Table 12.72. Group II contains mainly inorganic substances, such as chlorides, sulfates, phosphates, gluconates, carbonates, vitamins and other organic compounds (such as acetylsalicylate and alcohols), herbs, tinctures, homeopathics and other substances generally recognised as safe for the intended use. The fact that a substance is included in group II does not mean that its use is generally permitted. The legislation typically clearly defines the target organism and method of use. Great attention of control systems at the national and European level is focused on agents assigned in group IV, which include, for example, chloroform, chloramphenicol and chlorpromazine, which must not be present (detected) in animal products at all. In accordance with European legislation, prohibited substances are those with thyreostatic, oestrogenic, androgenic or gestagenic activities and some sympathomimetic agents (that stimulate the heart through activation of β-adrenoceptors; β-adrenoceptor agonists, also known as β-agonists, bind to β-receptors on cardiac and smooth muscle tissues). Legislation also includes 17β-oestradiol, stilbenes and all its derivatives. To allow the free trade of animal products within the EU, each member state must carry out official control and monitoring of residues of pharmaceuticals and biologically active substances.

Table 12.72 Examples of maximum residue limits for benzylpenicillin and ivermectin.

Animals	MRL (mg/kg)	Raw material
Benzylpenicillin		
All species	0.050	Meat, liver, kidneys, fat
	0.004	Milk
Ivermectin (dihydroavermectin B_{Ia})		
Cattle	0.100	Liver
	0.040	Fat
Sheep	0.020	Fat
Horse	0.015	Liver

12.8 Contaminants from packaging materials

Packaging has become an indispensible element in the food manufacturing process. Packaging maintains the benefits of food processing after the process is complete, makes food more convenient, gives the food greater safety assurance from microorganisms, biological and chemical changes, and enables food to travel safely for long distances from their point of origin and still be wholesome at the time of consumption.

12.8.1 Occurrence and main sources

Contamination of food by components of packaging materials is one of the most serious health problems relating to food packaging. In almost all cases, when the food is in direct contact with the packaging material, a reciprocal mass transfer proceeds between the food and the food packaging components, even when relatively stable packaging materials are used, such as glass. In order to maintain food quality, inert materials of high quality should be used for food packaging. Food packaging is therefore more expensive to produce than the packaging of the majority of other goods. The most important and commonly used packaging materials, which are in direct contact with the packaged food and can thus significantly affect its quality, are:

- metals

- glass and ceramics
- paper
- wood
- plastics.

12.8.1.1 Metals

Metals are the most versatile packaging materials as they offer a combination of excellent physical protection and barrier properties, decorative potential and recyclability. Tin, steel and aluminium have long histories of successful use in storing food. The basic problem of metals in food packaging materials is metal corrosion, which occurs due to the action of food (mainly acidic food) on the metal container, which leads to partial dissolution of the package and results in higher metal content in the food. The maximum permissible levels of some metals in foods are given in Chapter 6. The mechanisms of corrosion are basically twofold. Chemical and electrochemical corrosions can be distinguished. The possible ways to prevent corrosion are very diverse and widely used (such as tinning and passivation of the package, and use of lacquered packages).

Just under one third of the world's total tin production goes into the manufacture of tinplate, a sheet or strip of low-carbon steel (blackplate) coated with a thin layer of pure tin. Tinplate has been used for preserving food for well over a hundred years as it is an excellent barrier to gases, water vapour, light and odours, and can be heat-treated, sealed hermetically and easily recycled. About 25 000 million food cans are produced and filled in Europe *per annum*, about 20% of these having plain internal (unlacquered) tin-coated steel bodies. Plain internal tinplate cans may be used, for example, for tomatoes and other tomato-based products, white fruits and some vegetables (such as asparagus and mushrooms). Although tin provides steel with some corrosion resistance, tinplate containers are often lacquered to provide an inert barrier between the metal and the food product. Food grade lacquers are based on natural resins and also on a number of synthetic lacquers, such as phenol-formaldehyde resins, epoxy and vinyl resins, polyesters and others. Sometimes, the lacquers used to protect the internal surfaces of metal packaging may be sources of food contaminants. Their effect on food contamination is analogous to the effect of polymeric packaging materials.

Tin-free steel used for food and beverage cans is chromium or chrome oxide coated steel that was developed to meet economic requirements and surpass tinplate in paintability and paint adhesion. It requires a coating of organic material to provide complete corrosion resistance.

Aluminium's natural resistance to corrosion is advantageous for its role in packaging as, unlike iron, aluminium oxide forms a protective and not a destructive layer. Aluminium also provides an excellent barrier to moisture, air, odours, light and microorganisms. One of the most common end uses for more than 20% of the aluminium manufactured is in packaging, including drinks cans, foil wrappings and bottle tops. Lamination of packaging involves the binding of aluminium foil to paper or plastic film to improve barrier properties. As well as recent health worries linking aluminium to Alzheimer's disease, the main disadvantages of aluminium are its high cost compared with other metals (e.g. steel) and its inability to be welded.

12.8.1.2 Glass

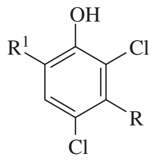
Glass has an extremely long history in food packaging, which is dates back to approximately 3000 BC. Glass is impermeable to gases and vapours, so it maintains product freshness for a long period of time without impairing its sensory properties and is reusable and recyclable. Glass is much more resistant to corrosion than most materials, so much so that it is easy to think of it as corrosion-proof. Nevertheless, glass may frequently be attacked by acidic solutions that remove the alkali from the glass surface and wash out ions of sodium, calcium and other alkali metals and alkaline earth metals with the formation of alkali silicates. These salts, if not removed by washing, can get into the food product. Water corrosion acts at a much slower rate than corrosion by acids, but may become important at high temperatures, especially during longer periods of rain or in case of condensation in glass containers which have been improperly stored before filling. In coloured glass, metal ions used for colouring (such as iron, manganese, chromium and some other metals) can be washed out, which may result in increased concentrations of these ions in packaged products.

12.8.1.3 Paper

The use of paper for food packaging dates back to the 17th century. Paper and paperboard are commonly used in corrugated boxes, milk cartons, bags and sacks and wrapping paper. Plain paper has poor barrier properties and poor resistance to moisture, and therefore is not usually suitable for direct contact with food of higher water activity or to protect food for long periods. When used in direct contact with food, paper is prepared from cellulose pulp by modified technological processes and it is often coated, laminated or impregnated with waxes, resins or lacquers to improve its functional and protective properties. Such products include papers treated with sulfate (kraft paper used to package, for example, flour and salt), sulfite (sulfite paper used, for example, to package confectionery), grease-proof paper (prepared by extended cellulose hydration), and parchment paper (prepared from sulfuric acid treated pulp). Paper laminates (paper coated, for example, with polyethylene or aluminium foil) are based on kraft and sulfite papers.

When in contact with food raw materials and foods under low moisture conditions, the migration of some paper components (such as fillers, binders, precipitation, fixation and retention agents, drainage accelerators, dispersants, flotation and antifoaming agents, preservatives, lubricants, optical brighteners, plasticisers and others) is possible. Possible contamination of food by paper laminates depends on the properties of these materials and is similar to the contamination caused by polymeric packaging materials. A special group are volatile substances, which may

be present in the paper and can pass into the packaged food. Such substances may include various chlorinated phenols (2,4-dichlorophenol, 2,4,6-trichlorophenol, 2,3,4,6-tetrachlorfenol and other substances, **12-237**), which arise, for example, in bleached papers and cork stoppers, and carbon disulfide that may be found in kraft paper. Paper made from recycled paper, which is still only rarely used in contact with foods, may contain polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs). Benzophenone (diphenyl ketone) may be present in cartonboard food-packaging materials as a residue from UV-cured inks and lacquers used to print on the packaging. It may also be present if the cartonboard is made from recycled fibres recovered from printed materials. The main odour-active compounds of cardboard include vanillin, (*E*)-non-2-enal, (R/S)-γ-nonalactone, 2-methoxyphenol, (R/S)-δ-decalactone, *p*-anisaldehyde and 3-propylphenol. Paper exposed to higher temperatures may contain degradation products of cellulose, such as 5-hydroxymethyl-2-furancarbaldehyde, which may adversely affect the flavour of packaged foods.



12-237, 2,4-dichlorophenol, R = H, R^1 = H
2,4,6-trichlorophenol, R = H, R^1 = Cl
2,3,4,6-tetrachlorophenol, R = Cl, R^1 = Cl

12.8.1.4 Wood

Wood packaging is generally unsuitable for direct contact with food as the wood components, in particular resins and tannins, are easily released to food products by leaching or volatilisation. Before their first use, packaging and containers intended for direct contact with food have to be treated with water and solutions of sodium carbonate or sulfites, or the inner surface has to be covered with a protective layer of, for example, polymer-based materials. Possibilities of food contamination are then dependent on the quality of the protective layer and the type of plastics. An exception is the storage of spirits and wines in oak barrels, where the extraction of wood components to the product is desirable.

12.8.1.5 Plastics

The production of plastic materials on an industrial scale began in the 1940s and 1950s, and world production reached 270 million tons in 2011 (57 million tons of which was in Europe). In 2011, food packaging applications used 39.4% of the worldwide plastics production. These materials included a range of organic polymers:

- **thermoplastics**, which soften upon exposure to heat and return to their original condition at room temperature;
- **thermosets** that solidify or set irreversibly when heated.

The advantage of thermoplastics is that they are low-cost materials, can easily be shaped into various products, such as bottles, jugs and films, have some functional advantages, such as thermosealability and microwavability, and are mostly recyclable. Thermosets are mainly used for kitchen equipment and cookware, because of the demand for heat- and corrosion-resistant properties, which are needed to withstand exposure to acids in food and to cleaning materials. They are also used for their flame resistance around machined parts (in steamers, fryers, meat cutters and other kitchen equipment).

Plastics that are most often used as food packaging materials include polyolefines, polyesteres, polyvinyl chloride, polyvinylidene chloride, polystyrene, polyamide, various resins and so on. For example, the world plastic demand in 2011 was dominated by polyethylene, including low density polyethylene (PE-LD), linear low density polyethylene (PE-LLD, 17%) and high density polyethylene (PE-HD, 12%), polypropylene (PP, 19%), polyvinyl chloride (PVC, 11%), polystyrene solid (PS) and expandable (PS-E, 7.5%), polyethylene terephthalate (PET, 6.5%), polyurethane (PUR, 7%) and other plastic types (20%). An overview of the main types of polymeric packaging materials is given in Table 12.73.

Mass transfer, which is commonly referred to as **migration**, is a typical interaction of food with packaging made from plastics. Low molecular weight substances are transferred to foods, especially residual monomers and several thousand different types of additives (antioxidants, plasticisers, thermal stabilisers, lubricants, condensation components, slip additives, anti-static and anti-blocking agents). Characteristically, the packaging material is not completely destroyed, but retains technologically important properties, while only certain components diffuse into the food. Migration is always a two-way process, as some food constituents migrate into food packaging materials and sometimes significantly affect the rate of transfer of contaminants into the food. In terms of food quality, it is of course desirable to limit the transfer of substances in both directions. From the hygienic and toxicological point of view, the level of contaminants migrating into the food is particularly significant. In principle, two basic types of migration are distinguished:

- **overall** or **global** migration
- **specific** migration.

The overall (global) migration refers to the transfer of all, in many cases unknown, components from the packaging to the food. Table 12.74 shows the typical values for the overall migration of plastic packaging materials used for food packaging. Specific migration is the transition of one or more substances, which are particularly important from the hygienic and toxicological point of view. Because of the enormous complexity and number of potential contaminants and the extent of the use of polymeric packaging materials, specific migration is one of the most significant problems of food contamination from packaging.

Several thousand substances based on polymers are used in the production of packaging materials. Products resulting from chemical changes of these additives arising during the processing

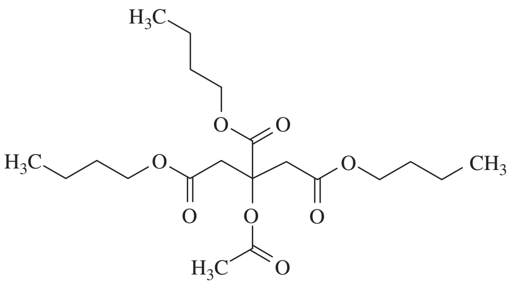
Table 12.73 Basic types of polymeric packaging materials.

Group of materials	Main types	Group of materials	Main types
Polyolefins	Polyethylene (PE-HD, PE-LD, PE-LLD) Polypropylene (PP)	Vinyl polymers	Polyvinyl chloride (PVC) Polystyrene (PS)
Nitrogen polymers	Polyamide (PA) Polyurethane (PUR)		Polyvinyl acetate (PVAc) Polyvinyl alcohol (PVOH)
Thermosets	Phenol-formaldehyde resins Amino-formaldehyde resins Epoxy resins	Polyesters	Polyethylene terephthalate (PET) Polycarbonate (PC) Thermoset polyesters

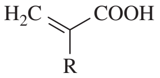
Table 12.74 Typical values of overall migration for plastic foils for food packaging.

	Migration (mg/dm^2)	
Polymer	**Aqueous simulants**	**Olive oil**
Low density polyethylene (PE-LD)	0.1–1.5	4–20
Linear low density polyethylene (PE-LLD)	0.1–1.0	1.5–5.5
Polyethylene terephthalate (PET)	<0.2	0.3–6.9
Polypropylene (PP)	0.1–1.5	0.5–5.0
Polystyrene (PS)	0.2–5	1.2–26
Polyamides (PA)	0.0–15	1.0–6,0
Polyvinyl chloride (PVC)	0.5–3	3.0–100

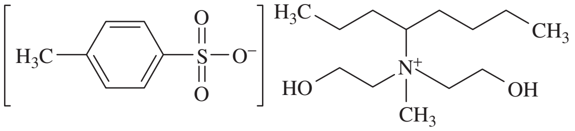
and use of packaging materials may also be released to food. An example is non-8-enal, an important contributor to plastic off-odor in polyethylene packaging, formed as a secondary product of oxidation of dodec-1-ene, which is one of the most abundant components of PE-HD volatiles. In practice, groups of structurally related compounds, such as phenols, primary and secondary amines and aromatic substances are often followed. The most important potential food contaminants are listed in Table 12.75, but this list is far from exhaustive. It does, however, illustrate the type of contaminants and the complexity of the potential contamination of foods from plastic packaging materials. Structures of the most important compounds are given in formulae **12-238** to **12-260**.



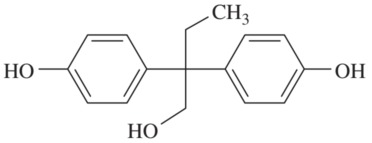
12-238, acetyl tributyl citrate



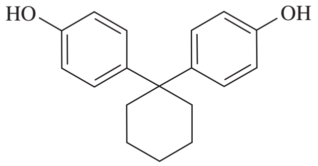
12-239, acrylic acid, R = H
methacrylic acid, R = CH_3



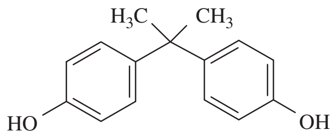
12-240, *N*,*N*-bis(2-hydroxyethyl)-*N*-(4-octyl)-*N*-methylammonium-*p*-toluenesulfonate



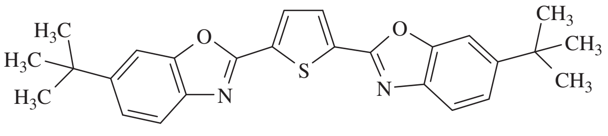
12-241, 2,2-bis(4-hydroxyphenyl)butan-1-ol



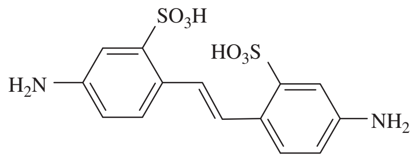
12-242, 1,1-bis(4-hydroxyphenyl)cyclohexane



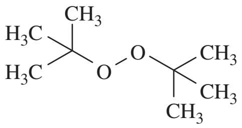
12-243, bisphenol A



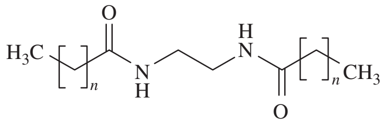
12-244, 2,5-bis(5-*tert*-butylbenzoxazol-2-yl)thiophene



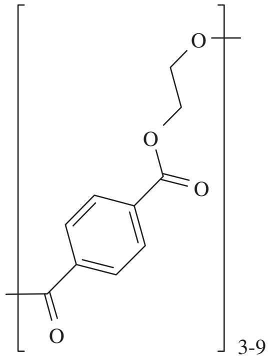
12-245, 4,4′-diamino-2,2′-stilbenedisulfonic acid



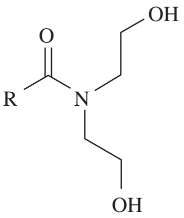
12-246, di-*tert*-butylperoxide



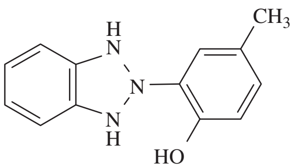
12-247, *N*,*N*¢-dipalmitoylethane1,2-diamine, *n* = 14
N,*N*¢-distearoylethane-1,2-diamine, *n* = 16



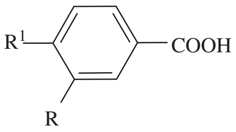
12-248, ethyleneterephthalate oligomers



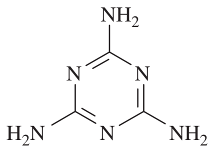
12-249, fatty acid diethanolamides



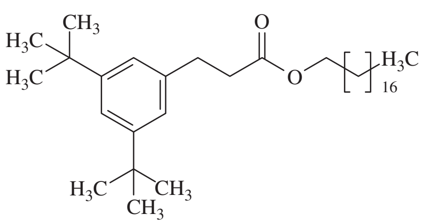
12-250, 2-(2-hydroxy-5-methylphenyl)benzotriazole



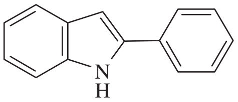
12-251, isophthalic acid, R = COOH, R^1 = H
terephthalic acid, R = H, R^1 = COOH



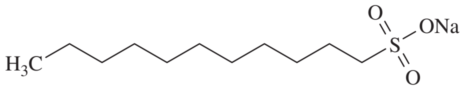
12-252, melamine



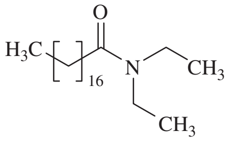
12-253, octadecyl-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate



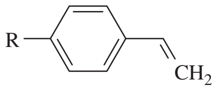
12-254, 2-phenylindole



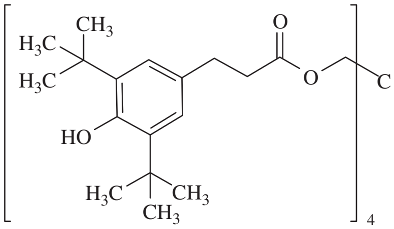
12-255, sodium 1-undecanesulfonate



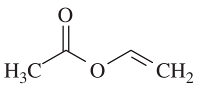
12-256, stearic acid *N*,*N*-diethylamide



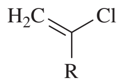
12-257, styrene, R=H
4-methylstyrene, R = CH_3



12-258, tetrakis[methylene-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl) propionyl]methane



12-259, vinyl acetate



12-260, vinyl chloride, R = H
vinylidene chloride, R = Cl

Table 12.75 Classification of contaminants from packaging materials.

Groups of contaminants	Compounds and examples of their occurrence[a]
Residues of monomers	Adipic acid dimethyl adipate (polyesters), acrylamide (acrylonitrile co-polymers), acrylonitrile (acrylamide co-polymers), acrylic acid (acrylic polymers), buta-1,3-diene (PS co-polymers, elastomers), butan-1,4-diol (polyesters), 2,2-bis(4-hydroxyphenyl)butan-1-ol (polyesters), 1,1-bis(4-hydroxyphenyl)cyclohexane (polyesters), 4,4′-(propane-2,2-diyl)-diphenol known as bisphenol A (polyesters), ethyleneglycol (polyestere), formaldehyde (phenol-formaldehyde resins), isophthalic acid (PET), caprolactame and C_6-C_{12} aminocarboxylic acids and their lactames (polyamides), melamine (amino-formaldehyde resins), methacrylic acid and methyl methacrylate (acrylic polymers), methylstyrene (PS and co-polymers), propyleneglycol (polyesters), sebacic acid and dimethyl sebacate (polyesters), styrene (PS and co-polymers), terephthalic acid and dimethyl terephthalate (PET), vinyl acetate (vinyl acetate co-polymers), vinyl chloride (PVC and co-polymers), vinylidenechloride (PVdC and co-polymers)
Residues of additives	
Initiators	Di-*tert*-butylperoxide, dibenzoylperoxide
Regulators	Dodecylmercaptan
Catalysts	Oxygen compounds of Al, Ti, Ca, Mg, Si, Cr, Sb, Mn, Li, Zn, Co and others
Emulsifiers	Sodium 1-alkylsulfonates (C_{12}–C_{18})
Protective colloids	Polyvinyl alcohol, lecithin, gelatin, carboxymethylcellulose
Solvents	Acetone, butyl acetate, dichloromethane, ethanol, ethyl acetate, hexane, pentane, toluene
Hardeners	Formaldehyde, glutaraldehyde, glyoxal and others
Stabilisers and antioxidants	2- and 3-*tert*-Butyl-4-hydroxyanisole (BHA), 3,5-di-*tert*-butyl-4-hydroxytoluene (BHT), 2-ethyl-dioctyl-tin-di-2-ethylhexyl-monooctyltintrithioglycolate (Irgastab 17 MOK), 2-phenylindole, octadecyl 3-(3,5-di-*terc*-butyl-4-hydroxyphenyl)-propionate(trade name Irganox 1076), tetrakis[methylene-3-(3,5-di-*terc*-butyl-4-hydroxyphenyl)propionyl]-methane (trade name Irganox 1010)
Plasticisers	Acetyl tributyl citrate, butylesters of soybean oil fatty acids, butyl stearate, dibutyl adipate, dibutyl sebacate, dioctyl adipate, dioctyl sebacate, epoxidised soybean oil, phthalates, glycerol, isobutyl stearate and others
Lubricants	Stearic acid diethylamide, *N*,*N*′-dipalmitoylethane1,2-diamine, *N*,*N*′-distaroylethane1,2-diamine, glycerol, stearic and palmitic acids, silicone oils, Ca, Mg, Al and Zn stearates
Antistatic agents	Fatty acid diethanolamides, *N*,*N*-bis(2-hydroxyethyl)-*N*-4-octyl-*N*-methyl-ammonium-*p*-toluenesulfonate
UV absorbers	2,4-Dihydroxybenzophenone, 2-(2-hydroxy-5-methylphenyl)benzotriazole
Optical lighteners	2,5-Bis(5-*tert*-butylbenzoxazol-2-yl)thiophene, 4,4′-diamino-2,2′-stilbenedisulfonic acid
Fillers	Silica, kaolin, graphite
Blowing agents	Isopentane or pentane, petroleum ether
Degradation products (of polymers and additives)	Acetaldehyde (PET), oligomers (PET), bisphenol A (polyesters), hydrochloric acid (PVC), dibutyl adipate (PVC), nitrosamines (elastomers, rubber)

[a] PS = polystyrene, PET = polyethylene terephthalate, PVC = polyvinyl chloride, PVdC = polyvinylidene chloride.

Table 12.76 Physical and chemical properties of phthalates.

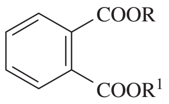
Phthalate	M_r	Boiling point (°C)	Melting point (°C)	Solubility in water (mg/l at 25 °C)	Vapour pressure (mPa) (25 °C)	pK_{OW}
Dimethyl phthalate	194.2	284	2	4000	220	1.53
Diethyl phthalate	222.2	294	−41	1080	220	2.35
Dibutyl phthalate	278.4	340	−35	11.2	1.87	4.57
Benzylbutyl phthalate	312.4	370	−35	2.69	1.15	4.91
Bis(2-ethylhexyl) phthalate	390.6	384	−50	0.3	0.86	5.11
Dioctyl phthalate	390.6	220 (at 670 Pa)	−25	0	-	-

12.8.1.5.1 Phthalates

Phthalates (esters of benzene 1,2-dicarboxylic acid, known as phthalic acid) belong to the group of virtually ubiquitous organic environmental contaminants. The reason for their abundant spread to all components of the environment is their suitable physico-chemical properties, which is why phthalates are used as plasticisers, substances improving the mechanical properties of plastics (mainly PVC), their flexibility, transparency, durability and longevity. Phthalates therefore occur in a wide variety of products ranging from common household products, such as floor coverings, curtains in bathrooms, rubber gloves and children's toys through to food packaging to specialised products used, for example, in health care and in bags for storage of blood and blood plasma, syringes and dialysis units. Plastic materials treated with phthalates may contain up to 40% plasticiser, which is not chemically bound to the polymer and may thus be released into foods that are in contact with plastics.

Structure and nomenclature

The U.S. EPA included six phthalic acid esters (**12-261**) on the list of priority environmental contaminants. Of these, the most widespread are dibutyl phthalate and bis(2-ethylhexyl)phthalate.



12-261, phthalates

dimethyl phthalate, R = R^1 = CH_3
diethyl phthalate, R = R^1 = CH_2CH_3
dibutyl phthalate, R = R^1 =$[CH_2]_3CH_3$
benzylbutyl phthalate, R = $CH_2C_6H_5$, R^1 = $[CH_2]_3CH_3$
bis(2-ethylhexyl) phthalate, R = R^1 = $CH_2CH(CH_2CH_3)$ $[CH_2]_3CH_3$
dioctyl phthalate, R = R^1 = $[CH_2]_7CH_3$

Properties

The phthalates molecule is a rigid planar aromatic ring with two flexible, generally non-linear, different or identical aliphatic side chains. Phthalates are odourless, relatively highly lipophilic liquids, with low vapour pressure and high boiling points (Table 12.76). Their lipophilicity (partition coefficient octanol–water, K_{OW}) increases with increased molecular weight. Like other esters, phthalates are easily hydrolysed in acidic and basic solutions (Figure 12.69). Owing to their low solubility in water, however, this reaction is very slow. Esters with branched bulky substituents, such as bis(2-ethylhexyl) phthalate, are more resistant to hydrolysis than the straight chain lower esters (e.g. dibutyl phthalate).

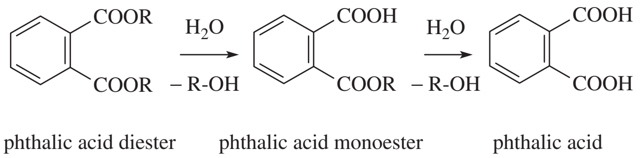


Figure 12.69 Hydrolysis of phthalates.

Occurrence and main sources

The main and probably the only source of phthalates is human activity. The release of phthalates into the environment occurs not only during their manufacture and production of materials containing phthalates, but also during use and subsequent disposal of materials containing phthalates. The atmosphere, waste water, soil and also foods may be contaminated.

Evaporation of phthalates in the atmosphere is negligible due to their low vapour pressure. Higher concentrations can occur near plants producing phthalates, or in enclosed areas (e.g. in cars and rooms with new flooring). Contamination in industrial centres or enclosed areas can reach values of tens of mg/m^3. In the air over the oceans, concentrations of phthalates are at the level of ng/m^3. As with other persistent contaminants, phthalates may be in the form of vapour (esters with lower relative molecular weights), aerosols or bound to dust particles. Phthalates can be transported over long distances in this form, especially bis(2-ethylhexyl) phthalate, or washed out by rain and snow precipitation.

Contamination of surface and groundwater can be caused by wastewater, solid waste and indirectly by rainfall. Amounts of phthalates vary by location and differ within one tenths to thousands

of μg/l, but in sediments, concentrations of hydrophobic phthalates can reach hundreds of mg/kg.

The main sources of soil contamination are industrial and municipal waste, agrochemicals and emissions. In the soil, phthalates tend to adsorb to organic matter, where they accumulate. The soil adsorption coefficient K_{OC} increases with the relative molecular weight of phthalates and their decreasing solubility in water, so that bis(2-ethylhexyl) phthalate is strongly sorbed and essentially immobile, while dimethyl phthalate is very mobile. Dimethyl and diethyl phthalates can easily leach into groundwater from soils and may be partially evaporated.

The migration of phthalates from packaging materials into food is generally influenced by many factors, such as:

- type of polymeric packaging material
- type of food (the amount of fat is important)
- temperature
- length of contact with foods.

The most important source of phthalates is food intake, but data on contamination of food are very limited. Generally, food contamination by phthalates may be in the range of hundredths up to units of mg/kg, with occasional extreme values primarily in fatty foods, such as cheeses, cakes and sandwiches that may readily contain phthalates in amount of tenths of mg/kg food. The occurrence of phthalates in food may be the result of contamination of raw materials, intermediates or finished products. In Europe, the estimated average maximum exposure to bis(2-ethylhexyl) phthalate from packaging is estimated at 0.02 mg per person per day, and exposure to all phthalates (expressed as dimethyl phthalate) is estimated to be 4.37 mg per person per day. Daily intake of bis(2-ethylhexyl) phthalate from food in the Netherlands is estimated at 0.5–0.8 mg, 2 mg in Japan and 0.25 mg in the United States (the total intake from food, water and air is about 0.27 mg).

Another source with respect to a specific population is blood transfusions, when the patient can obtain up to 300 mg in a single transfusion, and during dialysis of blood when the patient may receive 40 mg of bis (2-ethylhexyl) phthalate per day. In industrial plants with a maximum permissible concentration of bis(2-ethylhexyl) phthalate 5 mg/m, the daily intake of this phthalate by workers reaches 20 mg.

Degradation and metabolism

Hydrolysis and photodegradation of phthalic acid esters in the abiotic components of the environment is extremely slow, and higher esters, such as bis(2-ethylhexyl) phthalate and dioctyl phthalate, are virtually stable. The major route of elimination of phthalates from the environment is their biodegradation. Almost all organisms have the biochemical means (non-specific esterases) to be able to catalyse the hydrolysis of phthalates. Microbial degradation of phthalates occurs mainly under aerobic conditions in soil and by aquatic bacteria and fungi. The degradation process begins through hydrolysis to phthalic acid monoesters and subsequently to free phthalic acid. Degradation of phthalic acid via pyruvate and succinate produces carbon dioxide and water.

Immediately after entering the human organism via the lungs (by respiration) and intestines (via food), phthalates get into the blood and advance to the liver, kidney and testes. To a limited extent they are stored in the fat tissue. Metabolism of bis(2-ethylhexyl) phthalate begins by hydrolysis in the gastrointestinal tract to 2-ethylhexyl phthalate and 2-ethylhexan-1-ol. In the next metabolic step a small proportion of 2-ethylhexyl phthalate may be hydrolysed to phthalic acid and 2-ethylhexan-1-ol, but the major proportion of the monoester is oxidised in the aliphatic side chain to yield various metabolites (about 30 metabolites have been identified). In most mammals, 2-ethylhexyl phthalate and its oxidised derivatives react with D-glucuronic acid to form conjugates, which are excreted from the body. Metabolism of phthalates with shorter side chains is similar. Despite the relatively rapid metabolism and excretion of phthalates (60–90% is excreted in urine and faeces within 24 h), a certain proportion of lipophilic phthalates are accumulated in the body, because the rate of their intake exceeds the rate of metabolic conversion.

12.8.2 Health and toxicological assessment

Packaging materials are not considered toxic, but may contain toxic degradation products and many additives and plastics may occur as non-bound residual monomers, which have toxic properties. There is a risk with any packaging material that its components may be transferred in some way to the food. Fortunately, the level of contaminant transfer is extremely low in most cases, however, there are instances where a real hazard exists and must be controlled. No official internationally agreed guidelines exist, but in the EU there is a general requirement that food packaging components must not be transferred into food during its normal shelf life, pose a health risk, or adversely affect the quality, flavour, texture or appearance of the food. The major area of concern is the transfer of plastic material monomers and additives, especially plasticisers. The residual monomer content depends on polymer type and polymerisation technique. The contents of the monomers in various polymers vary from very low levels (mg/kg levels) up to 40 000 mg/kg. The amounts of additives used are also highly variable. Polyvinyl chloride (PVC), for example, requires the highest levels of additives, and accounts for 73% of the world's production of additives by volume, while polypropylene and polyethylene account for 10% and styrene for 5%. The toxicological aspects of these contaminants are briefly described in the following sections.

12.8.2.1 Plastic material monomers

In 1974, the monomer of PVC, vinyl chloride (chloroethene), was first reported to cause angiosarcoma (a form of tissue cancer that arises in the lining of blood vessels) of the liver both in humans and in animals. Additional research has demonstrated its

carcinogenicity to other organs. The target organs include the liver, brain, lung and probably the lymphohaematic system. According to the IARC, vinyl chloride is a Group 1 agent carcinogenic to humans. Dietary exposure to vinyl chloride is controlled by limiting either its content in food-contact material (typically less than 1 mg/kg) or migration to foods at the lowest technically achievable level (typically less than 0.01 mg/kg). Vinylidene chloride has some detrimental effects in mice and rats, but no carcinogenic effects have been seen. It is probably not carcinogenic to humans (a Group 3 agent).

Acrylonitrile, which is mutagenic after metabolic activation in the liver, is considered more toxic than chlorinated monomers and is possibly carcinogenic to animals and humans as a Group 2B agent. It is metabolised to cyanides, which are subsequently transformed into thiocyanates and excreted in the urine.

Reports of organ toxicity upon chronic exposure to styrene are rare; however, since the main intermediate in styrene metabolism is an epoxide (styrene-7,8-oxide), hepatotoxicity due to covalent binding at the site of formation appears to be a possibility. Both of these substances, styrene (a Group 3 agent) and its oxide (recently upgraded to a Group 2A as probably carcinogenic to humans) have been shown to produce chromosomal aberrations under certain conditions.

12.8.2.2 Plastic material additives

Among the additives used to modify the properties of polymeric packaging materials, plasticisers have raised much concern from the hygienic point of view. Butyl stearate, acetyltributyl citrate, alkyl sebacates and adipates are important because they are types of plasticisers that typically have low toxicities. Materials such as epoxidised soybean oil are widely used in polyvinyl chloride, polyvinylidene chloride and polystyrene as thermal stabilisers and lubricants at a level of 0.1–27%. Toxicity of epoxidised soybean oil is affected by the presence of oxirane, also known as ethylene oxide, which was upgraded to Group 1 as a carcinogenic agent to humans, based on mechanistic and other relevant data.

However, restrictions have been brought in on the use of phthalate plasticisers due to their potential carcinogenic effects. The risks from the presence of phthalates have been broadly discussed for decades, but only in the 1980s did suspicions over the possible carcinogenic effects of bis(2-ethylhexyl) phthalate, and in the 1990s on the weak oestrogenic activities (possibly related to increased incidence of testicular cancer or breast cancer) of dibutyl phthalate and benzylbutyl phthalate, result in interest in these compounds. The acute toxicity of phthalates is low and is manifested by gastrointestinal irritation, nausea, sleepiness, low blood pressure, dizziness, hallucinations, blurred vision and tearing. Inhalation of vapours leads to coughing and irritation of the throat and oesophagus. In terms of subacute and chronic effects, phthalates with branched side chains are dangerous, such as bis(2-ethylhexyl) phthalate. The primary target organs are the liver, which manifests by liver enlargement, increased pigmentation, fat sediments, increasing number of hepatic peroxisomes and mitochondria. The kidneys and other organs may also be affected. Chronic intake of phthalates, particularly of bis(2-ethylhexyl) phthalate, may likewise have teratogenic and carcinogenic effects (liver cancer) and might affect the reproductive ability of the body (weight reduction of testes, ovaries and sperm count). With regard to possible carcinogenic effects, bis(2-ethylhexyl) phthalate is classified as a possibly carcinogenic agent to humans (Group 2B) and butybenzyl phthalate as an agent that is not classifiable as to its carcinogenicity to humans (Group 3).

Bisphenol A occurs in polycarbonate plastics that have many applications, including use in some food and drink packagings, such as water and infant bottles, compact discs, impact-resistant safety equipment and medical devices, as well as in epoxy resins used as lacquers (such as the resin with the trade name Araldite). It is an endocrine disruptor, which has a high oestrogenic potential, and can mimic the natural hormone 3,17β-oestradiol, which may lead to negative health effects. Some studies have linked prenatal exposure to bisphenol A with later physical and neurological difficulties. Other studies have also presented a hypothesis that the current level of human exposure to growth hormones that fatten livestock, to pharmaceuticals that induce weight gain and, in addition, to bisphenol A can damage many of the body's natural weight-control mechanisms. Furthermore, it is posited that these effects, together with a wide range of additional, possibly synergistic factors, may play a significant role in the worldwide obesity epidemic. In 2010, Canada became the first country to declare bisphenol A a toxic substance. The European Union, Canada and recently the United States have banned the use of bisphenol A in baby bottles.

12.8.3 Mitigation

Requirements for the safety of food packaging materials and articles intended to come into contact with food are regulated by the Regulation (EC) No. 1935/2004 of the European Parliament and of the Council on materials and articles intended to come into contact with food. In addition to this document there are also requirements directly applicable in EC regulations, which are in particular: Commission regulation (EC) No. 1895/2005 on the restriction of use of certain epoxy derivatives in materials and articles intended to come into contact with food, Commission regulation (EC) No. 2023/2006 on good manufacturing practice for materials and articles intended to come into contact with food, Commission regulation (EC) No. 372/2007 laying down transitional migration limits for plasticisers in gaskets in lids intended to come into contact with foods and Commission regulation (EC) No. 282/2008 on recycled plastic materials and articles intended to come into contact with foods.

The legislation is based on three principles: positive list of substances, which may be used for the production of objects coming into contact with food; determination of specific migration limits for substances with proven adverse health effects; and compliance with the principles of good manufacturing practice for manufacturers of these items. For example, plastic materials and objects shall not transfer their constituents to foods in quantities exceeding 60 mg/kg of food, which is called the **Overall Migration Limit** (OML). In some cases, this limit may be expressed rather as 10 mg/dm^2 of surface of the material or object. To

determine whether a particular plastic formulation meets these criteria, legislative regulations describe in detail the terms and procedures of migration tests that are commonly performed not on individual foods, but on standardised food stimulants, which represent different conditions for leaching of undesirable substances. These are: distilled water, 3% aqueous solution of acetic acid, 10% aqueous solution of ethanol (or greater, if the alcoholic beverage in question has higher alcohol content) and olive oil. The regulations also specify which simulants should be used for each category of food. In general, there are no simulants listed for dried foods, which can be considered not to take up plastic constituents from contact materials. Very strict criteria in terms of the migration of harmful substances are also set for paper and cardboard, which are the traditional packaging materials coming into contact with food.

For substances with proven toxic effects, **Specific Migration Limits** (SMLs) have been declared in food simulants or the maximum amounts in a given material for unstable compounds are stated. An example can be the SML for melamine (2,4,6-triamino-1,3,5-triazine), which is set at 30 mg/kg. On the other hand, acrylamide cannot be detected at all in the migration tests (its detection limit is 0.01 mg/kg), although it is known as a common process contaminant. The SML value for dibutyl phthalate is 0.3 mg/kg and for bis(2-ethylhexyl) phthalate 1.5 mg/kg, but plasticised plastics should not be used for fatty foods. In sealing lids for jars intended for infant and baby food, the migration of epoxidised soybean oil is often controlled (SML = 30 mg/kg).
